OF
APPLIED CHEMISTRY

VOL. VII

A DICTIONARY OF APPLIED CHEMISTRY

BY

SIR EDWARD THORPE, C.B., LL.D., F.R.S.

EMERITUS PROFESSOR OF GENERAL CHEMISTRY AND DIRECTOR OF THE CHEMICAL LABORATORIES
OF THE IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, SOUTH KENSINGTON, LONDON;
LATE PRINCIPAL OF THE GOVERNMENT LABORATORY, AND A PAST PRESIDENT OF
THE CHEMICAL SOCIETY AND OF THE SOCIETY OF CHEMICAL INDUSTRY

ASSISTED BY EMINENT CONTRIBUTORS

REVISED AND ENLARGED EDITION

VOL. VII.

*WITH AN INDEX TO THE WHOLE WORK BY
FRANCES M. G. MICKLETHWAIT*

WITH ILLUSTRATIONS.

LONGMANS, GREEN AND CO. LTD.

INDEX.

This Volume concludes with an Index to the whole work, prepared by Miss FRANCES M. G. MICKLETHWAIT, M.B.E., F.I.C., A.R.C.S.

A

DICTIONARY

OF

APPLIED CHEMISTRY.

THALENITE. Silicate of yttrium (Y_2O_3 , 58·64 p.c.) with the approximate formula

Several other constituents are present in small amount, including 1·4–2·5 p.c. of gas (nitrogen and helium) liberated when the mineral is heated or treated with acids. It is yellow to flesh-red and translucent with a greasy lustre; sp.gr. 4·11–4·23; H. 6½; readily decomposed by dilute hydrochloric acid with separation of gelatinous silica. Monoclinic crystals and massive material occur with fluorite, gadolinite, and allanite in quartz at Osterby in Sweden.

L. J. S.

THALLIUM, sym. Tl., at.wt. 204·0, was discovered spectroscopically by Crookes in 1861 (Chem. News, 1861, 3, 193) in a seleniferous deposit from a sulphuric acid manufactory. It occurs in many iron and copper pyrites, in some micas, in zinc blendes, in the minerals *marcasite*, *hematite*, *crookesite* ($CuTlAg_2Se$, *lorandite* ($TlAsS_2$), *urbaitite* $TlAs_2SbS_6$, and in various other iron and manganese ores (Igelström, Z. Krist. Min. 1895, 25, 94; Antipoff, J. Russ. Phys. Chem. Soc. 1896, 28, 384; Hartley and Ramage, Chem. Soc. Trans. 1897, 533). It also occurs in small quantities in various mineral springs, and has been found in volcanic exhalations.

Its presence has been observed in crude zinc (Kosmann) and in platinum and its ores (H. N. Warren, Chem. News, 1887, 55, 241).

Thallium is prepared from flue dust by boiling it with dilute sulphuric acid and precipitating the chloride or iodide by treatment with hydrochloric or hydriodic acid, after which the metal can be obtained by electrolytic deposition, by the action of potassium cyanide or by electrolysis (Bunsen, Phil. Mag. 1865, [iv.] 29, 168; Foerster, Zeitsch. anorg. Chem. 1897, 15, 71). Traces of lead, tin, copper, and aluminium occur as impurities in commercial thallium (Pollock, Sci. Proc. Roy. Dublin Soc. 1909, 11, 338).

Thallium is a bluish-white, lead-like, crystalline, extremely soft metal, malleable, but of

low tenacity. It exists in two modifications, the transition temperature being 226° (235·3°, Richards and Smyth). Its sp.gr. is 11·85, its m.p. 303° (Potrenko, Zeitsch. anorg. Chem. 1906, 50, 133), its b.p. in vacuum 818° (Krafft and Knocke, Ber. 1909, 42, 202); at ordinary pressure 1515±2° (Isaac and Tammann, *ibid.* 1907, 55, 58); but its b.p. should be 1462° at 760 mm. It gives a monatomic vapour. For its absorption spectrum, see W. Grotrian, Zeits. f. Physik. 1923, 12, 218–231; Narayan, Gunnaiya and Rao, Proc. Roy. Soc., 1914, A., 106, 596. It commences to volatilise at 174° in vacuo. At a high temperature it may be distilled in a current of hydrogen. When heated it burns with a beautiful green flame, and its flame spectrum is characterised by a single green line. The heat of solution of thallium in thallium amalgams of 0·0–11·17 p.c. thallium has been determined by Theodore W. Richards and Charles P. Smyth by the adiabatic method (J. Amer. Chem. Soc. 1923, 45, 1435–1460). The following values of the heat of solution in joules at 20° of 1 gram-atom of thallium in amalgams of the composition stated are recorded: 0·92 p.c., 2706; 2·49 p.c., 2265; 3·81 p.c., 1917; 5·21 p.c., 1590; 5·80 p.c., 1975; 8·76 p.c., 486; 10·43 p.c., 45; 11·81 p.c., 234. These values are compared with those obtained by Richards and Daniels for concentrated amalgams, and found to be consistent with them (A. 1920, ii. 34). A short extrapolation of the composition-heat of solution curve above 0·92 p.c. gives a value for the heat of solution of thallium in an infinite quantity of mercury of 2970 joules, a value which is in fair agreement with 3220 joules, the value obtained by Lewis and Randall (Chem. Soc. Abstr. 1921, ii. 241) by calculation from the E.M.F. measurements of Richards and Daniels (*l.c.*) of thallium amalgam concentration cells (Abstr. J. Chem. Soc. 1923, 123, 124, ii. 536).

The temperature of transformation of α - into β -thallium was found by Asahara (Chem. Soc. Abstr. 1925, ii. 463, 645) to be 232°.

Thallium oxidises before the blowpipe. It dissolves readily in dilute nitric and sulphuric

THALLIUM.

acids, but more slowly in hydrochloric acid, and at a red heat decomposes water.

Thallium and its salts are very poisonous (Curci, Chem. Zentr. 1895, ii. 999; Swain and Bateman, J. Biol. Chem. 1910, 7, 137). Thallium forms alloys with a large number of metals, and an amalgam with mercury, which has been proved to be useful in thermometry (McIntosh and Johnson, J. Amer. Chem. Soc. 1912, 34, 910; Pavlovitch, J. Russ. Phys. Chem. Soc. 1915, 47, 29; Hildebrand and Eastman, J. Amer. Chem. Soc. 1915, 37, 2452). The existence of a solid compound Tl_2Hg has been established by Richards and Daniels (J. Amer. Chem. Soc. 1919, 41, 1732), who have studied the electro- and thermo-chemical behaviour, densities and freezing points of thallium amalgams (cf. Richards and Smyth, J. Amer. Chem. Soc. 1922, 44, 524). For references to alloys, see Masumi Chikashigé (Zeitsch. anorg. Chem. 1912, 78, 68); Kurnakov, Shemtschushin, and Tatarin (J. Russ. Phys. Chem. Soc. 1913, 45, 300); Rolla (Gazz. chim. ital. 1915, 45, i. 185; Di Capua, Chem. Soc. Abs. 1925, ii. 787). For the electric resistance of thallium in the temperature field of liquid helium, see H. K. Onnes and W. Tuyn (K. Akad. Amsterdam, Proc. 25, 1923, 9 and 10, pp. 443-450, Comm. No. 160A, from the Phys. Lab. Leiden).

Compounds.—Thallium forms two series of compounds—

(1) **Thallic (TlX_3) compounds** in which the metal is trivalent, corresponding to its position in the aluminium group. Like the compounds of aluminium, the thallic salts undergo hydrolysis in aqueous solution and form complex salts more readily than the corresponding thallous compounds (Spencer and Abegg, Zeitsch. anorg. Chem. 1905, 44, 379). Metallic thallium reduces the thallic salts to the thallous condition. They are also reduced by hydroxylamine in acid or alkaline solutions, by acid solutions of ferrous sulphate, by sodium arsenite solution and, on boiling, with finely divided copper (Berry, Chem. Soc. Trans. 1922, 394). In the absence of oxidising agents, even in the presence of thallous salts, thallic salts give the blue coloration of indophenols when α -naphthol and dimethyl-*p*-phenylene-diamine are added to an alkaline solution of the salt (Marigo, Gazz. chim. ital. 1907, 37, i. 55).

(2) **Thallous (TlX) compounds** in which thallium is monovalent. The thallous salts closely resemble the salts of the alkali metals; thus the hydroxide and carbonate are readily soluble and give an alkaline aqueous solution. Many of the thallous salts, like the sulphate, phosphate, &c., are isomorphous with the corresponding potassium salts and give double salts with platinum chloride Tl_2PtCl_6 . The alum $Tl_2SO_4 \cdot Al_2(SO_4)_3 \cdot 24H_2O$ and other double sulphates are also closely analogous to the corresponding potassium salts. The thallous halides and sulphides, on the other hand, resemble the corresponding lead and silver salts. Thallous salts react with a clear aqueous solution of antimony chloride and potassium iodide, giving a characteristic voluminous orange precipitate of the compound $3TlI \cdot 2SbI_3$ (Eppraim, Zeitsch. anorg. Chem. 1908, 58, 353).

Thermal studies of the systems formed by thallous nitrate with mercuric chloride, bromide,

and iodide show that no double decomposition occurs, but the following compounds are formed: $TlNO_3 \cdot HgCl$, m.p. 202.5° ; $2TlNO_3 \cdot HgCl$, m.p. 105° ; $TlNO_3 \cdot HgBr$, m.p. 152° (A. G. Bergmann, T. A. Henke, and F. M. Isakson, J. Russ. Phys. Chem. Soc. 1922, 54, 466; see also J. Russ. Phys. Chem. 1922, 54, 200).

Oxides.—Thallium trioxide (thallic oxide) Tl_2O_3 is formed when an alkaline solution of a thallous salt is treated with 3-5 p.c. solution of hydrogen peroxide. When the precipitation is made in the cold, the oxide is brown, is readily soluble in acids, and has sp.gr. 8.65 at 21° , but when the solutions are hot, the oxide is black, is sparingly soluble in acids, and has the sp.gr. 10.19 at 22° . The brown oxide is partly reduced when boiled with water, but the black oxide remains unchanged. At 100° the brown slowly changes into the black variety, and at 529° this change is complete within 24 hours (Rabe, Zeitsch. anorg. Chem. 1906, 48, 427; *ibid.* 50, 158; *ibid.* 1907, 55, 130). Thallic oxide may also be made by acting upon thallous sulphate with an alkaline solution of potassium ferricyanide (cf. Berry, Chem. Soc. Trans. 1922, 394). The crystalline oxide obtained by heating the nitrate has sp.gr. 9.97 (Thomas, Compt. rend. 1904, 138, 1697; see also Fortini, Gazz. chim. ital. 1905, 35, ii. 450). Thallous hydroxide is readily obtained in good yellow, micro-crystalline powder by adding to thallous ethoxide in the cold an equal volume of water, and drying the precipitate on porous plates out of contact with air. A determination of the heat of hydration of thallous oxide by finding the difference in the heat of solution of the oxide and hydroxide in dilute hydrofluoric acid gave a value 3.117 cal., compared with 3.331 cal. found by Thomsen. The heat of hydration is therefore very far removed from that of the oxides of the alkali metals, but thallous hydroxide is nevertheless an equally powerful base, and towards feeble acids, phenols, &c., shows even stronger basic properties than the alkali hydroxides. It can be estimated acidimetrically using phenolphthalein as indicator (R. de Forcrand, Compt. rend. 1923, 176, 873-876; J. Chem. Soc. 1923, 124, ii. 420).

The oxide dissolves in concentrated hydrochloric acid without evolution of chlorine, forming thallic chloride.

Thallium monoxide (thallous oxide) Tl_2O is obtained by shaking fine turnings of the metal with cold water in a current of oxygen or by heating the corresponding hydroxide at 150° - 200° in nitrogen. It is a black powder, m.p. 300° , readily dissolving in water with formation of the hydroxide $TlOH$, which crystallises with 2 molecules of water in yellow needles. The hydroxide is darkened by light, turns turmeric brown, and finally destroys the colouring matter.

With phenolphthalein, thallous hydroxide gives a yellow colour which is slowly discharged by moderately concentrated aqueous solutions, especially on warming. It dissolves isatin to form a deep purple liquid, the colour of which on warming with slight excess of the reagent changes to yellow, due to the formation of a salt of isatinic acid. Thallous salts are generally isomorphous with the salts of the alkali metals (Thorpe, J. 1876, i. 859).

Thallous salts of mono- and di-basic normal

aliphatic acids have been prepared. The *valerate* described by Kuhlmann (Annalen, 1863, 126, 78) is prepared by adding thallous hydroxide solution to valeric acid until the reaction is faintly alkaline to litmus, evaporating the solvent, and recrystallising the residue from benzene. The salt, m.p. 145° – 147° , is very soluble in water, ethyl alcohol, or hot benzene, readily soluble in amyl alcohol, and sparingly soluble in boiling ether, hot light petroleum, or cold benzene. It is not readily thrown out of solution in ethyl alcohol by addition of ether.

The *palmitate*, prepared by adding 33 p.c. thallous hydroxide solution to a hot alcoholic solution of palmitic acid until the reaction is neutral to litmus, crystallises from alcohol in feathery aggregates. It is readily soluble in hot alcohol, insoluble in ether, and soluble in water, the solution being opalescent when dilute. On shaking a warm dilute aqueous solution a froth forms on the surface, which disappears on cooling, and is not formed on shaking the cold solution. It softens on heating at 116° – 118° , but does not melt completely at 170° .

The *oleate* is prepared by adding the theoretical amount of thallous hydroxide solution to oleic acid, dissolved in alcohol, and evaporating the solution to dryness in a vacuum desiccator. The residual soap separates from ethereal solution in white needles, which are soft and can easily be bent. On drying they cohere to a solid, soap-like mass. The salt is also soluble in perfectly dry ether free from alcohol. It forms an opalescent solution and, on shaking, a froth permanent in the cold (distinction from the palmitate). It forms a jelly below the main bulk of the solution, the volume of the jelly being many times greater than that of the oleate left undissolved.

The normal *adipate* is prepared by accurately neutralising adipic acid with aqueous thallous hydroxide solution, using phenolphthalein as indicator. The solution is evaporated to small bulk and the crude adipate precipitated with ethyl alcohol. The salt is dissolved in ethylene glycol, in which it is very soluble, and butyl alcohol added with continued heating until a faint cloudiness is apparent in the boiling mixture; on cooling, the salt separates out in crystalline leaflets.

The normal *pinelate* is obtained by neutralising an aqueous solution of pimelic acid with thallous hydroxide solution, using phenolphthalein as indicator and evaporating the solution to dryness. It is much more soluble in water than the normal adipate, and is almost insoluble in ethyl alcohol, but can be recrystallised from amyl alcohol, in which at the boiling-point it is sparingly soluble, separating on cooling in long needles. The acid *pinelate* is readily soluble in water, almost insoluble in ethyl alcohol, and crystallises from amyl alcohol in prisms.

Thallous salt of ethyl acetonedicarboxylate.—Minute needles, melting at 125° (decomp.), readily soluble in cold ethyl or methyl iodide, thallous iodide being deposited on standing or on heating. This property is shared by thallous acetylacetonate (Kurowski, Ber. 1910, 43, 1078; Morgan and Moss, J. 1914, 106, 195).

Thallous salts of fumaric, maleic, succinic and

tartaric acids, and also of cresol, resorcinol, guaiacol, naphthol and vanillin are described by Christie and Menzies (J. Chem. Soc. 1925, 127, 2369).

Qualitative reactions of aqueous thallous hydroxide solutions with sugars.—In concentrated aqueous solution, fructose, glucose, and xylose give with thallous hydroxide solution in the cold yellow precipitates which, on heating, become reddish-yellow, and finally very dark; under suitable conditions mirrors are formed. With dilute solutions no precipitates are formed with glucose and fructose, but the same colour changes are observed on heating, and again on heating thallium mirrors are formed, provided only the thallous hydroxide is present in sufficient excess. Sucrose and mannitol can be boiled with 10 p.c. thallous hydroxide solution without change other than the appearance of a faint yellow colour, but after hydrolysis of sucrose with dilute sulphuric acid mirrors are formed on subsequent heating with thallous hydroxide solution. The formation of mirrors is favoured by addition of ammonium or sodium hydroxide. Good results are obtained by heating a mixture of N-glucose and thallous hydroxide with addition of 4 or 5 drops of N-sodium hydroxide solution in a clean test-tube for 2 minutes in a water-bath. The mirrors obtained can readily be removed from the glass by boiling with tap-water, but are permanent for some weeks under cold air-free distilled water. On adding tetra-methyl- γ -fructose to thallous hydroxide solution, a brown colour is developed in the cold, a small amount of a dark flocculent precipitate being also formed; on boiling this brown colour becomes darker and the precipitate dissolves. No mirror is formed. A standard solution of thallous hydroxide may be used for the titration particularly of organic acids. The thallous salts of organic acids are considerably less soluble than those of the alkali metals, are readily crystallised, and hence can be used as a convenient means of isolation and purification (Menzies and Wilkins, Chem. Soc. Trans. 1924, 125, 1148).

The *oxide* (TiO_2), probably $\text{Ti}_2\text{O}_3 \cdot \text{Ti}_2\text{O}_5$, is prepared by adding 175–200 grms. of 20 p.c. potassium hydroxide to 15 grms. of a 10 p.c. aqueous solution of thallous sulphate. The solution is filtered, cooled to -15° , and 3.5 grms. of a 3 p.c. solution of hydrogen peroxide is added with constant shaking. The oxide forms a bluish-black, lustrous precipitate, is quickly decomposed into thallic oxide and thallous hydroxide by cold water and by dilute acids. It readily absorbs carbon dioxide, and, unlike thallous salts, is oxidised by a current of oxygen at ordinary temperature to thallic oxide (Rabe, Zeitsch. anorg. Chem. 1908, 58, 23).

When a mixture of thallous sulphate and oxalic acid is electrolysed at the ordinary temperature with a current of 3–4 volts and 0.15–0.2 ampère, the oxide Ti_2O_3 or $\text{TiO}_2 \cdot \text{Ti}_2\text{O}_5$ is deposited on the anode. When the deposit is dissolved in dilute hydrochloric acid, chlorine is evolved and a yellow salt $\text{TiCl}_3 \cdot 3\text{TiCl}$ is formed (Gallo and Cenni, Atti R. Accad. Lincei, 1906, [v.] 17, 276).

The following complex salts of copper and thallium are described by G. Cannori (Gazz. chim. ital. 1922, 52, ii, 206), viz: $\text{Ti}_2\text{Cu}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$

THALLIUM.

blue crystals; $\text{Ti}_2\text{Cu}(\text{SO}_4)_2$, a yellow powder; $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, Cu_2SO_4 , Ti_2SO_4 , cinnabarised crystals soluble in aqueous ammonia to a blue solution; $\text{Ti}_2\text{Cu}(\text{S}_2\text{O}_8)_2$, a yellow, microcrystalline powder (Chem. Soc. Abstr. 1923, 124, ii. 74).

For the halogen and mixed halogen compounds of thallium, see Wells and Penfield (Zeitsch. anorg. Chem. 1894, 6, 312); Meyer (*ibid.* 1900, 24, 321; *ibid.* 1902, 32, 72); Thomas (Compt. rend. 1900, 131, 892, 1208; *ibid.* 1901, 132, 80, 1487; *ibid.* 1902, 133, 735; *ibid.* 1902, 134, 545; *ibid.* 1903, 135, 1051; *ibid.* 1906, 142, 838; *ibid.* 1907, 143, 282; Ann. Chim. 1907, [viii.] 11, 204); Cushman (Amer. Chem. J. 1900, 24, 222; *ibid.* 1901, 26, 505); Maitland and Abegg (Zeitsch. anorg. Chem. 1906, 49, 341); Stolzenberg and Huth (Zeitsch. physikal. Chem. 1910, 71, 641). Thallium halides form double salts with many other metals (Meyer, *l.c.*; Thomas, *l.c.*; Pratt, Zeitsch. anorg. Chem. 1895, 9, 19; Wells and Foote, Amer. J. Sci. 1897, 3, 466; Ephraim and Heymann, Ber. 1909, 42, 4456; Ephraim and Barteczko, Zeitsch. anorg. Chem. 1909, 61, 238; Gewecke, Annalen, 1909, 366, 217; Delépine, Compt. rend. 1909, 149, 1072; Gewecke, Zeitsch. anorg. Chem. 1912, 75, 272; Sandonini, Atti R. Accad. Lincei. 1913, [v.] 22, ii. 20; Scarpa, *ibid.* 1912, [v.] 21, ii. 719; Lunde, Chem. Soc. Abstr. 1925, ii. 941; Randall and Vanselow, *ibid.* 1925, ii. 33). Thallous chloride darkens on exposure to light and becomes blackish-brown, due to the formation of a photo-thallous chloride and thallous-thallic chloride (*cf.* Renz, Helv. Chim. Acta, 1919, 2, 704). When thallium is dissolved in hot dilute hydrofluoric acid, H_2TlF_6 is obtained crystallising in white prisms. On heating it evolves hydrofluoric acid; its aqueous solution is acid, but does not attack glass, the fluorine ion being masked. It forms two types of salts, KHTlF_6 and K_2TlF_6 (Barlot, Compt. rend. 1920, 171, 1143).

Thallic sulphide Ti_2S_3 is formed when the metal is fused with excess of sulphur. It is black and above 12° is plastic, but below 12° it is hard and brittle. When sulphuretted hydrogen is passed into a solution of a thallous salt, thallous sulphide Ti_2S is formed as a black precipitate, which can be obtained in a crystalline form (Staněk, Zeitsch. anorg. Chem. 1898, 17, 117; see also Loczka, Chem. Zentr. 1898, i. 657; Hawley, J. Amer. Chem. Soc. 1907, 29, 1011). According to Pélabon, (Compt. rend. 1907, 145, 118) the sulphides Ti_2S_7 , Ti_2S_8 also exist (see Hofmann and Höchtlein, Ber. 1903, 36, 3090). Double sulphides with copper and tin are also known (Bruner and Zawadzki, Bull. Acad. Sci. Cracow, 1909, 312; Hawley, J. Phys. Chem. 1906, 10, 654).

Thallium sulphates and their double salts are described by Stortenbeker (Rec. trav. chim. 1902, 21, 87); Kohn (Zeitsch. anorg. Chem. 1908, 59, 111); Piccini and Fortini (*ibid.* 1902, 31, 451); Locke (Amer. Chem. J. 1902, 27, 280); Marshall (Proc. Roy. Soc. Edm. 1902, 24, 306); Meyer and Goldschmidt (Ber. 1903, 36, 238). Many double salts of thallic and thallous sulphates have been described, but according to Benrath and Espenschied (Zeitsch. anorg. Chem. 1922, 121, 361), only two exist, viz. $\text{Ti}_2\text{SO}_4 \cdot \text{Ti}_2(\text{SO}_4)_3$ and $5\text{Ti}_2\text{SO}_4 \cdot \text{Ti}_2(\text{SO}_4)_3$, all others being regarded as mixtures of these. For

the reduction of thallic sulphate in presence of ferrous sulphate, see Berry (Chem. Soc. Trans. 1923, 123, 1109).

The solubility of thallic oxide, the basic sulphate, $\text{Ti}(\text{OH})\text{SO}_4 \cdot 2\text{H}_2\text{O}$, and the acid sulphate, $\text{HTl}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, has been determined in sulphuric acid of various concentrations from 10 p.c. to 90 p.c. at various temperatures and the stability diagram constructed. It is shown that no other thallic sulphate exists under the above-named conditions, and that the other thallic sulphates described in the literature are mixtures, the formation of which is due to the slowness of the change from one salt to another. The transition point of the two sulphates mentioned above lies at about 40° . The corresponding selenates have also been investigated, and are found to be very similar to the sulphates; the main point of difference between them is that the transition point lies at 45° (Julius Meyer, Rec. trav. chim. 1921, 43, 614-619; J. Chem. Soc. 1923, 123, 124, ii. 637).

Thallium sulphite is a white granular crystalline powder (Seubert and Elten, Zeitsch. anorg. Chem. 1892, 2, 434; *ibid.* 1893, 4, 44).

Thallium selenides Ti_2Se and TiSe , are known. The existence of a third Ti_2Se_3 (Pélabon), or Ti_2Se_5 (Murakami) is doubtful.

Thallium telluride is described by Brukl (Monatsh. 1924, 45, 471, (Chem. Soc. Abstr. 1925, ii. 895).

Thallium nitrates are described by Wells and Beardsley (Amer. Chem. J. 1901, 26, 257); Meyer (*l.c.*); Thomas (Compt. rend. 1904, 138, 1697); van Eyk (Zeitsch. physikal. Chem. 1906, 51, 721).

Thallium mercurous nitrate, m.p. 76° , sp.gr. 5.3, gives a clear mobile solution miscible with water and not reacting with sulphides. It forms a useful liquid for the separation of mineral sulphides (Retgers, Jahrb. Min. 1896, ii. 183).

Thallium nitrite forms double salts with cobalt and other metals (Przibylla, Zeitsch. anorg. Chem. 1898, 18, 448; Cunningham and Perkin, Chem. Soc. Trans. 1909, 1569; Tanatar and Petroff, J. Russ. Phys. Chem. Soc. 1910, 42, 94).

For nitrous-nitric complexes of thallium, v. Gazz. chim. ital. 1919, 49, ii. 217.

Thallous tetraborate $\text{Ti}_2\text{B}_4\text{O}_{10}$, hexaborate $\text{Ti}_2\text{B}_6\text{O}_{18} \cdot 3\text{H}_2\text{O}$, octoborate $\text{Ti}_2\text{B}_8\text{O}_{22} \cdot 4\text{H}_2\text{O}$, decaborate $\text{Ti}_2\text{B}_{10}\text{O}_{26} \cdot 8\text{H}_2\text{O}$, dodecaborate $\text{Ti}_2\text{B}_{12}\text{O}_{28} \cdot 7\text{H}_2\text{O}$, have also been prepared. Thallous perborate is also known.

Thallium azoinide or nitride TIN , remains unchanged when heated to 340° , but explodes when heated more strongly or when struck (Curtius and Risson, J. pr. Chem. 1898, [ii.] 56, 261; also Dennis and Doan, J. Amer. Chem. Soc. 1896, 18, 970; Franklin, J. Phys. Chem. 1912, 16, 682).

Thallium oxalate $\text{HTl}(\text{CO}_2)_2 \cdot 3\text{H}_2\text{O}$ is prepared by treating the freshly precipitated hydroxide at 25° with a large excess of a cold saturated solution of oxalic acid. When suspended in absolute alcohol, cooled to 0° , and treated with dry ammonia, the compound $\text{Ti}(\text{CO}_2)_2 \cdot \text{NH}_3 \cdot (\text{NH}_3)_2$ is formed; at a higher temperature the compound $\text{Ti}(\text{CO}_2)_2 \cdot \text{NH}_3$ separates. The pyridine salt $\text{Ti}(\text{CO}_2)_2 \cdot \text{HC}_5\text{H}_5\text{N}$ and the salt $\text{Ti}(\text{CO}_2)_2 \cdot (\text{NH}_3)_2$, as well as other oxalates $\text{Ti}(\text{CO}_2)_2 \cdot (\text{C}_6\text{H}_5)_3$, $3\text{H}_2\text{O}$ and $\text{Ti}_2(\text{CO}_2)_4 \cdot 3\text{H}_2\text{O}$

THEINE.

have also been obtained (Rabe and Steinmetz, Ber. 1902, 35, 4447).

Thallous alkyl oxides (Chem. Soc. Abstr. 1923, i, 84).

Thallous carbonate, nitrite, and cyanide are also known.

Thallous chromate is practically insoluble in dilute alcohol and may be employed for the quantitative separation and estimation of thallium (see Cuttice and Canneri, Gazz. chim. ital. 1921, 51, 2, 189).

Thallous picrolonate, see Giua (Gazz. chim. ital. 1924, 54, 204; Chem. Soc. Abstr. 1924, 126, i, 770).

For a number of other thallium salts, see Georgis, Gazz. chim. ital. 1894, 24, ii, 474; Stavenhagen, J. pr. Chem. 1895, [ii.] 51, 1; Joly, Compt. rend. 1894, 118, 640; Mauro, Real. Accad. Lincei, 1893, ii, 382; Hofmann, Zeitsch. anorg. Chem. 1896, 12, 55; Piccini, *ibid.* 1897, 13, 441; Piccini and Marino, *ibid.* 1901, 27, 62; Marino, *ibid.* 1909, 62, 173; Glauser, *ibid.* 1910, 66, 437; Dennis and Doan, *l.c.*; Wyruboff, Bull. Franc. Min. 1896, 19, 219; Hawley, J. Amer. Chem. Soc. 1907, 29, 300; Kurowski, Ber. 1910, 43, 1078; Buchala, J. pr. Chem. 1913, [ii.] 88, 771; Franklin, J. Amer. Chem. Soc. 1915, 37, 2279; Benrath, Zeitsch. anorg. Chem. 1915, 93, 161; for photochemical reactions of compounds of thallium, see Benrath, Zeitsch. wiss. Photochem. 1915, 14, 217; Renz, Helv. Chim. Acta, 1919, 2, 704; 1921, 4950; 1923, 1161; Goddard, Chem. Soc. Trans. 1921, 672; 1922, 36, 256, 482.

Thallium dimethyl fluoride TiMe_2F and the corresponding thallium diethyl fluoride and thallium diphenyl fluoride and similar compounds are described by Krause and von Grosse, Ber. 1925, 58 [B], 272, 1933; Chem. Soc. Abstr. 1925, i, 378, 1252.

For the constitution of aqueous solutions of thallium salts, see Drucker, Zeitsch. Electrochem. 1922, 28, 463-467.

Thallium may be determined by the electrolytic deposition of thallous oxide as follows: A solution containing 0.1-0.5 gram of thallous nitrate and 0.1 gram of free nitric acid is placed in a roughened platinum dish, diluted to 100 c.c., and either 10 c.c. of absolute alcohol or 5-10 c.c. of rectified acetone added. The dish is made the anode in the electrolysis, and the cathode is a disc of iridio-platinum of 12 sq. cm., which is rotated at 300 revs. per minute. The electrolysis is carried out at 60°-62°, directly from a single accumulator. After 10 hours the voltage is raised to 2.5-3.0 volts and a current of 0.05 amp. passed for a short time. The deposit, which is firm, is washed with water and dried at 160°-170°, preferably in an electrically heated oven; in any case reducing gases must not come into contact with the deposit. When dry the dish is cooled in a desiccator and weighed rapidly, since the deposit is somewhat hygroscopic. The method is good, the results being accurate to within ± 0.2 p.c. (W. Dieterle, Zeitsch. Elektrochem. 1923, 29, 493; J. Soc. Chem. Ind. 1924, 43, B, 79).

THALLOCHLORE. A name given by Knop and Schneidermann to the green colouring matter of lichens (Annalen, 56, 147).

THAPSIC ACID $\text{C}_{11}\text{H}_{18}\text{O}_4$. Obtained from the dried roots of *Asperula* (Linn.)

(Canzoneri, Gazz. chim. ital. 13, 514; 24, ii, 437); m.p. 123°-124°. The anhydride melts at 71°.

Thapsic acid is identical with tetradecane dicarboxylic acid obtained by the electrolysis of potassium ethyl azelate (Carmichael, Chem. Soc. Trans. 1922, 121, 2545).

THAUMASITE. Hydrated silicate, carbonate, and sulphate of calcium, crystallised in the hexagonal system. This mineral is of interest in containing three acid radicles, and the existence of such a compound, which has not been prepared artificially, may possibly have some bearing on the setting of plasters. The formula is $\text{CaSiO}_3 \cdot \text{CaCO}_3 \cdot \text{CaSO}_4 \cdot 15\text{H}_2\text{O}$. Since $13\text{H}_2\text{O}$ is expelled at 150°, and the remainder in four stages below a red-heat, corresponding to four hydroxyl groups, the formula may be written $[(\text{CaOH})\text{CO}_3][(\text{CaOH})\text{SO}_4][\text{CaOH}]\text{HSiO}_3 \cdot 13\text{H}_2\text{O}$. The mineral forms snow-white, alabaster-like masses or loose aggregates of small transparent hexagonal prisms. It is very light, sp.gr. 1.88; H. 3½; readily decomposed by dilute hydrochloric acid, and slightly soluble in water. It is known from two mines in Sweden, and has been found in considerable quantity with pectolite ($\text{HNaCa}_2(\text{SiO}_3)_2$) and apophyllite in cavities in basalt at West Paterson in New Jersey. Another occurrence is as a filling of small fissures in metamorphosed dolomitic limestone in Beaver Co., Utah.

Wilkeite is a similar complex combination of calcium salts, but containing in addition phosphate and a surplus of oxide, the formula being $3\text{Ca}_3(\text{PO}_4)_2 \cdot 3\text{Ca}_2\text{SiO}_3 \cdot 3\text{CaSO}_4 \cdot \text{CaCO}_3 \cdot \text{CaO}$. The hexagonal crystals have characters near those of apatite, sp.gr. 3.234. They are pink in colour and are found embedded in the blue calcite of a contact-metamorphic limestone at Crestmore in Riverside Co., California.

L. J. S.

THEBAINE v. OPIUM.

THEINE or *Caffeine* v. **CAFFEINE.** For the extraction of caffeine by various solvents, see H. E. Watson, K. M. Sheth, and J. J. Sudborough, (J. Ind. Inst. Sci. 1922, 5, 177-207).

The fact that theine (caffeine) exists in the leaves of the coffee plant has long been known, but it is only since the war that they have been commercially exploited to produce this drug. The idea originated in Sumatra, where under the present system of cultivation coffee is frequently attacked by insects of the genus *coccus*. With the failure of the berry crop, the growers, seeking a substitute for the ordinary caffeine-containing product, collected the leaves from which pure theine was prepared. With the war the demand for theine so greatly expanded that the process of extracting it from the leaves was resorted to on an extensive scale by the Dutch factories, which purchased them by the ton from the native growers and pickers. So far, the process of preparation has been kept secret, but there is no gainsaying the purity of the product. On the western side of the island of Sumatra the producers, and, in fact, the general public, have long used an infusion of torrefied coffee leaves as a beverage, the berries themselves all being reserved for export. The use of the leaves for this purpose has grown to such an extent that

THEINE.

it is now looked upon as an absolute necessary of life.

During the past four years Germany has been importing enormous quantities of coffee leaves from Sumatra and utilising them in the same way; and in some parts of Germany the infusion from the leaves has quite taken the place of the berry, the price of which has been an obstacle to its ready sale. Careful research work has resulted in proof that the extract obtained from the leaves has undoubted nutritive properties. In addition, a vast number of analyses have been taken which furnish data practically guaranteeing its safety as an article of diet, with an entire absence of deleterious effects. With a little boiled rice and infusion of the coffee leaf a man will support the labours of the field in rice-planting for days and weeks successively up to the knees in mud, under a burning sun or drenching rains, which he could not do by the use of simple water, or by the aid of spirituous or fermented liquors. Planters in Sumatra had opportunity of observing for twenty years the comparative use of the coffee leaf in one class of natives, and of spirituous liquors in another, the native Sumatrans using the former, and the natives of British India (imported labour) the latter. Records show, while the former expose themselves with impunity for any period to every degree of heat, cold and wet, the latter can endure neither wet nor cold for even a short period without danger to their health. Although the coffee berry can only be produced in certain climates and on soils containing marked peculiarities, the plant itself will flourish in any tropical country where the soil is sufficiently fertile, and in consequence the field for production of the leaves is almost unlimited. As a means, therefore, of providing caffeine for general consumption, free from deleterious qualities, and yet containing great nutritive properties, the leaves appear to be eminently suitable.

Samples of the leaves grown in North Queensland have already been shipped to Hamburg, where they have been most favourably commented upon. The shippers' withstood the long voyage well. They disclosed fairly regular fragments of shining leaves mixed with small pieces of stalk, all of deep brown colour. The odour is described as exceedingly fragrant and something like a mixture of tea and coffee. An infusion in boiling water produced a transparent, dark-amber to brown-coloured liquid, which, used in the same way as ordinary coffee, with the addition of milk and sugar, was pronounced by experts as excellent. The price of the leaves is only about one-half that of the berries for which they are proposed as a substitute (Pharm. J. 1924, 113, 59).

For the determination of theine in coffee, see Lucas (J. Soc. Chem. Ind. 1924, 43, B, 489).

THENARDITE. A mineral consisting of anhydrous sodium sulphate (Na_2SO_4), crystallised in the orthorhombic system. It is found as large crystals, 6 ins. or more in length, on the shores of salt, soda, and borax lakes in arid regions, and sometimes forms beds of considerable extent, together with glauberite, &c. Sp.gr. 2.68-2.69; H. 2-3. The water-clear crystals absorb water from a moist atmosphere and become cloudy. Localities are: Borax

Lake in San Bernardino Co., California; on the Rio Verde in Arizona; Rhodes Marsh in Nevada; Tarapaca and elsewhere in the Chilean nitrate deposits; Espartinas near Madrid; the oasis of Bilma in French Sudan; and the salt lakes north of the Caspian. It is of rare occurrence in the German abraum-salts and in the fumaroles of volcanoes. I. J. S.

THENARD'S BLUE. Cobalt blue v. PIGMENTS.

THEOBROMA CACAO v. *Coçôa*.

THEOBROMIC ACID $\text{C}_{19}\text{H}_{33}\text{COOH}$ is obtained from cocoa bitter and melts at 72° ; it is apparently identical with arachidic acid (q.v.).

THEOBROMINE v. **CAFFEINE**, Vol. I., 726. For the estimation of theobromine in cocoa and its products v. Wadsworth, Analyst, 1921, 32. The theobromine content of nibs from 21 different producing areas varied from 2.2 to 3.9 p.c. calculated on dry, fat-free material, the variation depending upon the variety of the bean and on the degree of fermentation, a process which considerably reduces the theobromine content. In the shell the theobromine varied from 0.19 to 2.89 p.c., the alkaloid being carried by the sweatings from nut to shell. No theobromine was lost from nibs or shells during roasting. In order to determine the amount of theobromine in cocoa, the cocoa is heated in a dry Kjeldahl digestion flask until the theobromine is sublimed and the cocoa completely carbonised. The theobromine is extracted with hot water, the solution filtered, and the filtrate evaporated to dryness on the water-bath. The residue is purified by extraction with absolute alcohol, treated with aqueous ammonia, and dissolved in chloroform. The chloroform solution is filtered and evaporated to dryness, the residue extracted three times with 3 c.c. of hot water, filtered, and the filtrate evaporated to dryness on a watch glass, dried at 100° - 105°C ., and weighed. The whole determination takes about $2\frac{1}{2}$ hrs. The percentage of theobromine in various samples of commercial cocoa varied from 0.45 p.p. to 1.17 p.c. (T. Ugarte, J. Pharm. Chim. 1923, 27, 420-423; J. Soc. Chem. Ind. 1923, 42, 675A).

Theobromine may be distinguished from caffeine by the differences in the colorations produced when the respective bismutho-iodides are reduced by hydriodic acid. For the distribution of theobromine during the fermentation of cacao, see Knapp and Wadsworth (J. Soc. Chem. Ind. 1924, 43, 124 T).

THEOBROMOSE, THEOCIN, THEOLACTIN, THEOPHORIN, THEOPHYLLIN, v. SYNTHETIC DRUGS.

THEOCYLENE. Compound of theobromine and aspirin.

THEOFORM. A condensation product of theobromine and formic acid.

THEOPHYLLINE v. **CAFFEINE**.

THEOPHYSEM. Iodoethylallylthioxy-urea.

THEOSALIN. Trade name for an addition product of theobromine sodium, and sodium sulphosalicylate.

THERMAL PROPERTIES OF GASES. In J. Phys. Chem. Feb., 1924, 28, 97, Pickering reviews the constants of the more common gases

THERMIT PROCESS.

and gives the following values as the most probable:—

Gas	Critical Temperature °C. abs.	Critical Pressure atm.	Critical Density gr. per c.c.

Determination of the normal boiling-points of oxygen, nitrogen, and hydrogen.—Henning and Heuse's (Zeits. f. Physik. 1924, 23 1, 105) final results reduced to the thermodynamic scale of temperature are:

Oxygen	—183.00±.02
Nitrogen	—195.81±.02
Hydrogen	—252.78±.02

Over the range —183° to —205° the variation of the boiling-point of oxygen with pressure is given by the equation

$$\log p_{mm} = -379.95/T - 0.0096219T + 1.75$$

$$\log T + 4.53939 \text{ (where } T = 273.20 + t)$$

and for nitrogen by

$$\log p_{mm} = -301.91/T - 0.0090272T + 1.75$$

$$\log T + 4.17643$$

The resistances of two Pt thermometers used over a period of twelve years in this work were again measured at these fixed-point temperatures. The values have remained practically constant, the greatest observed alteration only corresponding to a change of temperature of 0.02° (Sci. Abstr. 1924, 27, 645).

THERMIOL. Trade name for sodium phenylpropionate.

THERMIT PROCESS. 'In a thermit reaction a metallic compound (e.g. an oxide) is reduced by one or several metals or metallic alloys in such a way that when the mixture is ignited at one place, the reaction continues to go on spontaneously with complete oxidation of the reducing element, a fluid slag being formed, whilst the reduced metal is obtained as a compact

uniform regulus; if the oxide is used in excess, the reduced metal is free, or practically free, from the element used as reducing agent' (H. Goldschmidt, *Electrochem. and Metall. Ind.* 1908, 6, 360).

In 1898 Goldschmidt (Stahl and Eisen, 1898, 18, 408; J. Soc. Chem. Ind. 1898, 17, 543, 584, 649; Zeitsch. für. Elektrochem. 1898, 4, 494; 1899, 6, 53) succeeded in reducing the oxides of chromium, manganese, iron, copper, titanium, boron, tungsten, molybdenum, nickel, cobalt, zirconium, vanadium, columbium, tantalum, cerium, thorium, barium, calcium, sodium, potassium, lead, and tin very conveniently by means of aluminium. Such reduction processes had been anticipated, owing to the fact that measured with respect to the same quantity of oxygen, aluminium has a greater heat of oxidation than almost any other metal. Earlier attempts to carry out such experiments had, however, proved very unsatisfactory; either the reactions would not begin, or they occurred with explosive violence. Goldschmidt overcame the difficulty by mixing the finely-divided oxide intimately with powdered or granulated aluminium, and starting the action at one point by raising its temperature sufficiently high. The reaction being once initiated, the enormous heat developed causes it to spread quickly throughout the entire mass, the time of reaction not varying appreciably with the quantity of material employed, and being about 30 seconds in the case of iron oxide and aluminium. To start the reaction at one spot, Goldschmidt placed a small heap of a mixture of powdered aluminium (or magnesium) and barium peroxide on top of the mixture to act as a fuse, and inserted therein a strip of magnesium ribbon. On lighting the latter, the fuse ignites, and the thermit reaction is started.

Owing to the heat developed in these reactions and the rapidity with which they occur, an enormous temperature is produced, second only to that of the electric arc. It has been estimated at 2600°–3000°, and direct observation with a Fery radiation pyrometer has shown that the temperature of a stream of steel produced from iron oxide and aluminium, as it was poured from the crucible, was 3200° (the melting-point of steel is approximately 1350°). At such temperatures the entire contents of the crucible remain liquid; the reduced metal sinks to the bottom, covered with a layer of molten alumina.

Other metals have been tried for the reduction of metallic oxides. Perkin (Faraday Soc. Trans. 1907, 3, 115, 179), and also Goldschmidt have tried calcium, but the reactions are too violent to be of much use, whilst the slag is difficultly fusible. Silicon (made in the electric furnace) has also been tried; but the reactions are too slow. The so-called mixed-metal, which consists essentially of cerium, has, however, been successfully employed in the preparation of pure vanadium, columbium, and tantalum (Muthmann, Weiss, and Riedelbauch, *Annalen*, 1907, 355, 58; Weiss and Aichel, *ibid.* 1904, 337, 370).

A number of mixtures may be used in place of aluminium, and some have been patented. A mixture of equal parts of calcium-thermit and silicon-thermit, so that the active elements,

THERMIT PROCESS.

calcium and silicon, are in the ratio of 2 to 1, is especially effective (Fr. Pat. 361197, 1905). It reacts like an ordinary aluminium-thermit, yielding a thin fluid having approximately the composition $4\text{CaO} \cdot 3\text{SiO}_2$, and melting at 1425° (Boudouard, Iron and Steel, 1905, 352). The active mixture may be prepared either by mixing or alloying calcium with silicon (v. Fr. Pat. 388638, 1908). A mixture of magnesium and silicon may also be used to replace aluminium, giving a reaction like ordinary thermit (Eng. Pat. 3089, 1906; Fr. Pat. 364313, 1906; U.S. Pat. 902871, 1908), whilst magnesium itself acts similarly to calcium in its reactions with metallic oxides. *Magnesium-silicon* thermit is best mixed in proportions which yield a slag of the composition $7\text{MgO} \cdot 4\text{SiO}_2$. A third mixture, viz. *aluminium-thermit* and *calcium-thermit*, gives very good results. The proportions may vary between wide limits, avoiding too large an excess of calcium, and the calcium aluminate slag is more fusible than alumina. A mixture containing 40 p.c. calcium-thermit produces a very fluid slag $3\text{CaO} \cdot 2\text{Al}_2\text{O}_3$ and has a heat effect greater than that of aluminium-thermit (Fr. Pat. 361197, 1905; addn. Jan. 1906; U.S.A. Pats. 875345, 1907; 875666, 1907; 906009, 1908; Eng. Pat. 926, 1906). See also Watts and Breckenridge, *Electrochem. & Metall.* Ind. 1908, 6, 237; Weston and Ellis, *Faraday Soc. Trans.* 1907, 3, 170; 1908, 4, 60, 130; 1910, 6, 144; and Skinder, *Chem. Zentr.* 1909, i, 629.

Technical applications.—Although the thermit reaction (Goldschmidt's reaction only dates from 1898, it has acquired great technological importance, and the subject of 'aluminothermics' has been extensively developed.

Preparation of metals and alloys.—The following are obtained by reducing the requisite metallic oxides (or mixtures of oxides) with a slight deficit of aluminium; chromium, manganese, molybdenum, ferro-titanium, ferro-vanadium, ferro-boron, manganese-copper, manganese-zinc, manganese-tin, manganese-titanium, chromium-manganese. They are of great value in the iron and steel and other metallurgical industries; chromium, in particular, is largely employed in the manufacture of high-speed tool steel and armour plate. The metals and alloys produced are *carbon-free*. The crucibles in which the preparations are carried out must be lined with magnesia (Eng. Pat. 9610, 1905; Fr. Pat. 354597, 1906), one of the few oxides that aluminium is unable to reduce. The best method of procedure to ensure a maximum yield of chromium or manganese consists in mixing 1-4 p.c. of higher oxide with the bulk of lower oxide to be reduced to metal (Eng. Pat. 20004, 1905; Fr. Pat. 358071, 1905; U.S. Pat. 895628, 1908).

For experimental purposes, steel of any grade can be made by the thermit process, since the heat developed is sufficient to melt thoroughly small portions of even the most refractory metals. The thermit steel is free from carbon, but may be converted into high carbon steel by the addition of cast-iron shot.

The slag produced is also of commercial value. It may be employed in the preparation of aluminium, or used in place of natural corun-

dum. It is especially valuable for use in the manufacture of pottery, for which purpose it is mixed with clay and burned (D. R. P. 160780, 1901). *Corubin*, an abrasive material for making emery wheels, emery cloth, &c., is prepared by crushing the slag obtained as by-product in the manufacture of chromium.

Welding iron and steel, and repairing broken steel castings.—The advantages of the thermit process for these applications are, that it is simple, rapid, requires no special skill, and enables repairs to be made *in situ*, when any other process would necessitate a dismantling of apparatus.

The mixture employed is composed of powdered aluminium and magnetic iron oxide, and when ignited yields half its weight of molten steel. Its registered trade name is 'thermit.' The reaction

indicates that approximately 3 parts of aluminium powder require 10 parts of magnetic oxide, and produce 7 parts of iron. Early literature on the subject gives the reaction as

but examination of thermit with a magnet will show that the magnetic oxide is now employed. It is added in the form of granulated rolling-mill scale.

The firing of a charge of thermit produces a pure mild steel of the following average composition—

Carbon	. . .	0.05-0.10
Manganese	. . .	0.08-0.10
Silicon	. . .	0.09-0.20
Sulphur	. . .	0.03-0.04
Phosphorus	. . .	0.04-0.05
Aluminium	. . .	0.07-0.18

Two methods of welding are in use, (a) the reaction serving merely as a source of heat (Eng. Pat. 19328, 1899), and (b) the steel produced by the reaction being utilised as well (Eng. Pat. 10859, 1901; 20894, 1900; U.S. Pat. 729573, 1903). In process (a) pure materials need not be used, and, if necessary, the thermit may be diluted with a cheap oxide, e.g. iron ore or sand, to lower the final temperature reached. This process is used in the butt-welding of pipes and bars. The ends are cut square, smoothed, and clamped together. A mould is then clamped round the junction. A charge of thermit is fired in an ordinary magnesia-lined crucible, allowed to stand half a minute so that slag and steel may separate (the volume of the molten slag is three times that of the iron produced), and then poured out so that the slag comes first. As the slag is poured in the mould on to the pipe, it forms a hard casing around the metal, and the liquid which follows distributes its heat uniformly through this casing to the metal. In about a minute the pipes have been raised to welding heat. The ends are then pressed tightly together by means of screws arranged in position beforehand. The mould is then removed, the slag collar carefully knocked off, and the red-hot joint allowed to cool. Process (b) has been largely employed in welding together tram and railway line sections. The ends are brought together and clamped accurately in position. A refractory clay mould is clamped

round the ends and the requisite charge of thermit fired in a crucible placed over the pouring gate of the mould. At the end of the reaction, the crucible is tapped from the bottom (see Fig. 1), and the liquid steel flows into the mould, passes upwards from the bottom of the mould, surrounds the base and web of the rail, with which it fuses on account of its enormously high temperature, and on cooling makes a solid steel joint.

The welding of rails is a typical instance of the application of process (b) above, which is also employed for all kinds of repairing work, e.g. mending broken engine frames, driving rods

FIG. 1.—TAP-HOLE OF THERMIT CRUCIBLE.

and spokes, crank shafts, rudder and propeller shafts, stern-posts, &c., in fact, in the majority of cases where it is cheaper to repair than to replace. Where necessary, the fracture is opened out by drilling holes. A wax matrix is then built up over the break of the exact shape that the thermit steel collar to be fused into the casting is to have. Over this, in a sheet iron box, is constructed a mould, having a pouring gate, a preheating gate, and a large riser (Fig. 2). A gasoline torch, fed with compressed air, is then directed through the preheating gate. It melts out the wax, dries the mould, and heats

Fig. 2.

the junction to be repaired to a bright red heat. Meanwhile, the crucible containing the thermit is arranged over the pouring gate. The quantity of thermit required is given by the rule: take 32 times the weight of the wax used, or 18 times as many ounces of thermit powder as there are cubic inches of surplus space in the mould. The crucible (Fig. 1) is designed so as to be tapped from the bottom (Goldschmidt, *Zeitsch. Elektrochem.* 1901, 7, 935; Cohn, *J. Gasbeleucht.* 1901, 44). The gasoline torch is withdrawn when the junction is red hot, the preheating gate plugged with a sand core held in readiness, and the thermit fired without delay. After the reaction is over, and the molten liquid

has stood 30 seconds to allow the slag to rise, the crucible is tapped. The molten steel passes down the pouring gate, around the fractured joint, and up into the riser. The ends of the casting melt into the liquid steel, and on cooling one homogeneous mass is formed. The projecting collar of thermit steel around the joint is left on whenever possible.

The average tensile strength of a thermit steel joint is about 30 tons per square inch cross-section. If the projecting collar of thermit steel has to be planed off, and the tensile strength of the joint is less than that of the body of the casting, the weld may be made stronger by introducing nickel into the composition of the thermit; 1 p.c. of nickel increases the tensile strength of the weld about one-third. For a 1 p.c. alloy, 2 p.c. of nickel thermit may be added to the usual steel thermit, or 5 oz. of metallic nickel may be added to each 100 lbs. of thermit.

Thermit powder is supplied in 50 or 100 lb. drums. For use in repair work, about 2 p.c. of manganese and 5 p.c. of mild steel punchings are added. The former acts as a purifier of the steel produced; the latter serves to lower the final temperature of the reaction and so prevent the contents of the crucible from boiling over.

Use of thermit in foundry practice.—(a) The thermit reaction provides a ready means of introducing in an iron ladle a material which will stir up or pole the entire contents of the ladle, and at the same time produce an increase of temperature. For this purpose, the thermit is contained in cylindrical cans with a sleeve in the middle, suitable for passing on an iron rod. The can is held by the iron rod under the surface of the metal, where the reaction takes place. This procedure prevents the iron from becoming too dull to pour (U.S. Pat. 733957, 1903).

(b) A convenient means of purifying the iron in the ladle, by reducing the presence of harmful nitrogen in the molten metal, consists in holding a can of titanium-thermit under the surface as described in (a). This thermit is a mixture of pulverised aluminium and a titanium-iron oxide. The titanium set free in the reaction is sufficient to combine with the nitrogen in the ladle, titanium cyanonitride being produced. During this formation, the entire contents of the ladle are stirred up, to give the gases an opportunity of escaping. The iron is thereby rendered hotter and distinctly more fluid, and castings made from it are distinguished by their closeness of grain, being especially well adapted for withstanding pressure, e.g. cylinders, valves, &c.

(c) The enormous heat developed may be utilised to decrease the size of the risers of steel castings. The thermit, contained in suitable cans, is held in the neck of the riser, which is thus kept in the liquid state for a longer time than would otherwise be the case, thereby facilitating the proper feeding of the casting. The same principle is successfully applied to reduce the size of lost heads of steel ingots.

(d) In foundries where it is of importance to occasionally make a steel casting in a hurry, burning down the requisite quantity of thermit with an admixture of steel punchings affords by far the easiest method of procedure.

See also Hart's *Welding* (McGraw-Hill Book Co.).

THERMODIN. An acetyl derivative of *p*-ethoxy-phenylurethane. Used as an anti-pyretic.

THERMOMETERS. Changes of temperature are measured by the corresponding alterations produced in one or other of the physical properties of a substance. Thus the expansion of solids, liquids, and gases, the vapour pressures of liquids, the electrical resistance of metals, and other properties have been utilised for the determination of temperature.

In nearly every case the amount of change produced by a given rise or fall of temperature depends on the nature of the substance, and must therefore be carefully determined beforehand for the particular material employed.

There is, indeed, only one known method of measuring temperature which is theoretically perfect, that is to say, which is entirely independent of the nature of the substance; this method, proposed by Lord Kelvin, depends on the ratio of the work done by a reversible heat engine to the heat supplied to it, and the temperature, reckoned from absolute zero, may be defined as the reciprocal of Carnot's function. The method is not one, however, that is capable of practical application.

It has been found that within certain limits of temperature and pressure the expansion of all gases is very nearly the same for equal changes of temperature. Hence it is possible to devise a method of measuring temperature which, while practically independent of the nature of the (gaseous) substance employed, is at the same time fairly convenient for many purposes. It is important also to remark that the values given by an air or gas thermometer are in very close agreement with Lord Kelvin's thermo-dynamical temperatures.

The relation of the volume of a gas to its temperature and pressure may be stated simply as follows: The volume of a gas varies inversely as the pressure and directly as the absolute temperature, or $p \propto 1/v$, where p is the pressure, v the volume, T the absolute temperature, and c a constant depending on the units chosen. If the volume remains constant the pressure varies directly as the absolute temperature, or $p \propto T$, while if the pressure is kept constant the volume varies directly as the absolute temperature, or $v \propto T$.

It is true that the co-efficients of expansion of different gases are not absolutely identical, and that the law holds good only within certain limits of temperature and pressure; but under pressures not greatly exceeding that of the atmosphere the deviations are extremely small in the case of nitrogen, hydrogen, helium, and some other gases, except at very low temperatures. Very accurate investigations of the properties of gases at extremely low temperatures have been carried out by Kamerlingh Onnes and his collaborators at Leiden, and their results show that the constant volume hydrogen thermometer gives nearly accurate results down to -250° and the helium thermometer to still lower temperatures.

An 'air' thermometer may be so constructed that (1) the pressure remains constant and the alteration of volume is measured; (2) the volume remains constant and the change of pressure is observed; (3) both pressure and volume are

allowed to alter, and both are measured. The air or other gas is contained in a bulb of glass, or for very high temperatures of some other material, connected by means of a capillary tube with a mercury or sulphuric acid manometer. The bulb is heated to the required temperature while the other parts of the apparatus remain at the temperature of the room. If the pressure be kept constant the gas will expand, and at high temperatures a considerable portion of it will pass into the cold part of the apparatus and must be measured at the ordinary temperature; it is therefore usually considered better to raise the pressure so as to keep the volume of gas as nearly constant as possible. The vessel containing the gas expands, however, when the temperature rises, and a correction on account of this expansion must be introduced.

There are also three sources of error which are difficult to estimate, but they may be almost entirely eliminated by taking suitable precautions. The first depends on the fact that at ordinary temperatures air condenses to a slight extent as a sort of film on the surface of glass, while at high temperatures this condensed air is converted into gas, so that the apparent expansion is a little greater than the real. If, however, the bulb, after thorough exhaustion at a high temperature, is filled with air from which all moisture and carbon dioxide have been removed, the error becomes practically negligible (Callendar, Phil. Trans. 178A, 161).

The second is due to slight changes of volume which a glass vessel is liable to undergo after being strongly heated and allowed to cool again. The magnitude of the possible error becomes extremely small, however, if the bulb is heated for some hours to at least the highest temperature which is to be registered, before its volume is determined. This point will be more fully discussed when dealing with mercurial thermometers. The third source of error is due to the deformation of the bulb or to leakage of gas through it when the temperature and the internal gaseous pressure are greatly raised. This difficulty has been overcome by Day and Clement (Amer. J. Sci. 26, 1908), who employed a platinum-iridium bulb containing nitrogen, by surrounding the bulb with nitrogen at the same pressure as that within the bulb. Further precautions are described by Day, Sosman and Allen, Carnegie Inst. of Washington, Geophys. Lab. 1; Day and Sosman, Amer. J. Sci. 33, 517; and Ezer Griffiths, Methods of Measuring Temperature, 1918.

Of the numerous forms of air thermometer which have been devised, the three shown in the diagrams may serve as examples. The first (Fig. 1) represents a form of instrument employed by Regnault in his classical researches. The bulb A of the thermometer is connected by a capillary tube (passing through a perforation in the screen B) with the mercury manometer mm' , a front view of which is shown in Fig. 2. By addition of mercury to the open limb m' , or by its removal by means of the stopcock s , the mercury in the limb of the manometer connected with the air thermometer may be always kept at the same height, so that there is no alteration of the volume of air except that due to the expansion of the bulb when heated.

The calculation of the temperature is based on the fact that the mass of air remains constant, although its temperature, its pressure, and, to a small extent, its volume undergo change. Let

V = volume of bulb A at 0° ;

v = volume of capillary tube, together with the small portion of the manometer above the mercury in m , also at 0° ;

α = coefficient of increase of pressure of dry air at constant volume;

κ = coefficient of expansion of glass;

D = mass of 1 c.c. of air at 0° and 76 cms. pressure;

P = observed pressure—that is to say, the barometric pressure, plus or minus the difference of level of the mercury in m and m' .

When the bulb is placed in melting ice, while the capillary tube and manometer are at the

	p_0
Hydrogen	760 mm. 0.0036627
Helium	700 „ 0.0036626
Nitrogen	760 „ 0.0036714
Oxygen	663 „ 0.003674

If the volume of air be allowed to vary, the limb m of the manometer must be graduated, and should be surrounded by cold water of known temperature. In this case the additional volume v' at the temperature of the water must be brought into the equation.

Sulphuric acid may be employed with advantage in place of mercury, since it moves more freely in a narrow tube, and, being lighter, allows of more delicate readings; or a small sulphuric acid gauge may be interposed between the thermometer and the mercury manometer. An apparatus which can be employed either as a constant volume or constant pressure manometer has been described by Callendar (*l.c.*)

FIG. 1.

FIG. 2.

temperature t' of the room, the total mass of air will be

$$D.P. \left\{ V + \frac{v(1 + \kappa t')}{1 + \alpha t'} \right\}$$

When the bulb is heated to the unknown temperature x , the temperature of the capillary tube and manometer being now t' the mass of air will be

$$D.P. \left\{ \frac{V(1 + \kappa x)}{1 + \alpha x} + \frac{v(1 + \kappa t')}{1 + \alpha t'} \right\}$$

Therefore

$$P \left\{ V + \frac{v(1 + \kappa t')}{1 + \alpha t'} \right\} = P' \left\{ \frac{V(1 + \kappa x)}{1 + \alpha x} + \frac{v(1 + \kappa t')}{1 + \alpha t'} \right\}$$

an equation in which everything is known but x .

Values of α for several gases for the temperature range 0° to 100° are given below, p_0 being the initial pressure (at 0°).

FIG. 3.

and more fully by Callendar and Griffiths (*Phil. Trans.* 1824, 119). It is represented in Fig. 3.

When the measurement is to be made at constant volume the mercury in A is brought up to the zero point, and the stopcocks T_1 and T_2 are closed. The level of the sulphuric acid in the gauge is then regulated by means of an ordinary mercury manometer, not shown in the diagram, and the pressure is the algebraical sum of the barometric pressure, that registered by the mercury manometer, and the slight difference in level, if any, of the sulphuric acid in the two limbs of the gauge FK , divided by the specific gravity of mercury compared with that of sulphuric acid.

If the pressure is to be kept constant, the tube A is first filled from the reservoir Q until the level of the mercury stands at some point in the tube DE , recorded by the scale S , the pressure of the air in the bulb being equal to that of the atmosphere, as shown by the sulphuric acid gauge. (In this case the tube M is not connected with the mercury manometer, but is open to the air.) When the bulb is heated, mercury is allowed to escape by the three-way tap T_3 into the weighed beaker, the tap being closed as soon as the sulphuric acid gauge indicates that the pressure is again equal to that of the

atmosphere. The increased volume is calculated from the weight of mercury expelled. The narrow tubes DE and FG are calibrated and provided with scales. For the advantages of the sulphuric acid gauge see also Bottomley (Phil. Mag. 1888 (Aug.), 149).

Callendar has (Nature, 1891, 45, 212) described a modified constant-pressure air thermometer which appears to possess marked advantages over those previously devised, and gives extremely accurate results. The pressure of the air in the thermometer is not adjusted to equality with that of the atmosphere, but always with the same constant pressure, obtained by connecting the outer limb of the sulphuric acid gauge to a glass bulb filled with air and kept in melting ice.

The effect of changes of temperature of the connecting tubes on the readings is entirely eliminated by the employment of compensating tubes of the same size, and thus the troublesome and somewhat uncertain correction hitherto necessary is obviated. The compensation is perfect when (1) the two sets of connecting tubes are of equal volume and at the same mean temperature; (2) the mass of air inclosed in the standard pressure-bulb is equal to that in the thermometric and mercury bulbs; (3) the pressures are adjusted to equality. Under these conditions, the temperature of the thermometer bulb (on the air-thermometer scale) is given by the simple equation $\theta_1 = V_1 \theta_0 (V_0 - V_m)$, where V_1 is the volume of air in the thermometer bulb at θ_1° , V_0 and V_m are the volumes of air at 0° in the standard pressure bulb and the mercury reservoir (this being also surrounded by melting ice), and θ_0 is the temperature of melting ice on the air-thermometer scale.

For moderate ranges of temperature, and when extreme accuracy is not required, the apparatus may be greatly simplified, and may be so constructed that the temperatures are read directly on the sulphuric acid gauge; it is stated that such thermometers can be made to read to the tenth of a degree at 450° . This form of direct reading thermometer has been patented and is recommended for technical purposes.

Other forms of air thermometer have been described by Balfour Stewart, Phil. Trans. 153, 425; Codazza, Dingl. poly. J. 210, 255; Jolly, Pogg. Jubelband, p. 82; Mitscherlich, Annalen, 12, 146; Crafts, Ann. Chim. [v.] 14, 409; Andrews, Ber. 14, 2116; Pettersson, J. pr. Chem. [ii.] 25, 102; Caillaet, Compt. rend. 106, 1055; Berthelot, Ann. Chim. [iv.] 13, 144; Murray, J. Phys. Chem. 1897, i. 714; v. also Ezer Griffiths, *l.c.* A platinum bulb was recommended by Pouillet (Compt. rend. 3, 782), but it was pointed out by Becquerel (Ann. Chim. 58, 49) that at high temperatures air passes through the platinum. A porcelain bulb was employed by Weinhold (Pogg. Ann. 149, 188), by Deville and Troost (Ann. Chim. [iii.] 58, 265), and others. According to Holborn and Day (Wied. Ann. 68, 817; Amer. J. Sci. 8, 165; 10, 171), however, porcelain does not give satisfactory results at high temperatures. They recommend bulbs of Jena boro-silicate

No. 59m, containing hydrogen for temperatures up to 500° , and bulbs of a platinum-iridium alloy (10 p.c. Ir) with pure nitrogen gas from 500° to 1300° . The Pt Ir bulbs

should be heated electrically or else protected from gaseous combustion products, which are liable to pass through the alloy. Holborn and Henning (Ann. d. Physik. 35, 4, 761) used Jena glass No. 59m for nitrogen, hydrogen, and helium, and quartz for nitrogen. Day and Sosman (Amer. J. Sci. 1910, 20) have measured temperatures to 1550° . They describe special precautions required to obtain a uniform temperature about the bulb (*ibid.* 1912, 33, 517). Harker proposes to make bulbs of rare earths such as those used for Nernst filaments.

For very low temperatures, the glass bulbs should contain hydrogen or helium. A very complete account of the hydrogen thermometer in use at the cryogenic laboratory at Leiden is given by Kamerlingh Onnes and Clay (Comm. No. 95e), and of the helium thermometer by K. Onnes and Weber (Comm. No. 147b, 1915), and Cath and K. Onnes (Comm. 152a, 1918).

As regards the theory of the subject and the comparison of the temperatures registered by different gas thermometers with each other and with the thermodynamical scale, reference may be made to the following memoirs and papers: D. Berthelot, Sur les thermomètres à gas, Paris, 1903; Anh. d. poids et mesures, 1907, 13b, 3; Chappuis, Phil. Mag. 1900, 50, 433; 1902, 3, 234; Phil. Trans. 1900, 191, 37, 131; J. Phys. 1904, 3, 833; Ann. d. poids et mes. 1907, 13a, 3; Kamerlingh Onnes, Comm. 97a and b, 102b and d; Holborn, Ann. Physik. 1901, [vi.] 2, 242; Buckingham, Bureau of Standards, 1907, 3, 237; Phil. Mag. 1908, 15, 526; Rose-Innes, *ibid.* 1908, 14, 301; Kamerlingh Onnes and Holst, Comm. 141a; Report by Kamerlingh Onnes at Third International Congress of Refrigeration, 1913, section for Physics, Chemistry and Thermometry; Ezer Griffiths, *l.c.*; Cath and K. Onnes, Comm. No. 156a, 1922.

Air thermometers for technical purposes are generally provided with scales which are calibrated empirically by heating the bulbs to two or three known temperatures, so as to obtain a certain number of fixed points. The scales are then constructed by interpolation.

Thermometers of this class have been described by P. Schoon, D. R. P. 20345, 1882; Witz, Compt. rend. 91, 164; Beilby, J. Soc. Chem. Ind. 1885, 41; Coleman, *ibid.* 1885, 43; Heisch and Folkard, and by Bristol (Mech. Eng. 1900, 6, 916). They consist of a porcelain bulb, a copper capillary, and a pressure gauge constructed with two spiral tubes on the Bourdon principle. They can be constructed as recording instruments. The thermometer of Heisch and Folkard is very simple, and has been found by Hurter (J. Soc. Chem. Ind. 1886, 635) to give good results. The bulb A (Fig. 4) contains air under reduced pressure, and there is a vacuum over the mercury in the manometer M.

The mercurial thermometer.—For ordinary purposes the mercurial thermometer is the most convenient, for it may be made of any required size, is easily portable, and the bulb, if elongated, need not be wider or, indeed, so wide as the stem. The instrument consists of a spherical or cylindrical bulb fused to a capillary tube of suitable length. The bulb is filled with pure mercury, which must be boiled for some time to remove the film of gas or aqueous vapour which adheres obstinately to the surface of the glass.

If the thermometer is required for low temperatures only, there is usually a vacuum in the stem of the thermometer, but for high temperatures it is necessary, and for temperatures above 70° or 80° advisable, to fill the capillary

FIG. 4.

tube with nitrogen to prevent distillation of the mercury, a small bulb being blown at the upper end of the tube in order that when the mercury expands and compresses the nitrogen the pressure shall not rise too high.

An ordinary thermometer is graduated by placing it first in the steam from water boiling under known pressure and then in melting ice (v. Guillaume, *Traité pratique de la Thermométrie de Précision*, p. 112). The variation of the melting-point of ice with the pressure is so minute that this point may be taken as absolutely fixed, but the boiling-point of water varies considerably with the pressure, and therefore some standard pressure must be chosen. This is 760 mm. or 29.922 ins. of mercury measured at 0°C. and at the latitude of Paris for the Centigrade scale, and 29.925 ins. of mercury at 32°F. at the latitude of London for the Fahrenheit scale.

The position of the mercury in the stem is marked off at these two temperatures, and the space between these two fixed points is then usually divided into a certain number of equal parts—100 on the Centigrade scale, 180 on the Fahrenheit, and 80 on the Réaumur. On the Centigrade and Réaumur scales, the melting-point of ice is taken as the zero point, but on the Fahrenheit the zero of the scale is placed 32 divisions lower down, so that the melting-point of ice is 32°, and the boiling-point of water 212°.

A thermometer graduated in this manner does not, however, register true temperatures except at the two fixed points, for the following reasons:—1. It is impossible to obtain an absolutely cylindrical capillary tube, so that the volume corresponding to a scale division is not quite the same in all parts of the tube. Various methods have been devised for calibrating the stem (v. Brit. Assoc. Report, 1882, 145–204, also Guillaume, *l.c.* 43–99), but when this is done there remain other sources of error. 2. The position of the mercury in the stem at any

temperature depends on the expansion both of the mercury and of the glass, and in each case the rate of expansion increases with rise of temperature. Moreover, different kinds of glass have different rates of expansion, so that two thermometers made of different materials—even if the capillary tubes were perfectly cylindrical—would give different readings at the same temperature. The only really satisfactory method of correction of such a thermometer is to compare its readings either directly with an air thermometer, or with another mercurial thermometer which has previously been standardised by means of an air thermometer. Or a series of fixed points may be determined by immersing the thermometer in a number of freezing liquids (melting solids) or by heating it with the vapours of a series of pure liquids boiling under known pressures. The following table contains a list of suitable substances with their melting-points, transition-points, or boiling-points, and the variation of pressure corresponding to 1° at the boiling-points, temperatures outside the range of the mercurial thermometer being included for convenience:—

Temperature	Fixed point
–183.0°	b.p. of oxygen; $dp/dt=75.9$ mm. per degree.
–159.6	m.p. of isopentane.*
–126.3	m.p. of methyl cyclohexane.*
–116.3	m.p. of ethyl ether.*
–111.6	m.p. of carbon disulphide.*
–95.1	m.p. of toluene.*
–83.6	m.p. of ethyl acetate.*
–63.5	m.p. of chloroform.*
–45.2	m.p. of chlorobenzene.*
–38.87	m.p. of mercury.
–22.9	m.p. of carbon tetrachloride.*
0	m.p. of ice.
32.38	tr.p. of sodium sulphate.
46.2	b.p. of carbon disulphide; $dp/dt=24.8$.
50.67	tr.p. of sodium bromide.
78.3	b.p. of ethyl alcohol; $dp/dt=30.5$.
100.0	b.p. of water; $dp/dt=27.1$.
132.0	b.p. of chlorobenzene; $dp/dt=20.2$.
156.2	b.p. of bromobenzene; $dp/dt=19.4$.
184.1	b.p. of aniline; $dp/dt=19.6$.
218.0	b.p. of naphthalene; $dp/dt=15.2$.
231.8	m.p. of tin.
305.9	b.p. of benzophenone; $dp/dt=15.8$.
320.9	m.p. of cadmium.
356.7	b.p. of mercury; $dp/dt=13.3$.
419.4	m.p. of zinc.
444.55	b.p. of sulphur; $dp/dt=11.1$.
630.0	m.p. of antimony.
756.0	b.p. of cadmium; $dp/dt=8.1$ (calculated).
916.0	b.p. of zinc; $dp/dt=7.0$ (calculated).
960.5	m.p. of silver.
1063	m.p. of gold.

* Timmermans, Van der Horst and Kammerlingh-Onnes, Comm. No. 157, 1922. Samples of the liquids marked with an asterisk are supplied by the Bureau des Etalons physicochimiques, Université, Rue des Sols, Brussels. The m.p.s. are stated to be correct to 0.1° on the Leiden helium thermometer scale.

Temperature	Fixed point
1083 .	m.p. of copper.
1452±2 .	m.p. of nickel.
1549±2 .	m.p. of palladium.
1755±5 .	m.p. of platinum.
2910 .	m.p. (approx.) of tantalum.
3080 .	m.p. (approx.) of tungsten.

For additional fixed points between 0° and -160°, v. Timmermans, *Sci. Proc. Roy. Dubl. Soc.* 1912, and for a few very accurately determined temperatures, v. T. W. Richards, *J. Amer. Chem. Soc.* 33, 847; 36, 485, 1825; 40, 89. Steinmetz (*ibid.* 1918, 40, 96) gives the melting-points of a number of eutectic alloys. A table of melting-points of the elements has been published by the U.S. Bureau of Standards (v. *J. Soc. Chem. Ind.* 1919, 38, 67R). For the accurate calibration of short-range thermometers Richards and Shipley (*ibid.* 36, 1) recommend a floating-equilibrium method, hollow floats of glass or quartz being immersed in solutions of known concentration; Richards and Thorwaldson (*ibid.* 37, 81) have employed, with very satisfactory results, a method based on the heat of dilution of hydrochloric acid; and Richards and Tamaru (*ibid.* 42, 1374) describe a calorimetric method based on electric energy.

In this way a table or curve of corrections may be constructed showing the error at any scale reading of the thermometer. 'Normal' thermometers may now be purchased; they are compared with a standard thermometer before graduation, and nearly true temperatures are registered by them; or the thermometers may be sent to the National Physical Laboratory, the Reichsanstalt (v. Warburg, *Ann. Physik.* 1916, 48, 8, 1034), or the Bureau of Standards, and the necessary table of corrections obtained. The calibration of thermometers, as carried out at the Physik-Tech. Reichsanstalt, is described by Warburg (*Ann. d. Physik.* 1916, 48, 1034).

Tables of correction of readings of mercurial thermometers to true air-thermometer temperatures have been published by various observers; but as these tables must necessarily vary for different kinds of glass—the further correction for unevenness of bore being also required—they do not seem to possess much general value. It may be useful, however, to give references.—Rudberg, *Annalen*, 36, 121; Boescha, *Compt. rend.* 69, 875, 1185; Regnault, *ibid.* 69, 879, and *Mémoires*, 21, 239; Crafts, *ibid.* 95, 836; Recknagel, *Pogg. Ann.* 123; Guillaume, *Traité pratique de la Thermométrie de Précision*.

Even when the above corrections to true air-thermometer temperatures have been made, there remain some sources of error, the most important of which is the alteration of the capacity of the bulb, and doubtless also of the capillary tube after long-continued heating, and, indeed, after any considerable change of temperature. A vast amount of experimental work has been done on this subject, and the explanation of the observed changes has given rise to a great deal of discussion. The following references may be made to the literature of the subject:—Desspretz, *Compt. rend.* 4, 926; Person, *ibid.* 19, 1314; Legrand, *ibid.* 4, 173; Crafts, *ibid.* 91, 291, 370, 413; 94, 1298; Pernet, *ibid.* 91, 471; E. J. Mills, *T. Ed. 24, Part 2*, 587,

and Nature, 41, 100, 227, 538; Young, *ibid.* 41, 152, 271, 488; Tomlinson, *ibid.* 41, 198; Pernet, *Travaux et Mém. du Bureau Int. des Poids et Mesures*, i., B. 52, and I., 17; Guillaume, *Traité pratique*; Marchis, *Zeitsch. physikal. Chem.* 1899, 29, 1; 1091, 37, 553, 605; Ezer Griffiths, *l.c.* The most important facts regarding the alteration of zero point may be shortly described as follows:—

1. If a thermometer be graduated shortly after the bulb has been blown, the zero point will rise with comparative rapidity at first, then more and more slowly, and the elevation of the zero point may go on for many years. Joule (Scientific Papers, i. 558) took observations with one thermometer over a course of thirty-eight years, and the change, which then amounted to almost exactly 1°F., was still proceeding.

2. If a thermometer be maintained at a high temperature for a considerable time, the rise of the zero point takes place with much greater rapidity, and so far as is known the higher the temperature the more rapid is the rise, and apparently the higher is the final point reached. A total elevation of over 20° in the case of German soda glass has in several cases been observed, while larger glass bulbs, after continuous heating to 445°, or in one case 511°, have been found by Regnault, Crafts, and Callendar and Griffiths to suffer a contraction of from 0.25

0.34 per cent. In all cases the rise or contraction, which is rapid at first, becomes gradually slower, and it seems doubtful whether at any given temperature actual constancy of zero point or capacity has ever been attained. If, however, a thermometer has been heated for many hours to a given high temperature and then allowed to cool very slowly, subsequent heating to lower temperatures has very little effect on the zero point, and it is advisable to subject a thermometer to this process before determining the fixed points. According to Marchis (*l.c.*), a fluctuating high temperature is more effective than a steady one in raising the zero point. Hecker (*Zeitsch. f. Instrumentenkunde*, Beib. 1901, 5, 41) describes a method of electrical heating and slow cooling. Böttcher (*ibid.* Beib. 1903, 17, 154) states that the thermometer bulb should be heated for a short time to a temperature 100° above the initial softening temperature of the glass, and that slow cooling is unnecessary. The question is discussed by Dickinson (*Bureau of Standards*, 1906, 2, 189) and methods of treatment are recommended. Weibe (*Zeitsch. Instrumentenk. Beib.* 3, 21; 4, 33) states that Jena borosilicate glass 5914 thermometers should be kept at 500° for at least 10 days, and that slow cooling is of comparatively small importance.

3. Not only is the zero point liable to change, but the interval between the zero and 100° points may at the same time be increased, for the coefficient of expansion of glass suffers diminution after prolonged heating.

4. Internal or external gaseous pressure on the bulb appears to have little or no influence on the rise of zero point.

5. If a thermometer—even after its zero point has been rendered as permanent as possible—be heated and then cooled very rapidly, a fall of the zero point will be observed, but after a day or two the greater part of this

fall, will be recovered, and the remainder after a longer period. The alteration of the zero point depends greatly on the nature of the glass, and a special hard glass is used by Tonnelot of Paris, while Schott and Co. in Germany employ two kinds of glass, 'normal thermometer' glass, 16^{III}, and a boro-silicate glass, 59^{III}, for the best thermometers. The latter glass is now generally used; it has a very high melting-point and can be used up to 550°, the mercury being prevented from boiling by the introduction of carbon dioxide under pressure (*cf.* Murrie, *J. Soc. Chem. Ind.* 1885, 45, 189, 655). Glass suitable for thermometers is now being made in England, and information regarding composition and properties may be obtained from the Institute of Chemistry. It is stated by Ezer Griffiths that fused quartz is much superior to glass as regards changes of zero point.

Other possible sources of error are the following:—If the mercury in the stem of the thermometer—or a portion of it—is not heated to the same temperature as that in the bulb, a correction is required, *v.* DISTILLATION, *v.* also Dimmer, *Akad. Wiss. Wein. Ber.* 122, 2a, 1439. Wheeler (*J. Soc. Chem. Ind.* 1916, 35, 1198) gives a useful graph, based on Thorpe's formula, to facilitate this correction. In order to ascertain the mean temperature of the unheated column, Guillaume (*Compt. rend.* 1891, 112, 87) places a supplementary thermometer without a bulb at the side of the thermometer stem. Modifications of this method have been proposed by Mahlike, *Zeitsch. Instr.* 1893, 13, 58; 1894, 14, 73; and by Adam, *ibid.* 1907, 27, 101.

The bulb is slightly compressible, and considerable changes of external pressure affect the readings to some extent.

Mercury does not move very freely in a capillary tube, and in delicate thermometers, when the temperature changes, the movement of the mercury may take place in jerks instead of smoothly. This may be avoided by tapping the thermometer (Pickering, *Phil. Mag.* 1886, 21). Greater freedom of motion is attained (Duciaux and Hamelin, *J. Phys.* 1910, 9, 600) by placing dilute sulphuric acid over the mercury, and electro-capillary effects are prevented by means of a recess full of mercury at the upper end of the capillary, the mercury in recess and bulb being connected by a platinum wire. The increase in sensitiveness was found to be so great that variations in the melting-point of ice with moderate change of pressure were readily observed.

For temperatures below the freezing-point of mercury, -38.7°, various liquids have been suggested to take the place of that metal. Alcohol and toluene thermometers have been in use for many years, and, more recently, pentan has been found specially suitable for very low temperatures (Kohlrausch, *Wied. Ann.* 1897, 60, 463; Baudin, *Compt. rend.* 1901, 133, 1207; Rothe, *Zeitsch. Instr.* 1902, 22, 192; Hoffmann and Rothe, *ibid.* 1907, 27, 265). Baudin and Rothe recommend 'technical' in preference to pure pentane on account of its lower freezing-point. The b.p. is 25° to 33°, and the pentane thermometer can be used between 30° and -190°.

The molecular weight of a dissolved substance is very frequently calculated from the

depression of the freezing-point or the rise of the boiling-point of a solvent. Thermometers of small range but great sensitiveness have been devised for these determinations, by Beckmann, and a full description of various forms of the instrument is given by him (*Zeitsch. Chem.* 1905, 51, 329). The bulb is of large size and the same thermometer can be used for different temperature ranges by transferring part of the mercury from the bulb to a receptacle at the other end of the capillary. The value of a scale division is thereby slightly altered, and the necessary corrections are discussed and a table is given by Grützmacher (*Zeitsch. Instr.* 1896, 16, 171, 200).

Useful general information about mercurial thermometers is contained in the following papers: Chree (*Phil. Mag.* 1898, 45, 205, 299); Kohlrausch (*Zeitsch. Instr.* 1898, 18, 76); Scheel, (*ibid.* Beib. 1899, 9-13); Harper (*Bureau of Standards, Bull.* 8, 659); Coste (*J. Soc. Chem. Ind.* 1913, 32, 341; *v.* also Ezer Griffiths, *l.c.*

Other methods than those dependant on the use of the mercurial thermometer are in use for the determination of temperatures, but they are of varying degrees of accuracy. The method of determining the melting-points of minerals from the heating and cooling curves necessitates the use of a considerable amount of material, whilst the microscopic method lacks accuracy. Borgström (*Jahrb. Min.* 1816, 7, ref. 9-11) has made use of a method employed for organic substances, the substance being enclosed in a capillary tube of silica-glass and immersed in a transparent bath of fused salts (mixtures of sodium and potassium nitrates, sodium, potassium, and lithium chlorides, and sodium sulphate in various proportions according to the temperature required). A connection is traced between the melting-points and the geological occurrence of mineral substances, those with higher melting-points being found at greater depths in the earth's crust (*Chem. Soc. Abstr.* 1916, n. 191).

Platinum resistance thermometers.—The measurement of temperature by the alteration of the resistance to electricity of a platinum wire was suggested by Siemens (Bakeman Lecture, *Proc. Roy. Soc.* 1871), but in consequence of an adverse report to the British Association in 1874 this method was abandoned. Subsequently, however, the subject was investigated by Callendar (*Phil. Trans.* 1887, 178 A, 161; *Phil. Mag.* 1891, 32, 104; 1899, 47, 191); Griffiths (*Phil. Trans.* 182 A, 43), and both authors (*ibid.* 182 A, 119) with very satisfactory results. In order to insure accuracy the platinum wire must be pure in the first place; it must be prevented from alloying with silicon, carbon, tin, or other impurities, and it must not be subjected to strain—such as elongation. When these conditions were fulfilled, the resistance of a wire was always found to be constant at a given temperature. The form of thermometer recommended by Callendar and Griffiths is shown in Fig. 5. Two platinum wires are inter-wound in a double-screw thread, passing through holes in a thin mica plate *AB*. Each spiral is provided with a double and single electrode, symmetrically arranged. The six electrodes are insulated, and kept in place by passing through holes in thin mica wads

(one of which is shown at c) which are cut to fit the glass tube containing the thermometer. The electrodes are best made of platinum, the ends of the wires being fused to them by the oxy-hydrogen flame.

If R_0 and R_1 be the resistance at 0° and 100° , and R that at any other temperature, the corresponding value of the platinum temperature pt is deduced by the formula

$$pt = 100(R - R_0)/(R_1 - R_0).$$

To reduce the platinum resistance temperature to that of the air thermometer the following formula is employed

$$T - pt = \delta \left[\left(\frac{T}{100} \right)^2 - \frac{T}{100} \right]$$

the value of δ , generally 1.5, depending on the wire and being determined for each thermometer from observations at 0° , 100° , and 444.5° . The formula has been found to hold up to 1000° or 1100° . To avoid errors due to variation of the room temperature, compensating leads are used, and other improvements have been adopted from time to time. For further details, v. PYROMETRY; also, Mueller, Bureau of Standards, 1916, Bull. 13, 547; Sligh, J. Amer. Chem. Soc. 1921, 43, 470; Roebuck, J. Opt. Soc. Amer. 1922, 6, 865; and Ezer Griffiths, *l.c.*

For moderate temperatures, nickel is recommended in place of platinum by Marvin (Phys. Rev. 1910, 30, 522); Jaeger and v. Steinwehr (Ann. d. Physik, 43, 8, 1165; 45, 7, 1089) have studied mercury resistance thermometers. They are much less sensitive than platinum thermometers, but have the advantage that a preliminary

determination of resistance need only be made at a single normal temperature. Metallic oxide resistance thermometers have been constructed and investigated by Brown (Phys. Rev. 5, 126; 9, 205). Boron is recommended by Heraeus (D. R. P. 316416) (l. 4, 19) on account of its high temperature coefficient.

Dewar (Proc. Roy. Soc. 1904, 73, 244) states that platinum does not give good results at very low temperatures and recommends gold or silver. Meilink also (K. Akad. Wet. Amsterdam, 1904, 13, 212, 221) obtained better results with gold than with platinum. The resistance of gold, platinum, and other metals at low temperatures has been accurately determined by Kamerlingh Onnes and Clay, (Comm. 99c and 107c. Kamerlingh Onnes and Holst (Comm. 141d) found that platinum is unsuitable in the region of -200° , and that at the lowest temperatures manganin and constantan are more satisfactory than either platinum or gold; but Zernike (K. Akad. Amsterdam, Proc. 18, 6, 914) gives an interpolation formula for platinum which is claimed to be accurate to within 0.02° at all temperatures below -200° . The resistance of mercury, tin, cadmium, con-

stantan, and manganin down to the boiling-point of helium has been determined by K. Onnes and Holst (Comm. No. 142a), and of mercury with liquid helium (*ibid.* 142c); also of pure metals with liquid helium by K. Onnes and Tuya (*ibid.* 160a and b).

Comparisons of the platinum scale of temperature with the hydrogen, nitrogen, helium, or air scale have been carried out by Harker and Chappuis (Phil. Trans. 1900, 194, 37) at Sevres; Meilink (K. Akad. Wet. Amst. 1902, 10, 495); Holborn (Ann. Physik. 1901, [vi.] 2, 242); Harker (Proc. Roy. Soc. 1904, 73, 217); Travers and Gwyer (*ibid.* 1905, 74, 528); Kamerlingh Onnes and Clay (*l.c.*); Holborn and Henning (Ann. Physik. 1911, 35, 4, 761); Dickinson and Mueller (Washington Acad. Sci. 1912, 2, 176); Henning (Ann. Physik. 1913, 40, 4, 635); Kamerlingh Onnes and Holst (Comm. 141a); of the platinum, gold, and hydrogen thermometers by Kamerlingh Onnes and Clay (Comm. 95c, d, and e), and of platinum, gold, and helium thermometers between -218° and -246° by Cath, K. Onnes, and Burgess (Comm. 152c), completing the data from 0° to -258° ; v. also Timmermans (*l.c.*); Moeller, Hoffmann and Meissner (Zeitsch. Instr. 1912, 32, 217) give comparisons of mercury and platinum scales from 0° to 550° .

Thermo-electric thermometers.—The first attempt to employ a thermo-couple for the measurement of high temperatures was made by Becquerel in 1826, but he failed to obtain concordant results. In 1886, however, Le Chatelier devised an instrument which gave good results and came into practical use, and since then great improvements have been introduced.

The thermo-electric thermometer consists essentially of two fine wires of different metals or alloys, fused together at one end, and connected through a galvanometer at their other ends, the fused end being placed in the source of heat. An E.M.F. is developed, which is roughly proportional to the difference in temperature of the two ends of the couple. Le Chatelier employed wires of Pt and Pt-Rh (10 p.c. of Rh), and this couple may be used up to 1600° . The other couples which have been employed most frequently are Pt and Pt-Ir (10 p.c. Ir), and Cu and constantan (a Cu-Ni alloy with 40 p.c. Ni); the former may be used for temperatures as high as 1200° , the latter up to 500° . For full account of these thermometers v. PYROMETRY.

A great variety of couples have been tried for both high and low temperatures. For high temperatures the couples mentioned have been found to give the best results, but the Pt-Ir alloy has the disadvantage that the Ir volatilises, very slowly even at 900° , and much more rapidly at 1200° . Sosman (Amer. J. Sci. 1910, 30, 1) has investigated the Pt.—Pt.Rh (10 p.c. of Rh) thermo-element between 0° and the m.p. of Pt, $1755^\circ \pm 5^\circ$, and Adams and Johnston (*ibid.* 1912, 33, 534) the Cu-constantan thermo-element between 0° and 360° , and they give a standard scale of temperature between 200° and 1100° . Hevesy and Wolff (Phys. Zeitsch. 1910, 11, 473) find that the Ag—Ni thermo-element gives good results between -80° and 920° . Kowalko (Am. Electrochem. Soc. Trans.

FIG. 5.

1916, 29, 56) considers the Co—constantan element the best; cobalt withstands the action of hot gases better than nickel, remaining malleable and ductile. For low temperatures, Holborn and Wien (Wied. Ann. 1896, 59, 213) have recommended Fe—constantan; Pellat (Compt. rend. 1901, 133, 921), Fe—Zn; Dewar (Proc. Roy. Soc. 1905, 76, 316), Pt—German silver; whilst Kamerlingh Onnes and Clay (Comm. 1076) find that Ag—Au gives the best results. At about -256° this couple is about twice as sensitive as one of constantan—steel.

Comparisons of the thermo-electric scale of temperature with the air or hydrogen scale have been made by Holborn and Wien (Wied. Ann. 1895, 55, 95; 1896, 59, 213); Harker (Proc. Roy. Soc. 1904, 73, 217); and at low temperatures (-59° to -259°) by Kamerlingh Onnes and Crommelin, Comm. 95a; and with the platinum resistance scale by Waidner and Burgess, Bureau of Standards, Bull. 1909, 6, 149. White (Phys. Rev. 1910, 31, 135) discusses the utility of thermo-elements and the relative utility of thermo-elements and resistance thermometers.

The question of the calculation of the true temperature of the hot junction when the cold one is not at 0° has been fully discussed by Offenhaus and Fischer, Electrochem. Ind., New York, 6, 1908, 362.

Vapour pressure thermometer.—This form of instrument was recommended by Lord Kelvin (Pr. E. 1880, 432), and was introduced into practice under the name of the 'Thalpotassimeter' by Schaffer and Budenberg (Dittmar, J. Soc. Chem. Ind. 1885, 44). If the vapour pressures of a given liquid have been accurately determined through a certain range of temperature, any temperature within these limits may be afterwards determined by observing the pressure exerted by the vapour of the liquid.

The method possesses the great advantage that alteration of the capacity of the vessel containing the liquid and vapour is entirely without influence on the pressure, which is solely dependent on the temperature.

Probably the most serious objection to the method is the difficulty of filling the vessel or reservoir with the pure liquid *entirely free from air*, and if this difficulty be not overcome large errors may be introduced. For high temperatures, a mercury vapour pressure thermometer is sometimes serviceable (Ramsay and Young, Chem. Soc. Trans. 47, 651). The mercury must be well boiled to remove the film of air adhering to the glass, but this may be done without much difficulty. A liquid oxygen vapour pressure thermometer is recommended for temperatures between -183° and -200° by Stock and Nielson, Ber. 1906, 13, 39, 2066, and excellent results have been obtained with such an instrument by Kamerlingh Onnes and Braak, K. Akad. Wet. Amsterdam, 1908, 11, 333. Vapour pressure thermometers and pyrometers have been devised by Fournier, and an account of these instruments is given by Marieni (Electricità, Milan, 1908, 30, 82). H. v. Siemens (Ann. Physik. 1913, 43, 4, 871) describes a modification of Stock and Nielson's thermometer and gives the vapour pressures of CS_2 , CO_2 , O_2 , and N_2 , which he

determined by means of a Pt resistance thermometer. Stock, Henning and Küss (Ber. 1921, 54 [B], 1119) give vapour-pressure tables for measurement of temperature between 25° and -185° , and describe the apparatus they employ.

The following papers or memoirs on the subject of thermometry may be consulted: Sur les thermomètres à gaz, D. Berthelot, Paris, 1903; Kohlrausch, Zeitsch. Instr. 1898, 18, 16; Guillaume, Thermométrie de précision; Chrec, Phil. Mag. 1898, 45, 205, 299; Scheel, Zeitsch. Instr. 1899; Callendar, Nature, 1899, 59, 494, 519; Phil. Mag. 1899, 47, 191; Barus, Int. Phys. Congress, Paris, Rep. 1, 1900, 148; Burgess, Chem. News, 1913, 107, 169 and 182; Kamerlingh Onnes, Third Int. Congress of Refrigeration, 1913, section for Physics, Chemistry and Thermometry; Ezer Griffiths, Methods of Measuring Temperature, 1918; Scheel, Zeitsch. angew. Chem. 1919, 32, 347; Kayes, J. Amer. Chem. Soc. 1920, 42, 54; Het Natuurkundig Laboratorium der Rijks-universiteit te Leiden, Articles on Thermometry and Manometry, Keesom, p. 89, Crommelin, p. 211.

For the apparatus for the determination of the heat of evaporation of liquids of high boiling-points, see Awbery and Griffiths (The Phys. Soc. of London, 1924, 36, 303).

An inter comparison of high-temperature scales.

—An inter-comparison has been made by Forsythe (Astrophys. J. 1923, 58, 294) of the high-temperature standards used in certain research laboratories in the United States of America and abroad by the method of brightness temperatures as measured by the disappearing filament optical pyrometer. The 'brightness temperature' of a non-black body, as determined by measuring the brightness for a given wave-length λ with the pyrometer, is defined as the temperature to which a black body must be raised to give the same brightness for the same wave-length. Thus if the brightness temperature of a body is 1500°K. for $\lambda = 0.665\mu$, then for this wave-length the body has the same brightness as a black body for this same wave-length.

Several tungsten lamps which had been carefully aged in the Nela Research Laboratory were sent to the Bureau of Standards, the National Physical Laboratory of Great Britain, the University of Wisconsin, and the Research Laboratory of the General Electric Co., requesting that the temperatures of the lamps should be measured for specified currents. In each of the laboratories the temperatures were measured with a disappearing filament optical pyrometer, using a plate of red glass as the monochromatic screen. The results give not only a comparison of the brightness temperature of tungsten but also a valid comparison of the high-temperature scale. In each laboratory the high-temperature scale is based upon: (a) the melting-point of gold (1336°K.) or palladium (1828°K.), (b) extrapolation by means of Wien's equation using for C_2 the value 14350°K. Necessary reductions due to various factors such as a difference in the standard temperature, or a different value of the constant C_2 have been considered. A table is then given of the values obtained at the various

laboratories, the agreement being very good. Part of the table is given below :

Lamp		N.R.L. April, 1920	N.P.L. July, 1922	N.R.L. June, 1922	Bureau Jan., 1923	N.R.L. Jan., 1924

(Sci. Abstr. 1924, 27, 527).

The measurement of small sources of heat: The use of a compensated micro-calorimeter.—The instrument consists of a cell placed at the centre of a constant-temperature bath and separated from it by a thermal insulator. The evolution of the heat to be measured takes place in the cell. A thermopile, joined to a galvanometer, is connected by a series of junctions with the cell and by another series with the bath, and serves to measure the difference in temperature of the two media.

A second thermopile similarly placed is used to absorb, by the Peltier effect, the heat evolved. Compensation is effected by adjustment of the galvanometer deflection to zero. It is suggested that the method may be suitable for following the progress of chemical reactions where small changes in heat take place or for calorimetric observations in biology (A. Tian, *Compt. rend.* 1924, 178, 705; *Sci. Abstr.* 1924, 27, 527).

S. Y.

THERMONATRITE v. NATRON; TRONA.

THERMOSTATS. A thermostat may be defined to be an apparatus so arranged as to maintain the temperature of a space constant between certain definite limits. Previous to 1860, the forms of apparatus employed were comparatively few and simple, but during subsequent years refinement of physical and chemical experimental methods has led to the design of very numerous varieties of thermostats. Some few of these have been adapted to technical uses; in general these applications present little complexity and do not call for any detailed description. They have mainly been applied to the temperature regulation of steam and gas heating systems and more recently to the control of electrical heating. Among other purposes the temperature control of incubators heated by gas or electricity, of acetylene heated germinating stoves, and of pasteurising apparatus used in the sterilisation of milk are noteworthy. The automatic regulation of the temperature of fermenting vats, of dyevats, of evaporating pans and vacuum stills, has resulted in improvements in the sugar, spirit, and dyeing industries. Similarly, thermostats are extensively adapted to secure the more exact and economical working of lacquering, brazing, tempering, annealing, and roasting ovens and kilns. Numerous systems for the central heating of public buildings and houses by steam, hot water, gas, and hot air are now automatically regulated by thermostatic or electrical control apparatus. Similar thermostatic arrangements are also used in connection with steam-heating devices in railway carriages. In gas-testing stations, rooms are maintained at

a uniform temperature by thermostats controlling the gas-heating system. Automatic fire-alarm devices are usually supplied with thermometric or electrical thermostats arranged to give warning by telegraphic or mechanical signals.

The thermostats and thermo-regulators suggested may be classified as:—

I. Thermostats depending on a flow of heated liquid for the maintenance of a constant temperature.

II. Thermostats utilising the latent heat of the alteration of the state of aggregation or change of phase of a body:

(a) Change of phase at freezing-point or cryohydric-point.

(b) Change of phase at boiling-point.

(c) Change of phase at inversion-point.

III. Other thermostats not automatically regulated through mechanical or electrical means.

IV. Self-regulating thermostats, including—

(a) Mercurial or other single-liquid thermometers:

1. Acting directly on the gas supply or other heat source;

2. Acting on the source of heat through electrical arrangements;

3. Acting on the source of heat through mechanical arrangements;

(b) Gas thermometers:

1. Acting on the gas supply by transmission of pressure through a liquid column;

2. Acting through electrical arrangements;

3. Acting through mechanical arrangements;

(c) Vapour-tension thermometers:

1. Air and vapour;

2. Vapour in contact with its own liquid only;

(d) Thermostats depending on the differential expansion of solid substances;

(e) Electrically heated thermostats with electrical control;

(f) Other mechanical regulators.

The limits of this article preclude the description of more than a few of the more typical examples of each of these classes; details of other forms and references may be obtained from: *Temperature Regulators*, J. T. Brown; *Laspeyres*, *Togg. Ann.* 152, 132; H. Hammerl, *Carl's Rep.* 18, 1882; K. Arndt, *Zeitsch. Chem. Apparatenkunde* 1, 255-263; Fr. Grützacher, *Zeitsch. Instrumentenkunde*, 22, 184, 193, 201; W. C. Geer, *J. Phys. Chem.* 6, 85-105, 1902, who gives a general discussion and a useful bibliography; M. Bodenstein, *Zeitsch. physikal. Chem.* 1899, 30, 113-139, who supplies a detailed account of thermostats used in gas-reaction researches, and H. W. Fischer and O. Bobertag, *Zeitsch. Elektrochem.* 1908, 14, 375. See also Cumming, *Trans. Faraday Soc.* 1912, 7, 253; Bousfield, *ibid.* 260.

I. *Thermostats depending on a flow of heated or cooled liquid for the maintenance of a constant temperature.*—The form of apparatus invented by C. Blaufus-Weiss may be adapted for use either as a pressure or temperature regulator (D. R. P. 43574, 1887). As used in the latter capacity, it consists essentially of a cylindrical

valve controlling the supply of hot or cold currents of either liquid or vapour to a worm arranged in the vat to be maintained at a uniform temperature. The valve is formed by an elliptical slit in a sheet cylinder, which passes half round the circumference of the cylinder, and, when the latter revolves, is brought more or less opposite to tubes opening into the sides of the drum, which serves as a valve-box. The space within the revolving cylinder is furnished with tubes passing through the head of the drum to serve as supply or exit pipes. The valve is worked by the rise and fall of a vertical piston, actuated by the expansion and contraction of a quantity of mercury, which is contained in a bell-shaped vessel of which the wider end is applied to a small chamber which forms a side continuation of the vat. The vertical movement of the piston is transformed into the circular motion of the valve in a horizontal plane by means of a pin working in a screw slot on a hollow cylinder.

A simple thermostat for use in connection with the refractometric examination of oils and fats, by T. E. Thorpe (Chem. Soc. Trans. 1904, 257), uses a constant current of liquid, under a defined pressure head, heated by passing through a coil in the vapour of a boiling liquid (*v. vol. v.*, 652).

W. Behrens (Zeitsch. Wiss. Mikrosk. 1895, 12, 1) describes a neat air-worked expansion valve for controlling a hot-water current supplied to the hot stage of a microscope.

Other forms using this principle are given by J. Ph. Grünig, D. R. P. 75882, 1893; J. C. Schalkwijk, Zeitsch. Inst. 1901, 21, 338; and T. M. Lowry, Trans. Faraday Soc. 1907, 3, 119.

A thermostat for low temperatures has been described by Walton and Judd, J. Phys. Chem. 1914, 18, 717.

II. *Thermostats utilising the latent heat of the alteration of the state of aggregation or change of phase of a body.*—(a) References to types using the change of phase at the freezing-point and cryohydric point will be found in Geer's bibliography (*l.c.*). To these may be added Travers (Zeitsch. physikal. Chem. 1905, 52, 443), using alcohol and carbon dioxide snow for low temperatures.

(b) The change of phase at the boiling-point is more generally utilised. The vapour from a liquid boiling at the required temperature is caused to surround the oven or bath to be heated. Here the temperature will vary according to the pressure under which the liquid is boiled.

The liquids used for this purpose are:—Water, ether, methyl and ethyl alcohols, benzene, toluene, acetic acid, carbon disulphide, amyl alcohol, xylene, turpentine, aniline, naphthalene, glycerol, diphenylamine, the mono hydrate of sulphuric acid, mercury, paraffin, sulphur, zinc.

The temperatures so obtained lie between 22° and 1040°. At the ordinary atmospheric pressure one definite temperature is obtained for each substance used. Intermediate temperatures may be obtained in several ways:—

(1) The pressure under which the vapour is formed is varied; (2) mixtures of liquids in various proportions are used; (3) a solid is dissolved in a liquid, the boiling-point being

thus raised, and the vessel or bath is surrounded by the boiling liquid.

L. Meyer devised an apparatus for determining the boiling-point of a liquid at any pressure below that of one atmosphere. It may be used to control a constant-temperature bath (Annalen, 15, 303). The apparatus (see Fig. 1) is a pressure control valve. The mercury in AB cuts off the connection with the air-pump through H as soon as the pressure is reduced to the required point; CD is a mercury valve which admits air to the apparatus immediately the pressure falls below that fixed upon.

Brown has improved this apparatus, rendering it possible to use it for pressures higher, as well as lower, than one atmosphere. A mercury manometer is so constructed that, immediately the pressure falls below or rises above that determined upon, an electro-magnetic clutch, actuating a suitable stopcock, is placed in a battery circuit, and thus connection is made between the reservoir and the pump or outer air, as may be required for adjustment (Phil. Mag. 1879 [v.] 7, 411).

A. Fock has constructed a very serviceable bath, in which common petroleum is used as the mixture of liquids of different boiling-points. A double cylinder AB (Fig. 2), serving as a vapour-jacketed bath, is connected by means of the side tubes *a* and *b* with the reflux

FIG. 2.

condenser *c*. The tube *c* connected with the condenser communicates, through the stopcock *r* and tube *d*, with the reservoir flask *K*. A mixture of liquids (e.g. common petroleum) is placed

in the bath and distilled, the distillate passing through the open stopcock *r* into the flask *K*. At the moment when the required temperature is attained, as indicated by the thermometer *T*, the stopcock *r* is closed; the distillate now returns through the tube *b* to the bath, hence the temperature of *B* will remain constant for any length of time (Ber. 1885, 18, 1124).

Ramsay has used a vapour-bath in which the temperature is controlled by regulating the pressure under which a selected pure liquid is boiled (Chem. Soc. Trans. 1885, 640).

J. Traube and L. Pincussohn (Zeitsch. Inst. Beib. 1897, 17, 49) have also devised a simple thermostat using a boiling liquid under a controlled pressure. For other forms see Geer (*l.c.*); F. H. Dupré and P. V. Dupré (Analyst, 1913, 38, 308); Field (J. Amer. Chem. Soc. 1914, 36, 72). Brame has described a constant temperature heating apparatus for explosives and experiments on the decomposition of nitro-celluloses (J. Soc. Chem. Ind. 1912, 31, 159).

An easily adjustable vapour thermostat has been contrived by Fletcher and Tyrer (Chem. Soc. Proc. 1911, 28, 189).

(c) Richards and Churchill (Zeitsch. physikal. Chem. 1898, 28, 313) have similarly used the change at inversion points.

III. *Other thermostats not automatically regulated.*—Instruments serving as indicators only have been devised by Hall (Q. J. Sci. 1818, 5, 52); Doyère (Ann. Chim. 1850, [iii.] 28,

FIG. 3.

5); A. Fraser (Jour. Gas Lighting, 1881, 38, 798); J. Barnes (Chem. Soc. Trans. 1881, 39, 463); A. V. Harcourt (Proc. Roy. Soc. 1882, 34, 166); U. Kreusler (Chem. Zeit. 8, 1321); and C. Winkler (Ber. 1885, 18, 2533). Bunsen's thermostat (Annalen, 141, 273) is historically interesting. Exner's thermostat is of especial value, as it allows of constant temperatures being maintained between 0° and 10° (see Fig. 3). It consists of an inner flask, surrounded by two concentric glass vessels, with an air space between; the three vessels are fastened above to a zinc plate. A delicate thermometer and a thermoelement are placed in the centre of the flask; the stem and wires pass through a leaden pipe attached to the zinc plate. Between the two surrounding vessels is coiled a German-silver wire, the coils hanging freely without contact with either vessel; wires pass from the coil to a battery through the leaden tube. The whole is completely immersed in melting ice, contained in a fourth vessel; the leaden tube alone projects, and serves to keep the wires from contact with the ice. By passing an electric current through the German-silver coil, the temperature of the central vessel can be maintained at any desired point above 0° (Sitz. W. 1873, 6892).

The same principle is applied by H. Crew (Phil. Mag. [v.] 33, 89). The accompanying illustration (Fig. 4) shows the points in which this instrument differs from the preceding one.

Julien storage cells are used as the source of a constant current, which is regulated by alteration of the length of a resistance wire through which the current flows, by means of a slider and controlled by means of a Thomson balance. Other non-automatic instruments are described by Mahlke (Zeitsch. Inst. 1893, 13, 197),

FIG. 4.

Pulfrich (Zeit. Inst. 1898, 18, 49), and Rotho (*ibid.* 143, 1899, 19).

IV. *Self-regulating thermostats:* (a) *Single-liquid thermometers* (1) *acting directly on the gas supply or other heat source.*—Thermostats of this and allied types have been frequently utilised in connection with technical processes and heating systems; references to a number of these are given at the end of this article.

Reichert's form of regulator is essentially that of a mercury thermometer, with a reservoir at the top of the column. The gas-supply tube is placed so that its contracted opening is vertically over and near to the surface of the top of the mercury column. The leading tube takes off gas at the side of the reservoir. A small side tube on the stem is supplied with a screw by means of which the mercury level may at any time be adjusted, and the temperature maintained thus altered at will (Fig. 5) (Zeitsch. anal. Chem. 11, 34; Pogg. Ann. 141, 467; cf. Fontaine, *Ann. Chim. Anal.* 1911, 16, 52; Fänder, *Chem. Zeit.* 1913, 37, 40).

Gerhardt's modification permits the instrument to be filled easily with mercury.

Regulators of the same type, but varying somewhat in form, have been constructed by Page (Chem. Soc. Trans. 1876, 24), Fletcher (*ibid.* 1876, 488), and Roulin (Dingl. poly. J. 227, 263);

Whitaker (Chem. News, 1913, 107, 242). The instrument devised by Roulin is made of iron and steel (cf. Fig. 6). The height of the mercury column is adjusted by means of a sliding tempered-steel rod, held in position by the set screw *f*. As this rod passes down the centre of the gas-supply tube, the gas can only reach the burner tube by passing through the ring-shaped aperture *d*, near the

FIG. 5.

surface of the mercury. A small tap *g* maintains a sufficient supply of gas to the burner to avoid extinction of the flame by the complete interruption of the supply at *d*.

In the thermostat battery by Dibdin and Smith, in use at the metropolitan gas stations, large mercurial thermometers are employed. The tubes by which they communicate with the supply tube are provided with stopcocks, so that any one or more of them may be thrown out of action. They control the gas supply to the boiler connected with the hot-water pipes.

For more accurate work, the mercury has been replaced by 30 p.c. calcium chloride solution, alcohol, benzoline, petroleum, xylene, or toluene. The toluene regulator has gained general acceptance; a simple and easily constructed form, designed by H. Lunden and W. Tate (*Zeitsch. Chem. Appar. II.* 1, 13, 1907), is shown in the sketch (Fig. 7)

with dimensions in millimetres. The column of calcium chloride solution prevents contact of the toluene with the mercury and with the stopcock *R*, thus doing away with the slow

FIG. 7.

evaporation of the expanding liquid and allowing the use of ordinary lubricants with the stopcock provided to make temperature adjustments. This regulator, without the

aid of any form of pressure regulator (the gas pressure varying from 50 to 60 mm. of water), maintained the temperature of a water-bath of 150 litres capacity during 30 days constant in a room varying considerably in temperature. The greatest difference between the extreme temperatures (observed at regular and frequent intervals) was 0.02°. A small part of the heating gas only passed through the valve *D*, sufficient to heat the bath within a short interval of the required temperature was supplied direct from the main.

Another convenient form of toluene regulator is described by Lowry (*J. Soc. Chem. Ind.* 1905, 1033); there is a helical toluene reservoir tube coiled round a straight vertical stem containing mercury; it is provided with a wide bye-pass but has no provision for ready adjustment of the temperature, and the mercury and toluene are in contact near the lower end of the helix.

Slator has described (*J. Soc. Chem. Ind.* 1911, 30, 61) a modification of the ordinary toluene regulator by which it can be readily adjusted to any desired temperature.

Hannay (*Mon. Sci.* [iii.] 16, 1021) and F. W. Daffert (*Chem. Zeit.* 1886, 52, 789) have designed thermostats belonging to this class.

FIG. 8.

Further references are given by Geer (*J. Phys. Chem.* 1902, 6, 85); cf. Davis (*J. Amer. Chem. Soc.* 1915, 37, 1198). See also Starkey and Gordon (*J. Ind. Eng. Chem.* 1922, 14, 541).

(2) *Thermostats acting on the source of heat through electrical arrangements.*—The usual type of this class employs a mercury thermometer with one pole of a battery permanently connected with the mercury and a second adjustable pole which completes the circuit at the desired maximum temperature. An electro-magnetic arrangement in the circuit actuates a gas-cock, or works a gas valve either directly, or, by means of a plunger, indirectly controls a mercury valve of the usual type. This form of thermostat can be made very rapid in action and practically independent of variations in the gas pressure.

Scheibler has constructed an electro-thermostat, with the usual form of electric thermometer (Fig. 8). The electro-magnet is contained in the square box *A*; the upper end of the armature is provided with a leather pad, which works against the continuation of the gas-supply tube *b*, and with it forms a valve which cuts off the gas when the mercury comes into contact with the upper platinum wire. The extinction of the flame is avoided by having a small hole at *c* in the tube, more or less closed by means of the

screw *d*, through which a small stream of gas can escape into the box, and hence into the burner tube (Zeitsch. Anal. Chem. 1868, 88).

Kohlrausch adapted this principle to the regulation of the temperature of a hothouse (Dingl. poly. J. 389, 175). E. E. Reid (Amer. Chem. J. 1909, 41, 148-152) employs a mercury valve worked by a plunger controlled by an electro-magnet.

A high-temperature thermostat, capable of being kept constant to within 1° at 1000° , has been described by Haughton and Hanson (J. Inst. Metals, 1917, 18, 173).

A thermo-regulator for thermostats at temperatures close to ordinary room temperatures has been described by Powell (J. Soc. Chem. Ind. 1914, 33, 899).

An electrical contact vapour-pressure thermo-regulator has been contrived by Field (J. Amer. Chem. Soc. 1914, 36, 72). The regulator has proved sensitive to 0.1° - 0.005° .

Other forms are quoted by Geer (see iv. 1); to these we may add Clerget (Dingl. poly. J. 134, 23), Pfaundler (Carl's Rep. 18, 443), and Salet (Bull. Soc. chim. 1865); Morgan (J. Amer. Chem. Soc. 1911, 33, 344); Bunzel and Hasselring (J. Amer. Chem. Soc. 1914, 36, 949); Gouy (*ibid.* 1920, 42, 60).

The sensitiveness of a mercury thermo-regulator operated electrically is affected by the adherence of mercury to clean platinum. Mansfield Clark (J. Amer. Chem. Soc. 1913, 35, 1889) finds that by substituting a nickel or nichrome wire for platinum, the making and breaking of the circuit may be made to occur at temperatures much closer to one another.

For a description of a thermo-regulator with the characteristics of the Beckmann thermometer, see R. B. Harvey (J. Biol. Chem. 1920, 41, 9) in Abstract. Chem. Soc. Trans. 1920, ii. 161.

(3) *Thermostats acting on the source of heat through mechanical arrangements.*—Randall's apparatus (Dingl. poly. J. 224, 478) admits of direct technical applications, as it is adapted to the heating of large masses of water to a constant temperature by the use of steam. In Fig. 9 *b* is

FIG. 9.

a thin-walled tubular vessel containing some expansible liquid, the movements of the surface of which are followed by the piston *x*. This piston works a valve *v*, which controls the

steam supply. The spring *f* insures the return of the piston, the movements of which are recorded by the indicator *i*, which thus acts as a thermometer.

D'Arsonval constructed a very delicate thermostat (Fig. 10) by surrounding his oven with a

FIG. 10.

screw or by a cork through which a thermometer passes. Connected with this water chamber is the side tube *o*, closed by a caoutchouc membrane. Near to the centre of the surface of the chamber completely filled with water, which is introduced through an opening *v*, closed by a membrane the gas-supply tube terminates—in a small metallic valve-box, from which the gas is led off to the burner by the tube *d*. The expansion or contraction of the large volume of water in the outer chamber causes the caoutchouc membrane to lessen or increase the distance between the supply tube and its own surface, thus forming a very sensitive valve, which controls the supply of gas to the burner. This regulator is said to keep the temperature constant to $\pm 0.1^{\circ}$ (J. Pharm. Chim. [iv.] 26, 474).

To maintain constant higher temperatures than can be employed with water, D'Arsonval substitutes a brass tube (Fig. 11), containing petroleum or glycerol, for the surrounding water chamber. The membrane is replaced by a corrugated metallic plate such as would be used in an aneroid barometer; *b* is a leaden tube prolonging the brass tube; it is hermetically closed after charging the tube. The chamber at the back of the aneroid plate communicates with the main tube by two small tubes *m* and *n*.

Several other forms of this regulator, retaining the same kind of valve, have been constructed. The valve itself has been mounted separately on a stand, and provided with a funnel and stop-cock to adjust the amount of liquid in the connected reservoir and the lower part of the valve, and with a bye-pass to insure that the flame be never quite extinguished. The same type of valve has also been adapted to the

regulation of the flow of a cooling mixture, used for obtaining temperatures below that of the surrounding air.

G. Dorian (Bull. Soc. Ind. Mulhouse, 1900, 71, 249) described a combined heat and moisture regulator, in which the expansion of the liquid of a thermometer with a reservoir of spirally twisted tube controls a cock regulating the current of heating fluid and a hydrometer regulator works the moisture supply. T. S. Patterson (J. Soc. Chem. Ind. 1902, 21, 456),

FIG. 11.

FIG. 12.

N. A. Randolph (Jour. Franklin Institute, 1883, 116, 465), V. H. Veley (Chem. Soc. Trans. 43, 370), and Nauman (Dingl. poly. J. 226, 276), give other forms, and various technical adaptations will be found in the list given at the end of this article.

(b) *Gas thermometer regulators.*

(1) *Acting on the gas supply through a liquid piston.*—A thermostat on this principle was devised by Kemp (Dingl. poly. J. 117, 352) and improved by Westly.

Bunsen's thermostat is a modification of Kemp's. The gas supply and exit tubes are arranged as shown in Fig. 12; the supply tube *E* passes through a brass cylinder *H*, which screws into the loose brass cap *D*. At its lower end is a slit, and it is provided with a minute orifice at *o*; the exit tube *F* is joined on to the side of the cylinder *H*, the latter being continued by the glass tube *B* to the same depth as the supply tube. The cap is fitted on a brass tube supplied with a slit in which the tube *F* can slide. A glass cylinder closed at the lower end continues this brass tube. In the lower part of this glass vessel is a glass air-chamber opening downwards and closed by the mercury contained in the cylinder; this air-chamber preferably takes the form shown at *C*. The expansion of air in the chamber causes the mercury to rise in the cylinder, and thus partially closes the slit; the position of the slit is regulated by the screw cap until the required temperature is attained. The minute orifice *o* insures that the gas supply should never be completely cut off (Dingl. poly. J. 143, 342).

Bunsen's low-temperature regulator has a larger air chamber, and is provided with a side tube and stopcock, by means of which the

amount of mercury present can be readily altered (Desaga's Catalogue). Pontallie divides the gas supply after passage through a Bunsen's regulator, using one part to heat the regulator only, the remainder heating the bath. As these quantities are in exact and determined proportion, the temperature of the bath is maintained constant when that of the regulator does not vary.

Schorer separates the air-thermometer reservoir from the valve to enable the instrument to be used for high temperatures (Zeitsch. anal. Chem. 9, 213).

D'Arsonval adapted his thermostat for use at temperatures between 150° and 1200° by substituting an air reservoir for the petroleum reservoir employed at lower temperatures. The reservoir was made of glass or porcelain. The aneroid valve was at the same time furnished with a lever-arm and weight *P*, by means of which the pressure on the lower surface of the aneroid plate could be more or less compensated, and the amount of gas supplied altered at will (Fig. 13) (J. Pharm. Chim. [iv.] 26, 474).

Although a number of varieties of this type have been used (see Geer's bibliography; J. Martenson, Chem. Zentr. 1872, 513; Clowes, Chem. Soc. Trans. 24, 639; L. Saarbach, J. Amer. Chem. Soc. 18, 511, 1901), and the principle has been technically applied in connection with furnaces of moderately high temperature for low temperature work the toluene thermometer forms are to be preferred for accurate long period temperature regulation; all gas and vapour thermostats suffer from the defect of needing regulation with the changes in pressure of the air.

(2) *Acting through electrical arrangements.*—These devices resemble the instruments in

FIG. 13.

group iv. *a* (2). Pfaundler's apparatus (Carl's Rep. 18, 443) is similar to Scheibler's, the points of difference are sufficiently evident from the annexed figure (Fig. 14).

Solari (Bull. Soc. chim. 1923, [iv.] 33, 1000) has described an apparatus which consists essentially of a differential air thermometer with mercury as the moving liquid. One bulb is maintained at a constant temperature and the other is placed in a small auxiliary furnace of copper tube connected in series with the main furnace. The tube containing the mercury is

provided with three platinum contacts so arranged in connection with a resistance and a swinging commutator that automatic regulation of the current passing through the furnace is secured. If Q be the thermal capacity, R the radiating power, and C the conductivity of the tube carrying the heating coil of the main furnace, and q , r , and c the same constants for

FIG. 14.

the small one, then temperature control to within $\pm 5^\circ$ may be obtained by making Q/q very large, R/r very small (but r must not be too great), and C/c very small (c may be very large).

(3) *Acting through mechanical arrangements.*—Jeannel's thermostat (Fig. 15) is an air-thermometer thermostat in which the air reservoir consists of a metallic vessel of 300-400 c.c. capacity. This is connected with one limb of a

FIG. 15

U-tube containing glycerol. In the other limb a float G carries a steel needle working loosely in a fine caoutchouc tube O . By a rise of the liquid in r , the float, guided by the steel needle, brings the flat upper surface of the sealing wax H , in which the needle is mounted, near to the mouth of the tube O , thus forming a valve controlling the current of gas from the supply tube J to the exit tube P , of which O is a continuation. The pressure of the air in A is modified at pleasure by means of the caoutchouc pump S ,

with which connection is made through the tap R on a side tube (Ann. Chim. [iv.] 25, 386).

W. T. Richmond (Amer. Chem. J. 5, 287), Bendix and Lohse (D. R. P. 14242, 1880; Ber. 14, 2608), and Bechem (D. R. P. 18077, 1881; Ber. 15, 1226) have also devised self-acting thermo-regulators of this type.

(c) *Vapour-tension thermometers.*

(1) *Air and vapour.*—André's thermo-regulator is a Kemp thermostat in which the expansion of the air in the reservoir is increased by the addition of a small quantity of some readily volatile liquid. Such liquids as ether, alcohol, acetone, light petroleum and water may be employed for the purpose. Ether is particularly suitable, on account of the rapid increase of its vapour tension with increase of temperature. A thermostat of this form will maintain the temperature of a water-bath constant within $0.04-0.05^\circ$ (Wied. Ann. 4, 614).

Lothar Meyer has also made use of the same principle (Ber. 16, 1088).

The following mixtures of liquids of constant boiling-point, for use in constant temperature heating baths, have been suggested by A. Golodetz (Chem. Zeit. 1914, 38, 1253).

B.p.	Composition of liquid.
33°	Water and ether (heterogeneous).
36.5-37°	Alcohol (3) and ethyl bromide (97).
38°	Carbon disulphide (87) and methyl alcohol (13).
39-40°	Carbon disulphide (71) and methyl acetate (29).
42.5°	Carbon disulphide (91) and alcohol (9).
53.5°-54°	Methyl alcohol (12) and chloroform (88).
55.5°	Methyl alcohol (29.6) and carbon tetrachloride (70.4).
58°	Methyl alcohol (38.4) and benzene (61.6).
59°-59.5°	Alcohol (6) and chloroform (94).
62°	Methyl alcohol (47) and ethyl acetate (53).
64.8°	Benzene (74.1), alcohol (18.5), and water (7.4).
68°	Alcohol (32.4) and benzene (67.6).
71.5°	Alcohol (31) and ethyl acetate (69).
74.8°	Carbon tetrachloride (77.15) and alcohol (22.85).
79.5°	Benzene (90.5) and isobutyl alcohol (9.5).
84.5°	Water and toluene (heterogeneous).
87.7°	Water (26.3) and propyl alcohol (73.7).
91°-91.5°	Propyl alcohol (53) and toluene (47).
92.5°	Water (41) and pyridine (59).
91°-91.5°	Water and turpentine (heterogeneous).
95°	Water (7) and chloral (93).
98.5°	Water and ethylaniline (heterogeneous).
99°	Water and diethylaniline (heterogeneous).
104°	Toluene (70) and acetic acid (30).
113°-113.5°	Acetic acid (27) and xylene (73).
121°-122°	Amyl alcohol (30) and ethylene dibromide (70).
125°-126°	Amyl alcohol (52) and <i>m</i> -xylene (48).

Benott's thermo-regulator has the thermometer reservoir separated from the valve, connection being made by means of a caoutchouc tube containing mercury.

The reservoir consists of a thin tube, drawn out at one end for convenience in filling, which contains a small quantity of air, and a few drops of some volatile liquid; the remainder of the space in the tube is occupied by mercury in connection with the mercury in the valve by means of the caoutchouc tube. The valve differs somewhat from the ordinary form. It is provided with a side tube *A* (Fig. 16), by which a small amount of gas can directly pass from the supply tube *x* to the burner tube *y*. Mercury can be added by means of the side tube *B*, or withdrawn from the cock *c* to adjust the level within the valve. The whole is mounted upon a sliding board, fixed by the clamp-screw *m*, at any convenient height (Wied. Beibl. 4, 296; Guillaume's *Thermométrie*, 130).

(2) *Vapour in contact with its own liquid only.*
—The instrument devised in 1886 by G. W. A.

FIG. 16.

Kahlbaum belongs to this class. There is the usual mercury valve, the supply tube being bevelled off at the open end at an angle, and having a small hole opposite the exit tube to provide against total extinction of the flame. It may be adjusted according to the temperature required by the rack and pinion shown (Fig. 17). The other limb of the U-tube contains a liquid of boiling-point just below the temperature required in the bath or oven. For facility in changing the liquid, this end of the tube is closed by a tightly-fitting cork held in place by a clamp working against an india-rubber seat fixed on the collar of the glass tube.

The temperature rises just above the boiling-point of the liquid *x*, a portion of this volatilises, and mercury is forced up the limb *a*; the pressure on the liquid being now greater, its boiling-point is raised, and the temperature must increase for further volatilisation to occur. Owing to the rise of mercury in *a*, the gas supply is diminished, and hence the temperature falls.

Consequent on the fall of temperature, a portion of the vapour condenses, the valve is opened to a greater extent, and the temperature again rises. These actions soon reach a point of equilibrium, and a constant temperature is then maintained (Ber. 19, 2860).

(d) *Thermostats depending upon the differential expansion of solid bodies.*—Bonnemain (Dingl. poly. J. 16, 285) and Ure (*ibid.* 42, 173) devised regulators depending upon the expansion of simple or compound metallic bars.

FIG. 18.

Hipp's thermostat is only available for temperatures between 30° and 40° (see Fig. 18). It consists of a copper vessel *K*, surmounted by a wooden box *C*, having glass front and back. A system of tubes on the walls of the oven communicate with the vessel *K*, and serve for the circulation of the water heated in that vessel. They are provided with openings for filling in water, and to serve as escape vents in case the

FIG. 19.

water may be accidentally boiled. The temperature is controlled by a regulator consisting of a bent compound metallic bar fixed upon the back wall of the oven at *a*; the free end *b* is connected by a copper wire with the lever *A* working a conical valve *c*; *z* is a regulating screw, by means of which any desired initial opening of the valve may be obtained; *s* is the gas-supply tube, and *t* draws off gas for the burner from the valve-box *a* (Dingl. poly. J. 191, 306).

Lothar Meyer in 1884 devised a sensitive temperature regulator on this principle (Fig. 19).

It consists of a long brass tube placed vertically in the bath, and closed at its lower extremity; in this tube a slightly longer glass rod is placed. The tube supports a rod carrying a movable lever-arm *A*, from which depends a floating valve *B*. The valve may be placed at varying distances along the lever-arm *A*, so that the difference between the expansions of the brass tube and glass rod may be magnified to a greater or less extent in the amount of movement imparted to the valve. The supply tube is a narrow-bore tube passing up the arm *x* of the valve working in the glycerol seal tube *m*. The supply tube and seal may be adjusted to any required height. A precisely similar arrangement allows of the drawing off through *o* of the gas for the burner. The valve *z* is essentially a Bunsen mercury-and-slit-tube valve. The mercury vessel is adjustable to any required height (Ber. 17, 478).

L. von. Babo arranged a gas regulator, in which the control valve depends for its action upon the unequal expansion of glass and copper. In Fig. 20, *A* is a copper tube, *B* a glass rod. The

FIG. 20.

valve *z*, which regulates the flow of gas from the supply *g* to the burner tube *e*, is fixed in position by the glass rod *B*, against which it is pressed by a spiral spring *c*. The screw *d* serves to adjust the position of the glass rod, and renders it possible to obtain a greater or smaller supply of gas at will. As the temperature rises, the expansion of the copper tube being greater than that of the glass rod, the valve *z* is pressed by the spring *c* nearer to its seat, and so there is less gas supplied; the temperature then falls, and the valve partially re-opens, and so on (Ber. 13, 1221).

Kohlrausch employed a Breguet's metallic thermometer to make and break an electric current, which heated a fine platinum wire (Pogg. Ann. 125, 626).

E. Gumlich (Zeitsch. Inst. 1898, 18, 317) claims, by the use of a nickel and brass Breguet's spiral governing the gas supply through intermediary electrical arrangements, to have maintained a dry oven within 0.4° for long intervals.

Rieth's instrument consisted of a compound metallic bar working a cone valve, supplied with a regulator screw (Chem. Zentr. 1871, 615).

In Taliani's thermo-regulator (Ann. Chim. Applicata, 1914, 1, 405) two bimetallic zinc-steel vertical strips are fixed at their lower ends with the more expansive metals facing inwards. The free upper ends are connected by means of a very thin copper wire, on the middle point of which rests the valve regulating the flow of gas to the lamp of the thermostat. The valve is raised by the separation of the strips and lowered by their approach. By means of a slider operated from without the effective lengths of the strips, and consequently the constant temperature obtained, may be varied.

(e) *Electrically heated thermostats with electrical control.*—Thermostats of this type allow of more sensitive and rapid adjustment than

any other; they are particularly suitable for accurate scientific work but are not without technical applications.

Rothe (Zeitsch. Inst. 1899, 19, 143) gives a very complete account (with illustrations) of a thermostat designed for use in thermometer work at the Phys. Tech., Reichsanstalt. The same author (Zeitsch. Inst. 1902, 22, 14) adapts this principle to the construction of an instrument for use with very low temperatures. A Dewar vessel serves to prevent conduction of heat from without; the heating coil is of constantan wire wound on the ebonite ring of a stirrer, the stem of which is of glass tubing through which pass the leading wires for the current.

W. C. Geer (J. Phys. Chem. 1902, 6, 94) claims for his thermostat a variation of 0.002° only for a 9 hours' run with a 30-litre bath. A somewhat simpler form, which is essentially a modified Geer thermostat, is described by F. A. Osborn (*ibid.* 1905, 9, 297). The accompanying diagram (Fig. 21) shows its essential features. The heating of the 50-litre bath is accomplished by means of an iron wire *cc* carrying a current from the large storage battery *B*. The wire forms a layer of five turns against the sides of the bath, which latter is encased in a non-conducting layer of felt. *m* is a glass worm, 9.5 cm. diameter and 16 cm. long and holding 110 c.c. of mercury, serving as a reservoir of a regulating thermometer with a capillary stem. The bath is stirred by a

FIG. 21.

mechanically-driven stirrer represented by *D*. A platinum fused-in wire permanently connects an electro-magnet *R* with the mercury of the thermometer. *B* is connected through a storage cell *B'* with a second adjustable wire *p*. When the required temperature is reached, the mercury completes the circuit with *p* and the main current is broken at *AA* by the movement of the armature. The spring shown establishes the main circuit as soon as the mercury breaks contact with *p*.

This form can be brought to the required steady temperature in 15 minutes and shows no change of a hundredth of a degree in 8 hours.

Other forms are given by S. W. Young (J. Amer. Chem. Soc. 1901, 23, 327); C. Marie

and R. Marquis (Compt. rend. 1903, 136, 614), who use an acetone thermometer with mercury make and break and current through platinum wire; R. A. Macumber and C. G. L. Wolf (J. Path. Bact. 1904, 10, 105); H. Darwin (Phil. Mag. [vi.] 7, 408, 1904); J. P. Magnusson (J. Phys. Chem. 1907, 11, 25); Regaud and Fouilland (Ann. Chim. anal. 1909, 14, 141); L. Kolowrat (J. Phys. 1909, 8, 495), who describes the automatic regulation of an electric oven.

(f) *Other mechanical regulators* have been devised by J. W. Eichler and H. Hartig (D. R. P. 5492, 1878), and by Appold, whose instrument was a balance regulator (Proc. Roy. Soc. 1866, 15, 144).

FIG. 22.

The invention of G. J. Meurlin (D. R. P. 4703, 1878) consists of a self-regulating cone valve to control the pressure of a gas supply, and hence the temperature of a space heated by the flame. The pressure of the gas in the chamber *a* raises the cone *b* (Fig. 22), partially closing the hole in the plate *x*, and thus restricting the current. The hole in the summit of the cone *b* prevents extinction of the flame.

• A. Schwabe (D. R. P. 93152, 1896) describes a device by which an areometer works a chain controlling the source of heat.

The choice of the type of thermostat most suitable will be governed by the requirements in each special case. Technical applications of these instruments are most frequently adequately met by the use of the simple mercury thermometer valve at moderate temperatures and the air-thermometer mercury-valve at higher temperatures, some form of differential expansion instrument being used when the liability to vibration or shock has to be provided for.

For accurate work, the reliability, sensitiveness, and independence of atmospheric changes are the most important considerations. Electrical thermostats with electrical control appear best able to fulfil the necessary conditions (see Geer, J. Phys. Chem. 1902, 6, 85); W. P. Bradley and A. W. Browne (*ibid.* 1902, 6, 118) claim to have constructed a thermostat sensitive to one thousandth of a degree. The toluene thermometer mercury-valve thermostat has found wide use; T. M. Lowry (J. Soc. Chem. Ind. 1905, 1030) discusses the conditions governing its sensitiveness and A. W. C. Menzies (Chem. News, 1902, 85, 68), in dealing with the same subject, shows that this type is able to keep a bath at 6° above room temperature constant within one hundredth of a degree.

The principal ways in which thermostats have been applied to technical purposes have been mentioned; recent instances of such applications are to be found in the following, not otherwise readily accessible, references.

A number of dyes, belonging generally to the triphenylmethane class, such as methyl violet, malachite green, and erythrosin, have the property of gradually and completely disappearing without residue when heated, the time taken for disappearance depending on the temperature, other conditions being the same. Such dyes can be used as heat indicators in a number of ways for the control of industrial operations, for instance, in cases where a certain amount of heat has to be applied during a certain interval of time, the disappearance of the dye indicating the completion of heating. Another use is to determine the heat distribution in a heated body. The method may be applied in the annealing of glass, the burning of cements, or to detect overheating of electrical equipment (P. A. Kober, Ind. Eng. Chem. 1923, 15, 837-838; J. Soc. Chem. Ind. 1923, 43, 913A).

THESPASIA MACROPHYLLA (Blume) [T. Lampas (Dabz.).] This is a small bush common to the tropical jungles of India, Burma, and Ceylon. In Watts' Dictionary of the Economic Products of India, there is no mention of the use of this plant as a dyestuff, but, on the other hand, the capsules and flowers of the

allied *T. populnea* (Soland.) are stated to give a yellow dye.

According to Perkin (Chem. Soc. Trans. 1909, 95, 1859) the flowers of the *T. macrophylla* yield quercetin and some quantity of *proto-catechuic acid*.

With mordanted woollen cloth* the flowers produce fairly good shades, but are in no way superior to the better-known Indian natural yellow dyestuffs. A. G. P.

THEVETIN *v.* **DIGITALIS**.

THIAZINE COLOURING MATTERS. The thiazines are colouring matters containing the group

The simplest member of this series is *thionine*

the hydrochloride of which constitutes Lauth's violet (see METHYLENE BLUE). The tetramethyl derivative is methylene blue (*q.v.*), which is by far the most important dyestuff of this class. The general method of preparation of these colouring matters has already been indicated (see METHYLENE BLUE).

Gentianine (Gy.), produced by oxidising *p*-phenylenediamine and dimethyl-*p*-phenylenediamine with ferric chloride in presence of sulphuretted hydrogen, is probably the zinc double chloride of a mixture of Lauth's violet and methylene blue; it dyes tannined cotton in bluish-violet shades.

By the oxidation of methylene blue with acidified bichromate elimination of methyl groups occurs with the formation of **methylene azure**. This dye is the mixed chloride of di- and tri-methylated Lauth's violet; on cotton mordanted with tannin and tartar emetic it furnishes reddish-blue shades fast to washing.

Methylene green (S.C.I.), **Methylene green paste** (L.B.H.)

is obtained by treating methylene blue with sodium nitrite and nitric acid at 50°, the product being salted out and converted into double zinc chloride. It dyes in bluish-green shades on mordanted cotton, being the fastest green basic colouring matter used in silk dyeing and printing and in calico printing.

Thionine blue GO, O (M.); Thionine blue B, R (By.)

is prepared like methylene blue except that dimethyl-*p*-phenylenediaminethiosulphonic acid is oxidised together with methylethylaniline

instead of dimethylaniline. It dyes tannin-mordanted cotton blue.

Thiocarmine R (C.)

Benzylethyl-*p*-phenylenediaminethiosulphonic acid is oxidised in presence of sodium thiosulphate to sulphobenzylethyl-*p*-phenylenediaminethiosulphonic acid; the latter is oxidised together with benzylethylanilinesulphonic acid and the sulphoindaminethiosulphonate thus obtained is heated to boiling. The dyestuff is an indigo-blue powder giving a pure blue solution in water and dyeing wool and silk from an acid bath in blue shades (Cassella and Co., Eng. Pat. 4596, 1890; D. R. P. appl. C 3264; Amer. Pat. 434493; see also J. Soc. Chem. Ind. 1892, 11, 30; J. Pr. Chem. 1907, [ii.] 76, 498).

Toluidine blue O, $2C_{11}H_{10}N_2SO_2 \cdot ZnCl_2$;

Dimethyl-*p*-phenylenediaminethiosulphonic acid (*cf.* METHYLENE BLUE) is oxidised together with *o*-toluidine. The insoluble green indamine formed is boiled with a solution of zinc chloride and the resulting leuco compound is oxidised. The colouring matter is a dark green powder giving a bluish-violet aqueous solution and dyeing mordanted cotton blue (Badische Anilin und Soda Fabrik; Eng. Pat. 10314, 1888; D. R. P. 47374; U.S. Pat. 416055; Meister, Lucius und Brüning, D. R. P. 47345).

New methylene blue N (B), NSS (B.D.C)

Ethyl-*p*-tolylenediaminethiosulphonic acid, obtained by the oxidation of *p*-aminoethyl-*o*-toluidine in presence of sodium thiosulphate, is oxidised together with ethyl-*o*-toluidine and the green indamine obtained is heated. The solution of the dyestuff in water is violet-blue when cold and pure blue when hot. Tannin-mordanted cotton is dyed in redder and fuller shades than those produced by methylene blue (Cassella and Co., Eng. Pat. 8407, 1891; D. P. R. appl. C 3603; Amer. Pat. 469329). A satisfactory discharge is obtained with glucose and caustic soda.

Brilliant alizarin blue (Bayer); Indochromine T (Sandoz)

SO_2Na

1:2-Naphthaquinone 4:6-disulphonic acid is condensed with dimethyl-*p*-phenylenediaminethiosulphonic acid. The dyestuff gives fast blue

shades on chromed wool, cotton or silk, and is suitable for calico printing (F. Bayer and Co., Eng. Pat. 825, 1893; D. R. P. 83046, 86717; Fr. Pat. 227675).

Leucogallothionine (P.H.), a generic term, covering a group of leuco compounds of the following general formula (Eng. Pats. 5692, 1893; 20397, 1906; D. R. PP. 189479, 73556)

where R_1 are alkyl groups, R' is OH, NH_2 , or some other substituent in the carboxylic group of gallic acid. They are produced by condensing together *as*-dialkylated diaminoaryl-thiosulphonic acids such as

and gallic acid or a derivative such as gallamic acid. On chrome mordanted wool these acidic leuco-compounds dye with oxidation in violet to blue shades fast to light and washing.

The Gallothionines are obtained in bulk by oxidising a mixture of gallic acid (or a derivative) and a mercaptan of an *as*-dialkylated-*p*-phenylenediamine such as $N(CH_3)_2 \cdot C_6H_3(NH_2) \cdot SH$.

Indochromogen S (Eng. Pat. 3886, 1894; D. R. P. 109273)

resulting from the action of β -naphthaquinone 4 : 6-disulphonic acid on *as*-diethyl-*p*-phenylenediaminethiosulphonic acid in alkaline solution. Bright greenish-blue tints are produced on chrome mordanted fabrics, the colour being discharged with alkali chloride and ferrocyanide.

Uranis blue (W.D.C.), (Eng. Pat. 13118, 1896; D. R. P. 90275;) a bluish-violet acidic dye with bronzy lustre, obtained by oxidising with aqueous chromic acid a mixture of *as*-dimethyl-*p*-phenylenediaminethiosulphonic acid and di- β -naphthyl-*m*-phenylenediaminedisulphonic acid. It dyes wool and silk from an acid bath in pure greenish-blue shades.

G. T. M.

THIAZOL DYESTUFFS v. PRIMULINE AND ITS DERIVATIVES.

THIET-SIE or **THITSI**. A resinous substance used as a varnish by the Burmese. It exudes from a tree in the form of a light-brown, very viscid liquid of the consistence of treacle, but on exposure to the air for a few minutes becomes quite black and hard on the surface. The same change takes place instantly in contact with potassium hydroxide. The resin spread in a thin layer on wood or other solid body quickly forms a hard deep-black coating of great brilliancy. On digesting the unaltered substance with alcohol of 80 p.c. at a gentle heat,

the greater part gradually dissolves; and on decanting the clear liquid from the insoluble residue, and distilling off the alcohol, there remains a very tenacious gummy residue of a rich-brown colour, which undergoes no change of colour on exposure to the air, but very slowly hardens. In contact with potassium hydroxide, however, it blackens like the original substance.

The residue, insoluble in alcohol, dissolves or the most part in ether, forming a dark-brown solution, and leaving a light-brown solid resin. The ethereal solution, when evaporated, leaves a residue which, on exposure to the air, instantly becomes quite black, and after a short time nearly solid. This, then, is the portion of the original substance to which the property of blackening on exposure to the air is due.

The solid resin, insoluble in alcohol and ether, which forms but a small part of the original substance, is quite unalterable in the air. When heated with nitric acid, it yields a crystalline acid which may be sublimed and which exhibits the characters of succinic acid. For reports of its uses and value as a lacquer, see Bull. Imp. Inst. 1917, 15, 42.

THIGAN. *Silver thiogenol.*

THIGENOL. Trade name for the sodium salt of ichthoform (condensation product of formaldehyde and ichthyol).

THIOACETAMIDE $CH_3 \cdot CS \cdot NH_2$, is prepared by the action of hydrogen sulphide on acetonitrile (Bernthsen, Annalen, 192, 46); or of phosphorus pentasulphide on acetamide in benzene solution (Hantzsch. *ibid.* 250, 264; cf. Hofmann, Ber. 1878, 11, 340). It crystallises in monosymmetric plates or prisms, m.p. 107.5°-108.5°, and is readily soluble in water or alcohol, less so in ether. Acids or bases decompose thioacetamide, yielding acetic acid, ammonia and hydrogen sulphide, whilst with silver nitrate solution, a precipitate of silver sulphide is obtained. It gives difficultly soluble compounds with mercuric chloride and with other metallic chlorides (Kurnakow, J. Russ. Phys. Chem. Soc. 1893, 25, 613).

THIOACETANILIDE $CH_3 \cdot C(SH) : N \cdot C_6H_5$ or $CH_3 \cdot CS \cdot NH(C_6H_5)$ is prepared by the interaction of acetanilide and phosphorus pentasulphide (Jacobson, Ber. 1886, 19, 1067; Hofmann, *ibid.* 1878, 11, 339), or of the chloride of acetanilide, $CH_3 \cdot CCl : N \cdot C_6H_5$ and hydrogen sulphide (Leo, *ibid.* 1877, 10, 2134). It crystallises from water in needles, m.p. 75°. On distillation it yields phenylamino-phenylimino-ethane

It is soluble in sodium hydroxide solution, from which it is precipitated by the addition of acids. The sodium derivative

is formed by the action of sodium ethoxide. Thioacetanilide yields two series of alkyl derivatives, viz. the normal alkyl thioacetanilides $CH_3 \cdot CS \cdot NR(C_6H_5)$ and the alkyl isothioacetanilides $CH_3 \cdot C(SR) : N \cdot C_6H_5$. The former are obtained by the action of phosphorus pentasulphide on alkylacetanilides, and the latter by the action of alkyl iodides on the sodium derivative of thioacetanilide.

THIOACETIC ACID $CH_3 \cdot COSH$ is best prepared by heating glacial acetic acid with phos-

phorus pentasulphide (Tarugi, Gazz. chim. ital. 1895, 25, i. 273; Schiff, Ber. 1895, 28, 1205; cf. Kekulé and Linnemann, Annalen, 123, 278; Kekulé, *ibid.* 90, 311). It may also be prepared by the interaction of acetyl chloride and potassium hydrosulphide (Jacquemin and Vosselmann, J. 1859, 354), or of lead acetate and anhydrous sodium thiosulphate (Froehde, Zeitsch. Chem. 1866, 543). It is an unpleasant smelling liquid, b.p. 93°, sp.gr. 1.074 at 10°, soluble in water and in alcohol: for electrical conductivity v. Ostwald, Zeitsch. physikal. Chem. 3, 182. By heating in a sealed tube with water at 180°–200° or by boiling with zinc and sodium hydroxide, the sulphur is removed (Schulze, Zeitsch. physiol. Chem. 1898, 25, 16). Strong sulphuric or nitric acid reacts explosively with thioacetic acid. Phosphorus pentachloride yields acetyl chloride, phosphorus trichloride and hydrogen chloride, whilst zinc chloride yields ethenyl trisulphide, $C_2H_4S_3$, acetic acid and hydrogen sulphide. Thioacetic acid condenses with aldehydes, ketones and ketonic acids in the presence of hydrogen chloride (Bongartz, Ber. 1886, 19, 1934). It has been recommended as a substitute for hydrogen sulphide in qualitative analysis (Schiff and Tarugi, *ibid.* 1894, 27, 3437; Tarugi and Marchionneschi, Boll. Chim. Farm. 45, 629). For salts, v. Ulrich, Annalen, 109, 275; Tarugi, Gazz. chim. ital. 1895, 25, i. 341; 1897, 27, i. 316; ii. 153.

Ethyl ester.—Prepared by the interaction of acetyl chloride and ethyl hydrosulphide, but not from ethyl acetate and phosphorus pentasulphide (Michler, Annalen, 176, 182). Unpleasant-smelling liquid, b.p. 116.0°–116.2° at 749.3 mm. (Beckmann, J. pr. Chem. [ii.] 17, 461).

Dithioacetic acid, methylcarbothionic acid $CH_3CS\cdot SH$ is prepared by the action of carbon disulphide on magnesium methyl iodide in well-cooled ethereal solution. The product is decomposed with ice and hydrochloric acid. It is a reddish-yellow oil, b.p. 37°/15 mm., sp.gr. 1.24 at 20°, readily soluble in organic solvents. It displaces acetic and formic acids from their salts. It is readily oxidised to thioacetyl disulphide by water and produces black spots on the skin. The alkali, alkaline earth, silver and magnesium salts are soluble in water, giving coloured precipitates with the salts of the heavy metals (Houben and Pohl, Ber. 1907, 40, 1303).

Methyl ester.—Prepared as the acid, substituting ammonium chloride for hydrochloric acid. The product is shaken with methyl sulphate, and the red oil so formed distilled; b.p. 140°/760 mm., 80°–81°/95 mm., 71°/70 mm.; sp.gr. 1.096 at 21°/4° (Houben and Schultze, Ber. 1910, 43, 2481).

THIOANTIPYRINE or **THIOPYRINE**, $C_{10}H_{11}N_2S$. Prepared by treating the methochloride or methiodide of 1-phenyl-3-methyl-5-chloropyrazole with potassium hydrogen sulphide. Large soluble crystals, m.p. 166° (Michaelis and Bindewald, Ber. 1900, 2873).

THIOBENZYL DYE STUFFS v. PRIMULINE AND ITS DERIVATIVES.

THIOBENZOPHENONE v. KETONES.

THIOCHROMOGEN v. PRIMULINE AND ITS DERIVATIVES.

THIOCOLL v. SYNTHETIC DRUGS.

THIOCYANATES v. CYANIDES.

For the chlorides of thiocyanogen, see Kaufmann and Liepe (Ber. 1924, 57, [B] 923; Chem. Soc. Abstr. 1924, 126, 1, 839).

Addition of excess of a ferric salt to the solution of a commercial ferrocyanide, followed by filtration, results in a blood-red coloration in the filtrate if the ferrocyanide is contaminated with thiocyanate. The quantity of thiocyanate may be determined as follows: 10 grms. of ferrocyanide are dissolved in water to 100 c.c., the solution is filtered, and 10 c.c. of the filtrate are introduced into a 300 c.c. beaker, diluted with 50 c.c. of water, mixed with 25 c.c. of 5 p.c. ferric chloride solution, and filtered through a pleated paper into a 500 c.c. cylinder; the filter is washed with 0.5 p.c. potassium chloride solution until the latter passes through colourless, the total filtrate being then made up to 500 c.c. Into a similar 500 c.c. cylinder containing 10 c.c. of 5 p.c. ferric chloride solution, 1 p.c. ammonium thiocyanate is run from a burette until the two cylinders exhibit equal depths of colour. The method gives satisfactory results (F. Perciabosco, Annali Chim. Appl. 1923, 13, 346; J. Soc. Chem. Ind. 1924, 43, B, 252).

For the production of thiocyanogen by electrolysis of alkali thiocyanates, see Kerstein and R. Hoffmann (Ber. 1924, 57, [B] 491; Chem. Soc. Abstr. 1924, 126, i. 717).

THIODIALURIC ACID

obtained by hydrolysing with dilute potassium hydroxide thiopseudouric acid

(Noncki, Ber. 1871, 4, 772), or potassium thio-

cyanobarbiturate $CO \begin{array}{c} \text{NH} \cdot CO \\ \text{NH} \cdot CO \end{array} > CH \cdot SCN$ (Trz-

cinski, *ibid.* 1883, 16, 1057); forms bright microscopic plates. The potassium salt is a yellow crystalline compound, sparingly soluble in water. Thiodialuric acid dissolves in nitric acid to form a pale red solution, and on warming a violent reaction takes place and dilituric acid is formed.

THIOFLAVINE T S v. PRIMULINE AND ITS DERIVATIVES.

THIOFORM and **THIOGENOL**, v. SYNTHETIC DRUGS.

THIOGLYCOLLIC ACID, α -thiolacetic acid, $SH \cdot CH_2 \cdot CO_2H$ was first prepared by Carius (Annalen, 1862, 124, 43) by heating 3 parts of monochloroacetic acid in concentrated aqueous solution with 5 parts of potassium hydrogen sulphide. Thiodiglycollic acid is formed at the same time, thus:

(v. Claassen, *ibid.* 1877, 187, 113).

Thioglycollic acid is also formed by treating sulphochloroacetyl chloride, $SO_2Cl \cdot CHCl \cdot COCl$ with tin and hydrochloric acid (Siemons, Ber. 1873, 6, 659); by treating glyoxylic acid with sulphuretted hydrogen in presence of silver oxide, thiodiglycollic acid also being formed in this case (Böttinger, Annalen, 1879, 198, 215); by boiling

thiohydantoin⁶ or rhodanic acid with baryta (Andreasch, Ber. 1879, 12, 1385; Ginsburg and Bondzynski, *ibid.* 1886, 19, 117); or by treating salts of chloroacetic acid with alkali or alkaline earth polysulphides and subjecting the products, thus formed to the action of reducing agents (Kalle and Co., D. R. P. 180875).

Thioglycollic acid is an uncrystallisable oil, soluble in water, alcohol, and ether. It has a faint smell, acts as a strong acid and forms a number of metallic salts (Claessen, *l.c.*; Ber. 1877, 10, 1354).

These are generally crystalline substances, readily soluble in water, but decomposing in aqueous solution especially in light, with production of a metallic sulphide (Myers, J. Lab. Clin. Med. 1921, 6, 359).

If a drop of ferric chloride is added to a slightly acidified thioglycollate, a transient indigo-blue colour appears, which changes to a deep violet-red on adding excess of ammonia and shaking in air. On standing the colour disappears, but it is reproduced by shaking the solution with air (Andreasch, Ber. 1879, 12, 1390). Thiodiglycollic acid does not give this reaction. Thioglycollic acid reacts with aldehydes yielding compounds of the type

with ketones to form the compounds

and also with ketonic acids (Bongartz, Ber. 1886, 19, 1931; *ibid.* 1888, 21, 478). It also unites with cyanamides forming hydantoins (Andreasch, Monatsh. 1881, 2, 735; Ber. 1880, 13, 1421).

Thioglycollamide $CH_2(SH)CONH_2$ forms thin white leaflets, m.p. 149° (Holmberg, J. pr. Chem. 1905, [ii.] 71, 264).

Ethyl thioglycollate $CH_2(SH)CO_2C_2H_5$ is formed by boiling the acid with absolute alcohol in the presence of a few drops of sulphuric acid (Claessen). It is an offensive smelling heavy oil, b.p. above 155° (decomp.), insoluble in water and in alcohol. For some of its derivatives, see Wislizenus, Annalen, 1868, 146, 145; Heintz, *ibid.* 1865, 136, 223; Letts and Collie, J. 1878, 685.

Ethylthioglycollic acid $CH_2(C_2H_5S)CO_2H$ is formed by the interaction of ethyl chloracetate and sodium mercaptide, the ethyl ester thus formed being hydrolysed with baryta water (Claessen, Bull. Soc. chim. [ii.] 23, 444). It is an oil soluble in water, alcohol, and ether, and yields metallic salts and esters. Its amide

has m.p. 440°.

Nitrosothioglycollic acid $(SH)CH(NO)CO_2H$ is obtained, together with cyanamide and dicyanamide, by boiling nitrosothiohydantoin with baryta water. A number of its metallic salts have been prepared (Andreasch, Ber. 1880, 13, 601).

Dithioglycollic acid $(SCH_2-CO_2H)_2$, forms leaflets or prisms, m.p. 100°, gives metallic salts, an ethyl ester, b.p. 280° (decomp.), and is reduced by zinc and hydrochloric acid to thioglycollic acid (Claessen, Ber. 1881, 14, 410; Ginsburg and Bondzynski, *l.c.*).

Thiodiglycollic acid $S(CH_2-CO_2H)_2$ may be prepared by treating calcium chloracetate with calcium hydrogen sulphide in presence of hydro-sulphide (Schreiber, J. pr. Chem. [ii.] 13,

472); or by mixing a concentrated aqueous solution of sodium chloracetate with an equivalent amount of sodium sulphide dissolved in the smallest quantity of water. The mixture is acidified with sulphuric acid and the thiodiglycollic acid is shaken out with ether (Lövén, Ber. 1884, 17, 2818; *ibid.* 1894, 27, 3059). It forms rhombic tablets, m.p. 192°; gives metallic salts; a dimethyl ester, b.p. 135°/11 mm. (Anschütz and Biernaux, Annalen, 1893, 273, 69), and a diethyl ester, b.p. 267°-268° (corr.) (Wislizenus, *l.c.*). Also a chloride $S(CH_2COCl)_2$, an anhydride

(Anschütz and Biernaux, *l.c.*), and amides.

THIOINDIGO DYESTUFFS v. INDIGO, ARTIFICIAL, AND INDIGOID DYESTUFFS; VAT DYES.

THIOINDOXYL. Thioindoxyl carboxylic acid v. 2-HYDROXYTHIONAPHTHEN-1-CARBOXYLIC ACID.

THIOKETONES v. KETONES.

THIOL v. SYNTHETIC DRUGS.

o-THIOBENZOIC ACID. Thiosalicylic acid.

THIOLINE v. ABIETENE.

THIONINE v. METHYLENE BLUE and THIAZINE COLOURING MATTERS.

THIONURIC ACID v. PYRIMIDINES.

THIOPHEN. THIOPHENE. Thiofurfuran

Discovered by Victor Meyer in coal-tar benzene, which contains about 0.5 p.c. of thiophen (Ber. 1883, 16, 1465; see also Bull. Soc. chim. 1900, 23, 384; *ibid.* 24, 357; Heusler, Ber. 1895, 28, 488; Witzcek, Chem. Zentr. 1903, i. 1053). In order to extract the thiophen, a large quantity of the best commercial benzene was shaken for some hours with one-tenth of its volume of concentrated sulphuric acid, the black acid layer separated, diluted with water, and converted into the lead salt of the sulphonic acid thus obtained. This lead thiophen-sulphonate, which was contaminated with lead benzeno-sulphonate, was dried, mixed with one-fourth of its weight of ammonium chloride, and distilled. The sulphonic acid was thus hydrolysed, and an oil passed over which was purified by shaking with caustic alkali to remove mercaptans, dried over calcium chloride and rectified.

K. E. Schulze (Ber. 1885, 18, 497) recommends that the thiophen sulphonic acid, after diluting the crude acid with water, should be hydrolysed by steam-distillation. Thiophen may also be completely removed from commercial benzene by treating the latter with form- or acet-aldehyde or with phthalic anhydride (D. R. P. 211239; *Frdl.* 1908-1910, 9, 96).

According to Steinkopf (Chem. Zeit. 1911, 35, 1098), thiophen may be very readily prepared by passing acetylene over pyrites or marcasite heated to 300°, the thiophen separated from the other products by fractional distillation. Among the products occurs a substance $C_4H_4S_2$, b.p. 36°-38° of garlic-like smell which, when treated with alkalis, loses some sulphur and also its unpleasant smell. Thiophen has been artificially prepared by numerous methods: amongst others by passing

74, 1347, Marousson, *ibid.* 1893, 26, 2457; Töhl and Schultz, *ibid.* 1894, 27, 2834; *ibid.* 1895, 28, 2217; Eberhard, *ibid.* 2385).

Thiophen diiodide $C_4H_2I_2S$ forms crystalline plates, m.p. 40.8° , and is sometimes used as a substitute for iodoform in surgical cases.

In the presence of anhydrous ether, magnesium dissolves in 2-iodothiophen giving magnesium thiophen iodide which reacts with ketones forming tertiary alcohols, some of which products are described by Thomas (Compt. rend. 1908, 146, 642; see also Tschelintzeff, Chem. Zentr. 1905, i. 146).

Tetra-iodothiophen C_4I_4S is an odourless, tasteless, pale yellow, crystalline powder, m.p. 198° (Paolini and Silbermann, Atti R. Accad. Lincei, 1915, [v.] 24, ii. 206).

Sodium thiophen sulphonate $C_4H_2S \cdot NaSO_3$ is a white crystalline powder which has been employed in prurigo, being non-toxic and non-irritant: it has proved more effective than β -naphthol. Nitrothiophen (Stadler, Ber. 1885, 18, 530), like nitrobenzene, yields, with reducing agents, the corresponding amino compound (Stadler, *ibid.* 1490; 2316; Goldschmidt and Schulthess, *ibid.* 1887, 20, 1701).

Homologues of thiophen are present in coal-tar benzene and may be separated by methods similar to those used for separating thiophen (Messinger, Ber. 1885, 18, 563, 1636; Keiser, *ibid.* 1896, 29, 2560). Many of these α - and β -homologues are known and may be obtained by a variety of synthetic methods. By treating a mixture of 2-iodo-thiophen and methyl iodide with sodium, 2-methylthiophen (thiolen) can be obtained (Kues and Paal, Ber. 1886, 19, 555; Meyer and Kreis, *ibid.* 1884, 17, 1558). 2-Ethylthiophen may be obtained similarly. For various homologues and their halogen and other derivatives, see Grünwald (Ber. 1887, 20, 2585); Zelinsky (*ibid.* 2017; *ibid.* 1888, 21, 1835); Thiele (Annalen, 1892, 267, 133); Opolski (Chem. Zentr. 1905, i. 1255; *ibid.* ii. 1796) amongst others.

2-Phenylthiophen is obtained by distilling β -benzoylpropionic acid or benzoylsuccinic acid with phosphorus tri- or penta-sulphide (Kues and Paal, *ibid.* 1886, 19, 3142). It crystallises in small plates, m.p. $40-44^\circ$.

3-Phenylthiophen is obtained by the interaction of thiophen and nitroacetanilide. The compound obtained by Möhlau and Berger (*ibid.* 1893, 26, 2001) from diazobenzene chloride and thiophen in the presence of aluminium chloride is a mixture of 2- and 3-phenylthiophens (Bamberger, *ibid.* 1897, 30, 36). 3-Phenylthiophen crystallises in plates, m.p. $90-90.5^\circ$, b.p. $254-260^\circ$. Renard (Compt. rend. 1889, 109, 699) describes another phenylthiophen, n.p. 330° , which was obtained by passing a mixture of the vapours of toluene and sulphur through an iron tube heated to redness.

Di-, tri-, di-, and other diarylthiophens may be obtained by heating mixed aliphatic aromatic ketones in the presence of water and monium sulphide at 215° under pressure (Willgerodt and Scholtz, Chem. Zentr. 1910, 1909). For another method of obtaining the phenylthiophens, v. Baumann and Fromm (1895, 28, 2001).

Dianisylthiophen $C_{12}H_{10}S$, and **benzothiophen**, have been isolated from the pro-

duct obtained from the interaction of the vapours of sulphur and naphthalene at a red heat. The former crystallises in pearly yellow scales, melts at 250.5° (corr.), and boils above 440° . It yields a hexabromo derivative $C_{10}H_6Br_6S$, m.p. 260° , and a tetranitro derivative $C_{10}H_6(NO_2)_4S$, m.p. 210° (corr.). Oxidation with chromic acid gives phthalic acid. The latter crystallises in ruby red leaflets, melts at 118.5° (corr.), and boils at 345° . It gives the thiophen reaction with sulphuric acid and isatin. From it a tetrabromo derivative $C_{10}H_6Br_4S_2$, m.p. $247-248^\circ$, and a tetranitro derivative $C_{10}H_6(NO_2)_4S_2$, decomposing at 300° , have been obtained (Lanfray, Compt. rend. 1911, 152, 92, 1254). Other naphthalene thiophens have been described by Dziewonski (Bull. Soc. chim. 1904, [iii.] 31, 925).

Dithienyl (C_4H_2S) $_2$, m.p. 83° , is formed when the vapour of thiophen is passed through a red-hot tube, just as diphenyl (C_6H_5) $_2$ is formed under these conditions from benzene (Nahnsen, Ber. 1884, 17, 789). Töhl (*ibid.* 1894, 27, 665) obtained another dithienyl, m.p. 33° , by the action of anhydrous feebly fuming sulphuric acid on ice cold thiophen. A third dithienyl, m.p. 132° , was obtained by Auwers and Predt (*ibid.* 1741) by heating butane tetracarboxylic acid with phosphorus sulphide.

Thiophen carboxylic acids may be obtained by oxidising the corresponding alkyl thiophens and also by various other methods (Nahnsen, Ber. 1884, 17, 2197; Peter, Ber. 1885, 18, 542; Messinger, *ibid.* 563; Nahnsen, *ibid.* 2304; Schlechter, *ibid.* 3015; Damsky, *ibid.* 1886, 19, 3282; Levi, *ibid.* 656; Curtius, Chem. Zentr. 1902, i. 457; Holleman and Voerman, Proc. K. Akad. Wetensch. Amsterdam, 1907, 9, 514; Rec. trav. chim. 1907, 26, 293; Schorigin, Ber. 1910, 43, 1938). Thiophen 2-carboxylic acid, m.p. $126-127^\circ$; thiophen 3-carboxylic acid, m.p. 136° ; and three dicarboxylic acids are known.

Thiophen aldehyde $C_4H_2S \cdot CHO$, a pale yellow oil, b.p. 198° , having a pleasant smell, is obtained by the distillation of α -thienylglyoxylic acid $C_4H_2S \cdot CO \cdot CO_2H$ (Biedermann, Ber. 1886, 19, 1853) or by the action of sulphuretted hydrogen on chlorodiketopentamethylene

(Hantzsch, *ibid.* 1889, 22, 2838; Hantzsch and Witz, *ibid.* 1901, 34, 841). On oxidation it yields the α -acid. Many of its derivatives are known. Thiophen ketones and a large number of other derivatives of thiophen have been prepared.

This compound, which was discovered by L. E. Levi (Ber. 1887, 20, 513), is an analogue of malachite green. The leuco base

is first prepared by heating a mixture of one part of thiophenaldehyde, 2 parts of dimethylaniline with a little alcohol, and 3 to 4 parts of zinc chloride for 6 hours, adding the zinc chloride gradually, and, if the mass becomes thick, diluting slightly with water. The product

is made alkaline with caustic soda, steam-distilled, extracted with ether, and the crystalline residue which is left on evaporating the ether recrystallised from alcohol. This crystalline leuco base is then oxidised with manganese dioxide and dilute sulphuric acid, when it yields thiophen green. The colouring matter is extracted with hot water, filtered from manganese dioxide, precipitated with ammonium chloride and ammonia, and extracted with ether. It is, as represented by the formula, the carbinol corresponding with the leuco base. Like malachite green, it forms a double salt with zinc chloride. It dyes silk and wool a shade very much like that of malachite green, but somewhat yellower.

W. Krause (Internat. Monatschr. Anat. u. Physiol. 4, 2; J. Soc. Chem. Ind. 1887, 507) recommends the use of the zinc double salt of thiophen green for staining sections, especially as a complementary colour to carmine. It dissolves readily in water, alcohol, and chloroform, but is insoluble in benzene.

THIOSACCHARIN $C_6H_4 < \begin{smallmatrix} CS \\ SO_2 \end{smallmatrix} > NH$, obtained by heating an intimate mixture in equimolecular proportions of saccharin and phosphorus pentasulphide to 220° and extracting with boiling benzene. Crystallises in yellow needles, m.p. 180° . Has a bitter taste. Hydrolysed by water, alkali hydroxides and carbonates with production of saccharin and hydrogen sulphide. Soluble in ammonia solution from which it is precipitated unchanged by acids. Heated with dilute hydrochloric acid forms ammonium o-sulphobenzoate (Mannessier, Gazz. chim. ital. 1915, 45, i. 540).

THIOSALICYLIC ACID (o-Thiolbenzoic acid)

$CO_2H \text{---} \text{C}_6H_4 \text{---} SH$. (1) Formed by heating sodium o-chlorobenzoate with sodium hydrogen sulphide and copper powder to $150^\circ\text{--}250^\circ$, dissolving the product in water and precipitating by acid (Cassella & Co., D. R. P. 189200). (2) A mixture of anthranilic acid and strong hydrochloric acid is diazotised, and the solution is mixed with a cooled aqueous alkaline solution of sodium sulphide containing sulphur in suspension. After nitrogen ceases to be evolved, the solution is acidified with hydrochloric acid, filtered, the residue dissolved in sodium carbonate solution, filtered from sulphur, and heated with finely divided iron or zinc dust until no hydrogen sulphide is evolved after acidification. The product is then treated with hot sodium hydroxide solution, filtered, and the thiosalicylic acid precipitated by hydrochloric acid (Kalle & Co., D. R. P. 205450). Colourless or pale yellow crystals, m.p. $164^\circ\text{--}165^\circ$.

THIOSEMICARBAZIDE v. HYDRAZINES.

THIOSINAMINE, allyl-thiourea

Formed by the action of ammonia on allyl-mustard oil

A white crystalline substance, sparingly soluble in water. Used in the treatment of lupus, and in relaxing scar-tissue. With ethyl iodide forms iodine, which is readily soluble in water.

THIOSTANNIC ACID v. TIN SALTS AND OXIDES.

THOLAFORM. Trade name for a mixture of menthol and trioxymethylene.

THOMAS SLAG v. FERTILISERS.

THOMSONITE. A zeolitic mineral with the composition $(Na, Ca)O \cdot Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$ crystallised in the orthorhombic system. Sp.gr. 2.3–2.4; H. 5–5½. A massive variety known as *lintonite*, with a radially fibrous structure and concentric bands of green, red, and white, is occasionally used as a gem-stone. This occurs in amygdaloidal basalt at Grand Marais in Minnesota, and is collected as water-worn pebbles on the shores of Lake Superior.

L. J. S.

THORIANITE. A heavy, black mineral consisting of thoria (51–80 p.c.) with uranium oxides (11–32.7 p.c.), &c. It is isomorphous with pitchblende (q.v.) and very similar to the crystallised varieties of this in most of its characters. The principal difference between the two minerals is in the relative amounts of the thorium and uranium oxides, thorianite being essentially $(Th, U)O_2$ and pitchblende $(U, Th)O_2$. Thorianite is derived principally from Ceylon, where it is found in the stream-beds and in the gem-bearing alluvial gravels at several spots in the Central, Sabaragamuwa, and Southern provinces. The heavy minerals occurring with it, and separated by the gemmers from the alluvia by a simple process of washing, are zircon, ilmenite, thorite, gold, &c. The largest amounts have been obtained from the Kuda Pandi-oya, a small stream in the Bambarabotuwa district, about 20 miles from Balangoda in the Sabaragamuwa province; but the deposits are of limited extent, and soon become exhausted. The occurrence of the mineral *in situ* has also been noted at one or two places (Gampola and Maddegama) in Central province, a few crystals having been found in pegmatite-veins. Prospecting for the original sources is, however, difficult, owing to the thick growths of jungle.

Two isolated crystals from an unknown locality in province Betroka in the south of Madagascar have been described by A. Lacroix (1914). This material is richer in thoria than the Ceylon thorianite; analysis gave: ThO_2 , 93.02; UO_2 , 4.73; Fe_2O_3 , 0.29; PbO , 1.80 = 99.84; sp.gr. 9.33. The mineral has also been found as water-worn grains in the gold-sands of the Boshogocha river, Transbaikial, Siberia. Analysis of this material gave: ThO_2 , 74.2; UO_2 , 14.1; Ce_2O_3 , etc., 6.3; Fe_2O_3 , 3.1; SiO_2 , 0.8 = 98.5 (S. D. Kuznetsov, Bull. Acad. St. Pétersbourg, 1912, 6, 361). It is recorded from Travancore, a preliminary analysis showing ThO_2 , 32.27; U_2O_5 , 39.86 p.c. (Rec. Geol. Survey, India, 1917, 48, 9).

Thorianite is found as small, simple cubes, usually only a few mm. across, and only exceptionally reaching 2 or 3 cm. Interpenetration twins, like those of fluor-spar, are occasionally met with. The colour is jet-black, and, when the surface is not water-worn and dulled, the lustre is bright and pitchy. The streak is brown with a tinge of green; thin sections are translucent and optically isotropic. The high sp.gr. of about 9.5 is a striking feature; hardness nearly 7. The mineral is soluble in nitric acid.

and in sulphuric acid, but is scarcely attacked by hydrochloric acid. It is the richest known source of helium, 8.2-9.5 c.c. per gram being given off when the mineral is heated or dissolved in acid. Its radioactivity is less than that of pitchblende, there being less radium but more radiothorium. Nipponium and some other possibly new elements have been extracted from thorianite (M. Ogawa, 1908; C. de B. Evans, 1908).

Analysis I of thorianite from near Balangoda (W. R. Dunstan and B. M. Jones, Proc. Roy. Soc. 1906, A, 77, 546). II, same locality (Dunstan and G. S. Blake, *ibid.* 1905, A, 76, 253). III, ditto (Dunstan, Nature, 1904, 69, 510). IV, ditto (E. H. Büchner, Proc. Roy. Soc. 1906, A, 76, 385). V, and VI, from Galle, Southern province (Dunstan and Jones, *l.c.*).

	I	II ¹	III ²	IV ³	V	VI
ThO ₂	78.98	78.86	72.24	70.96	62.16	58.84
UO ₂		6.03			10.32	
UO ₂	13.40	9.07	11.19	13.12	18.88	32.74
Ce ₂ O ₃		1.02	6.39			
(La,Di) ₂ O ₃	1.47	—	0.51	1.96	1.84	0.85
PbO	2.54	2.03	2.25	2.42	2.29	2.56
Fe ₂ O ₃	0.87	0.46	1.92	2.05	1.11	1.31
CaO	0.91	1.13		0.13	0.59	0.19
H ₂ O	1.28			3.20	1.05	1.26
Insol.	0.47	0.20	0.41		0.77	0.45

¹ Also Hc, 0.39.

² Also ZrO₂, 8.68 (due to enclosed zircon); SiO₂, 1.84; sp.gr. 8.98.

³ Also ZrO₂, 0.23; SnO₂, 0.65; Sb₂O₃, 0.11; Al₂O₃, 0.15; etc.

Thorianite contains a higher percentage of thorium than any other known mineral, and it has been employed as a source of thorium for use in incandescent gas mantles. The amount exported from Ceylon in 1905 was about 9 tons, which sold for £1600 to £1700 per ton; since then, however, the price of thorium has fallen considerably.

For local details of occurrence, &c., see Administration Reports, Ceylon, Colombo 1903-6, &c.; Colonial Reports, Miscell. Ser. Ceylon Mineral Survey, London, 1904-14, &c. Bull. Imp. Inst. London, 1916, 14, 321.

L. J. S.

THORITE. A mineral consisting essentially of thorium silicate, ThSiO₄, crystallising in the tetragonal system and isomorphous with zircon. Analyses show: SiO₂, 12-19; ThO₂, 48-74 (the formula requires 81.5); U₂O₃, 1-10; Ce₂O₃, 0-3; H₂O, 6-10 p.c. The presence of water appears to be due to secondary alteration; and the fact that the mineral is frequently optically isotropic and amorphous indicates that it is not fresh. The colour is yellow to dark brown, and in the orangite variety (*q.v.*) a bright orange-yellow; the lustre is resinous; sp.gr. 4.4-5.4. The mineral occurs as small masses and indistinct crystals in the augite-syenite on the Langesundfjord and near Arendal, and a few other places in the south of Norway. It is also found, together with thorianite, in the gem-gravels of Ceylon. Small amounts are collected for the preparation of thorium compounds and used principally for the mantles of incandescent gas-lights.

L. J. S.

THORIUM. Sym. Th. At.wt. 232.2 This element, which has the highest atomic weight of

the metals of the rare earth series, was identified by Berzelius in 1829 as occurring in the form of silicate in the mineral thorite, obtained from the island of Löv-ön (near Brevig, Norway).

For position in the Periodic system, see Vogel (Zeitsch. anorg. Chem. 1918, 102, 177-200).

Occurrence.—Thorium occurs as a constituent of most rocks of volcanic origin to the extent of 3×10^{-3} in acid, and 0.22×10^{-3} in basic deposits. It is present as the main constituent in thorite, orangite, and their alteration products, mackinoshite, auerlite, calcliothorite, and freyalite, and in thorianite (Dunstan and Jones, Proc. Roy. Soc. 1905, 76 A, 253; 1906, 77 A, 546; Szilárd, Compt. rend. 1907, 135, 463). It occurs also in tthocrasite (Amer. J. Sci. 1906, [iv.] 22, 515). The only source of commercial importance, however, is monazite sand, which contains from 2 to 10 p.c. ThO₂.

Extraction and Purification.

1. *Separation from thorite, orangite, and thorianite.*—These minerals are easily decomposed by the strong mineral acids when silicic acid separates, and the solution containing the metallic constituents is freed from lead, bismuth, &c., by hydrogen sulphide. Thorium is then separated in the form of its octahydrated sulphate Th(SO₄)₂.8H₂O, which separates from aqueous solutions below 47°, by stirring into the cold chloride or nitrate solution (about 20 p.c.) a moderate excess of cold 50 p.c. sulphuric acid. This salt is re-dissolved in water, and oxalic acid added to precipitate thorium oxalate, which is then ignited to thorium and the cycle of operations repeated. For this purpose the thorium must be attacked by concentrated sulphuric acid; the product is dissolved in ice and water, and the solution warmed to 20° or 30° to separate the hydrated thorium sulphate (Krüss and Nilson, Ber. 1887, 20, 1665).

Thorium salts may be separated from those of the cerite metals by solution in excess of alkali carbonate or oxalate. But this process brings into solution also small amounts of the cerium and yttrium earths, which, however, do not occur in thorium minerals except monazite to any large extent; moreover, the extraction of the thorium is never complete. Solutions of thorium salts readily undergo hydrolytic change when boiled with sodium thiosulphate, a basic thorium thiosulphate being precipitated mixed with sulphur; this operation separates thorium from all rare earth metals excepting scandium and zirconium, but the separation is not perfect if more than 2 to 3 p.c. of other earths are present (Bunsen, Pogg. Ann. 1875, 155, 379; Moissan and Étard, Compt. rend. 1896, 122, 573; Urbain, Bull. Soc. chim. 1896, [iii.] 15, 338; Brauner, Chem. Soc. Trans. 1898, 73, 951).

2. *Separation from monazite sand.*—Monazite, an orthophosphate of the cerite metals which contains varying proportions of thorium, is very widely diffused in the earth's crust, occurring primarily as an accessory constituent of certain plutonic rocks (granites, diorites, gneisses, &c.). It is, however, chiefly in its secondary form of monazite sand that the mineral is exploited for the gas-mantle industry. The erosive action of rivers and tides on the original monazite

containing rocks gives rise to enormous accumulations of monazite sands found in littoral and fluviatile deposits.

Up to 1909 the deposits on the coast of Brazil (6 to 7 p.c. ThO_2), and since then the richer sand discovered on the coast of Travancore (9 to 10 p.c. ThO_2) have been exploited to the extent of 1600 to 2000 tons annually. Attempts have also been made to work commercially the sand of Ceylon (Bull. Imp. Inst. 1916, 14, 321-369). Monazite is also found in Australia, North and South Carolina, and the Malay Archipelago.

For an account of the Travancore workings, see E. White (Pharm. J. 1922, 440).

In addition to the yellow grains of monazite, the sand contains fragments of magnetite, chromite, titanite, quartz, felspar, hornblende, rutile, brookite, zircon, and small quantities of rare-earth minerals (e.g. samarskite, aschynite). The sand is concentrated by washing, followed by electromagnetic concentrations, until it contains 90 to 96 p.c. of actual monazite.

The monazite sand is decomposed by heating with a minimum of concentrated sulphuric acid, and the product dissolved in cold water, the residue containing the unattacked constituents of the sand, quartz, zircon, titanite, &c. Another way of effecting the initial breakdown of the monazite by fusing in an electric furnace with carbon, lime, and calcium fluoride, slaking the product with water and washing off the lime from the residual heavy rare earth carbides, is recommended by Baskerville (U.S. Pat. 1087099, 1914), but does not appear to be used. The acid solution is partially neutralised with magnesia, sodium hydroxide or ammonia, or suitably diluted with water, until precipitation of the phosphates of the rare-earth metals occurs, when thorium phosphate, being the least soluble of this series, is concentrated in the first fractions. The use under varying conditions of acidity and dilution of pyrophosphoric acid (J. Amer. Chem. Soc. 1914, 36, 1134-11439; D. R. P. 286087, 1914; U.S. Pat. 1182880, 1916; Eng. Pat. 112380, 1917) and of sodium hypophosphate (Koss, Chem. Zeit. 1912, 30, 686; Fr. Pat. 444798, 1912; Wirth, Chem. Zeit. 1913, 37, 773-774) have been proposed for the separation of thorium at this stage. The phosphate is dissolved in hydrochloric or sulphuric acid and the thorium precipitated by oxalic acid. The greater part of the phosphoric acid is thus removed. The sparing solubility of thorium oxalate in solutions containing excess of mineral acid serves also to separate thorium from the commoner metals (iron, manganese, calcium, &c.). Sometimes the separation with oxalic acid is replaced by precipitation with hydrofluoric acid.

The crude, well-washed thorium oxalate when warmed with excess of aqueous sodium carbonate yields a solution containing the greater part of the thorium, together with small quantities of the cerium and yttrium earths.

The thorium in the filtered carbonate solution is precipitated either as oxalate by adding acid or as hydroxide by adding caustic soda. Alternatively, the oxalate may be converted into sulphate previous to solution in sodium carbonate. Final purification is effected by converting the nearly pure oxalate or hydroxide into sulphate and crystallising repeatedly the

octahydrated salt until it is free from didymium and phosphate (Koppel and Holtkamp, Zeitsch. anorg. Chem. 1910, 67, 266).

Pure thorium sulphate obtained by the foregoing or by a slightly modified process is converted almost exclusively, via the hydroxide, into thorium nitrate. For this purpose it may be dissolved in slight excess of ammonium carbonate, the diluted solution freed from iron and heavy metals with hydrogen sulphide and boiled until ammonia ceases to be evolved. The precipitated thorium is washed and dissolved in nitric acid.

It is customary to adjust the solution so that the finished nitrate will contain sulphate equivalent to 1 or 2 p.c. H_2SO_4 , since in this form it is most generally suitable for use in the gas mantle industry. It is then concentrated until it contains 48 p.c. ThO_2 , and vigorously stirred as it cools, when the granular thorium nitrate of commerce is obtained.

Few commercial chemicals attain such a high degree of purity as thorium nitrate, since an extremely pure product is essential for the manufacture of gas mantles. Didymium and other rare earths must be entirely absent, phosphoric acid must not exceed 0.004 p.c. P_2O_5 , and lead, iron, lime, silica and soda are not permissible except in the merest traces.

Many processes for the separation of thorium from the other rare earths have been described, most of which have no commercial value. Hydrated thorium peroxide is precipitated by hydrogen peroxide from very slightly acid (preferably nitric) solutions of thorium salts, but in presence of cerite metals a certain amount of cerium is co-precipitated. The operation must be repeated several times to effect a complete separation (Wyrouboff and Verneuil, Bull. Soc. chim. 1898, [iii.] 19, 219; Compt. rend. 1898, 127, 412).

A separation of thorium and zirconium from the cerium and yttrium elements is brought about by stirring thoroughly into a dilute solution of the nitrates (containing trivalent cerium) an excess of freshly-prepared lead carbonate. After 12 hours the hydrates of thoria, zirconia, and ferric oxide are completely precipitated, the hydroxides of aluminium, chromium, and uranium are partially deposited, whilst cerium, yttrium, and other rare earth metals remain in solution. The precipitate is re-dissolved and the thoria present is further purified (Giles, Chem. News, 1905, 92, 130). The sparingly soluble basic acetate (Böhm, Die Darstellung der seltenen Erden, vol. i. 40, 1290) and the chromate (Ber. 1900, 33, 2028) have been recommended for separating thorium from the cerite metals, and the acetate method has been used commercially. The acetylacetone may be employed in purifying small quantities of thoria; the well-dried salt is extracted with chloroform, in which thorium acetylacetone alone dissolves (Urbain, Bull. Soc. chim. 1896, [iii.] 15, 338, 347; Ann. Chim. 1900, [vii.] 19, 184). Repeated precipitation of thorium by potassium azide is recommended as a mode of separation and purification (Dennis and Kortright, Amer. Chem. J. 1894, 16, 79; J. Amer. Chem. Soc. 1896, 18, 947).

Thorium is precipitated quantitatively as iodate from even very dilute solutions by iodine

acid or potassium iodate in the presence of excess of nitric acid; hydrochloric acid should be absent (Meyer, Zeit. anorg. Chem. 1911, 71, 65-69).

Thorium in neutral solution is precipitated quantitatively by sebacic acid at the boiling-point (D. R. P. 266459, 1912), by phenoxycetic and pyrotartaric acids (Smith and James, Chem. News, 1912, 105-109), and by the ammonium salt of nitrosophenylhydroxylamine (Thornton, Chem. News, 1916, 114, 13-14). Thorium can be determined volumetrically as molybdate (J. Ind. Eng. Chem. 1912, 4, 493-495).

m-Nitrobenzoic acid precipitates thorium quantitatively as thorium *m*-nitrobenzoate from neutral solutions of the rare-earth nitrates derived from monazite, and a repetition of the process affords a complete separation from cerium, lanthanum, neodymium, and praseodymium, but the first of these elements must be in the tervalent condition, otherwise the sparingly soluble yellow ceric *m*-nitrobenzoate is deposited (J. Amer. Chem. Soc. 1904, 26, 780; Zeitsch. angew. Chem. 1905, 18, 92). This method avoids the use of alcohol, which is required in the separation of these metals with fumaric acid.

Certain organic bases have a selective action in the precipitation of the hydroxides of the rare earths; *p*-toluidine separates thorium and zirconium from lanthanum, neodymium, and praseodymium, whilst hexamethylenetetramine and the chloranilines serve to separate thorium from zirconium (Hartwell, J. Amer. Chem. Soc. 1903, 25, 1128).

The separation of thorium from rare earth mixtures by the electrolysis of solutions with a mercury cathode (Dennis and Ray, J. Amer. Chem. Soc. 1918, 40, 174-181; U.S. Pat. 1115513, 1914), and from tungsten by fusion with sodium carbonate are described (Ann. Chem. Analyst, 1913, 18, 257-260).

For the estimation of thorium in monazite sand by an emanation method, see Helmick, J. Amer. Chem. Soc. 1921, 43, 2003; J. Soc. Chem. Ind. 1922, 96 A.

Metallie thorium. The isolation of the metal in a pure state is a matter of considerable difficulty owing to its infusibility, and to its power of combining with nitrogen, hydrogen, carbon, silicon, and the metals. The reduction of thoria with magnesium is not complete (Ber. 1891, 24, 873); the action of silicon and aluminium on thoria or on potassium thorium fluoride leads respectively to the formation of a silicide ThSi_2 , and an alloy ThAl_3 (Compt. rend. 1906, 142, 157, 280). Thorium can also be obtained by passing the vapour of the iodide over a heated tungsten filament (van Arkel and de Boer, Zeitsch. anorg. Chem. 1925, 148, 345; Chem. Soc. Abstr. 1925, ii. 1193). The pure metal is said to be obtained by the action of metallic calcium on the oxide (Fr. Pat. 419043, 1909; U.S. Pat. 1085098, 1914), and by the treatment at 500°C. of the anhydrous chloride with sodium in a steel bomb exhausted of air (Zeit. anorg. Chem. 1914, 87, 209-228). So prepared the metal is leaden grey in colour, ductile and in the coarse form unattacked by water. A rolled specimen of the metal obtained by reduction melted at 1450° and had sp.gr. 12.14 (Ber. 1883, 16, 163; Compt.

rend. 1883, 96, 346; Ann. Chim. 1906, [viii.] 8, 182; Zeitsch. Elektrochem. 1908, 14, 768). Electrolysis of thorium chloride dissolved in a fused mixture of sodium and potassium chlorides contained in a graphite crucible affords a product melting at 1700° (*ibid.* 1909, 15, 866). Alloys of thorium are obtained by reducing, with sodium or with carbon and sodium hydroxide, mixtures of thorium salts with those of more fusible metals (Sn, Pb, Sb, Al, or Cu), and thorium fluoride heated with tin or lead gives thorium alloys of these metals (D. R. P. 146503). The alloys of thorium with tungsten are of commercial importance (Grotthus Metall. u. Erz. 1913, 10, 844; D. R. P. 2939532, 1913).

Reduction of thoria by amorphous boron leads to the formation of two thorium borides, ThB_4 , prismatic crystals, sp.gr. 7.5 at 15°, and ThB_3 , reddish-violet mass, sp.gr. 6.4 at 15°; the former is soluble and the latter insoluble in concentrated hydrochloric acid (Compt. rend. 1905, 141, 191).

Thoria is reduced to thorium by heating with tungsten, the tungsten oxide combining with unchanged thoria to form a thorium-tungsten bronze.

Colloidal thorium is prepared by rubbing 95-96 p.c. thorium with cold dilute hydrochloric acid and washing the mass on a filter until a grey opalescent solution passes through; this liquid is stable to acids, but not to alkalis. On electrification the thorium particles are found to carry a positive charge (Zeitsch. Chem. Ind. Kolloide, 1909, 5, 191).

Thorium hydride ThH_4 is stated to be produced by direct combination of the metal and hydrogen at red heat, or by absorption of the gas by a heated mixture of thoria and magnesium. It is not decomposed by water, but evolves hydrogen on treatment with hydrochloric acid (Ber. 1891, 24, 873; Compt. rend. 1900, 131, 891; 1901, 132, 36; Ann. Chim. 1907, [viii.] 10, 130). Its existence has also been observed by Klauber and von Mellenheim (Zeitsch. anorg. Chem. 1920, 113, 306), who formed it by the action of water or dilute acids upon an alloy of thorium and magnesium. It was said to be decomposed by heat yielding metallic thorium. Its existence is denied by Schwarz and Konrad (Ber. 1921, 54, [B] 2122).

Thorium carbide ThC_2 , yellow microscopic crystals, sp.gr. 8.96 at 18°, prepared by heating an intimate mixture of thoria and carbon in the electric furnace (900 amperes, 50 volts), is decomposed by cold water evolving acetylene, methane, ethylene, and hydrogen (Compt. rend. 1893, 116, 1227; 1896, 122, 573; Ann. Chim. 1897, [vii.] 12, 427; Bull. Soc. chim. 1914, 15, 367-370).

Thorium silicide ThSi_2 , quadratic plates, sp.gr. 7.96/16°, produced by heating to 1200° a mixture of potassium silico- and thorofluorides and aluminium (Chem. Zeit. 1906, 29, 1031; Compt. rend. 1906, 142, 157).

Thorium nitride Th_3N_4 , brown powder, obtained by direct union of its components at high temperatures, rapid cooling of the product is said to cause decomposition; by heating a mixture of thorium and ammonium chlorides in hydrogen chloride, or by passing ammonia over heated thorium carbide; it is decomposed by water with evolution of ammonia (Compt. rend. 1896, 122,

573; 1900, 131, 837; 1901, 132, 36; Ann. Chim. 1897, [vii.] 12, 427; 1907, [viii.] 10, 130).

Thorium sulphide ThS_2 , dark-brown lamellae, sp.gr. 6.7 at 0°, and **thorium oxysulphide** ThOS , yellow crystalline powder, sp.gr. 8.42 at 0°, are produced by passing hydrogen sulphide over a mixture of thorium chloride and excess of sodium or potassium chloride at red heat (Compt. rend. 1908, 146, 815; cf. Zeitsch. anorg. Chem. 1907, 53, 74), or at a temperature below that at which the chloride sublimes (U.S. Pat. 941071, 1909).

Thorium fluoride ThF_4 , white amorphous powder, resulting from the interaction of hydrogen fluoride and thorium chloride or bromide at 354°–400° (Compt. rend. 1908, 146, 973). The *hydrate* $\text{ThF}_4 \cdot 4\text{H}_2\text{O}$, a gelatinous precipitate, obtained on adding hydrofluoric acid to solutions of thorium salts, changes to a heavy white powder, the insolubility of which in excess of the precipitant serves as a separation of thorium from zirconium (Bull. Soc. chim. 1897, [iii.] 20, 69); *double fluorides* have been prepared approximating to the composition $\text{KTh}_2\text{F}_9 \cdot 6\text{H}_2\text{O}$ and $\text{KThF}_5 \cdot \text{H}_2\text{O}$, and not to the typical fourth-group formula $\text{K}_2\text{R}^{\text{IV}}\text{F}_6$ (Zeitsch. anorg. Chem. 1903, 35, 424).

Thorium chloride ThCl_4 can be prepared by the following methods, but unless oxygen and moisture are carefully excluded, the product is always contaminated with oxychloride: (i.) heating metallic thorium in hydrogen chloride (Ber. 1887, 20, 1665; Zeitsch. physikal. Chem. 1887, 1, 301); (ii.) heating thoria in carbon tetrachloride vapour or in a mixture of carbon monoxide and chlorine (Compt. rend. 1901, 132, 36, 1908; 147, 1046; Ann. Chim. 1907, [viii.] 10, 130); (iii.) heating thoria in the vapour of sulphur chloride (Bourion, Ann. Chim. 1910, [viii.] 20, 547; 21, 49; cf. Compt. rend. 1904, 138, 631; Ber. 1905, 38, 817; Zeitsch. anorg. Chem. 1914, 87, 209–228); (iv.) decomposing the heated carbide with chlorine (Compt. rend. 1905, 140, 1510). When purified by sublimation *in vacuo* (720°–750°) the chloride is obtained in colourless needles or prisms, sp.gr. 4.59, m.p. 820°.

Thorium oxychloride ThOCl_2 is an intermediate product obtained in the foregoing operation (No. ii.); it crystallises from alcohol and absorbs $6\text{H}_2\text{O}$ from moist air. The *hydrate* $\text{ThCl}_4 \cdot 8\text{H}_2\text{O}$ is readily soluble in water or alcohol, and the soluble *hydroxy-chlorides* $\text{Th}(\text{OH})\text{Cl}_3 \cdot 7\text{H}_2\text{O}$ and $\text{Th}(\text{OH})_2\text{Cl}_2 \cdot 6\text{H}_2\text{O}$ have been isolated.

Thorium chloride combines with ammonia to form several additive compounds, of which $\text{ThCl}_4 \cdot 4\text{NH}_3$ alone is stable above 120° (Compt. rend. 1910, 151, 387). Additive compounds are also formed with organic bases and with alcohols, aldehydes, and ketones (Zeitsch. anorg. Chem. 1903, 35, 424; Ber. 1904, 37, 3662; Jantsch and Urbach, Helv. Chim. Acta, 1919, 2, 490).

Thorium bromide ThBr_4 , transparent colourless needles, sp.gr. 5.62, unstable in the light, evolving bromine, boils at 725° and sublimes *in vacuo* at 600°–620° (Compt. rend. 1905, 140, 1510; 1907, 145, 243).

Thorium platino-cyanide $\text{Th}[\text{Pt}(\text{CN})_4]_2 \cdot 16\text{H}_2\text{O}$, yellow rhombic prisms from thorium sulphate and barium platino-cyanide.

Thorium hydroxide $\text{Th}(\text{OH})_4$, heavy white

powder, readily soluble in mineral acids or in aqueous alkali carbonates. It dissolves readily in less than its equivalent of hydrochloric or nitric acid, forming solutions which are colloidal, but which readily revert to the normal salts on boiling with a slight excess of acid. The hydrosol form of this hydroxide is produced by dialysing solutions of thorium nitrate or by adding thorium nitrate solution gradually to the well-washed hydrosol and boiling the mixture until an opalescent solution is obtained. Thorium hydroxide hydrogel is also converted into the hydrosol form by diluted (N/20) hydrochloric acid, or by solutions of aluminium or ferric chloride (Biltz, Ber. 1902, 35, 4436; 1904, 37, 1100; Müller, *ibid.* 39, 2857; Zeitsch. anorg. Chem. 1908, 57, 314; J. Chim. Phys. 1907, 5, 488, 495; Zeitsch. Electrochem. 1916, 22, 145–161; J. Soc. Chem. Ind. 1916, 688; Lemoine, Compt. rend. 1916, 162, 702–708).

The electrometric precipitation of thorium hydroxide has been studied by Britton (Chem. Soc. Trans. 1925, 127, 2110).

The so-called *thorium meta-oxide* is a soluble modification of thoria, produced by igniting the oxalate or hydroxide at comparatively low temperatures and evaporating the residue with hydrochloric or nitric acid until a syrup is left, which dissolves in water to a milky solution, appearing yellow by transmitted light (Cleve, Jahrb. Min. 1874, 161; Stevens, Zeitsch. anorg. Chem. 1901, 27, 41; Wyruboff and Verneuil, *ibid.* 28, 90; Compt. rend. 1898, 127, 863). It corresponds with the colloidal hydroxide described by D. R. P. 228263, 1909.

Thorium dioxide (*thoria*) ThO_2 , white powder, sp.gr. 10.220 at 17°, is obtained by heating the hydroxide or the thorium salts of volatile acids.

It is ordinarily very resistant to the action of even concentrated hydrochloric and nitric acids, but particles reduced to sizes less than 1μ are soluble in hydrochloric acid (J. Chem. Soc. 1917, 112, [ii.] 300). It melts and volatilises at 2000°C. in the cathode ray furnace (Zeitsch. anorg. Chem. 1914, 87, 129–168). Advantage is taken of the refractory nature of the oxide for the making of cupels, &c. (U.S. Pats. 1121988; 1121890, 1914).

The resolution of thoria into three chlorides differing in volatility and containing respectively three elements with different atomic weights has not been confirmed (Baskerville, *ibid.* 1904, 26, 922; Ber. 1905, 38, 1444; cf. R. J. Meyer and Gumpertz, *ibid.* 1905, 38, 817; Eberhard, *ibid.* 38, 826).

Thorium peroxide is a gelatinous white precipitate, retaining acid and of somewhat uncertain composition, formed by adding hydrogen peroxide to solutions of thorium salts; its peroxide character is manifested by the liberation of iodine from potassium iodide (Compt. rend. 1898, 126, 340; Bull. Soc. chim. 1898, [iii.] 19, 219; Ann. Chim. 1906, [viii.] 6, 441; Zeitsch. anorg. Chem. 1900, 25, 378; 1902, 31, 359; R. Accad. Sci. Torino, 1911, 46, 195; Gazz. chim. ital. 1912, 42, ii. 21–28).

Thorium sulphate $\text{Th}(\text{SO}_4)_2$, obtained in the anhydrous condition by treating thoria with concentrated sulphuric acid, dissolves in ice-cold water to a 25 p.c. solution, which is super-saturated at all temperatures from 0° to 100° and yields between 0° and 43° either spon-

taneously or after seeding, monoclinic prisms of the *nonahydrate* $\text{Th}(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$, and above the latter temperature needles of the *tetrahydrate* $\text{Th}(\text{SO}_4)_3 \cdot 4\text{H}_2\text{O}$; these hydrates are isomorphous with the corresponding uranous compounds $\text{U}(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$ and $\text{U}(\text{SO}_4)_3 \cdot 4\text{H}_2\text{O}$ (Zeitsch. Krist. 1900, 32, 250; 1901, 34, 307).

The *octohydrate* $\text{Th}(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, prismatic crystals, separates under conditions similar to those which favour the formation of the more stable nonahydrate, and is the hydrate usually obtained in practice. It owes its production to the existence of a metastable phase having a very low velocity of transformation (Bull. Soc. chim. 1901, [iii.] 25, 105; Bull. Soc. Min. 1901, 24, 105; Ber. 1887, 20, 1665; 1905, 38, 817). The octo- and nonahydrates are very sparingly soluble in cold water and (in presence of excess of sulphuric acid) in mineral acids. For the solubility of the sulphate, see Wirth (Zeitsch. anorg. Chem. 1912, 76, 174-200; Bull. Soc. chim. 1912, 11, 645-648).

The *acid sulphate* $\text{ThSO}_4(\text{HSO}_4)_2$, needles, is obtained by drying *in vacuo* at 130° , the product of the action of concentrated sulphuric acid on a saturated solution of the anhydrous normal sulphate (Zeitsch. anorg. Chem. 1904, 38, 322); a *hydrated acid sulphate* $2\text{Th}(\text{SO}_4)_2 \cdot \text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$ (Gazz. chim. ital. 1903, 32, ii. 523); and a *basic sulphate* $\text{ThOSO}_4 \cdot 2\text{H}_2\text{O}$ (Compt. rend. 1883, 96, 1860; 1910, 151, 70; Ber. 1910, 43, 2776) have been described. The following *double sulphates* have been isolated: $\text{K}_2\text{Th}(\text{SO}_4)_4 \cdot 2\text{H}_2\text{O}$, sparingly soluble; $\text{K}_2\text{Th}(\text{SO}_4)_6 \cdot 2\text{H}_2\text{O}$; the corresponding ammonium salt series:

$\text{Cs}_2\text{Th}(\text{SO}_4)_3 \cdot 2\text{H}_2\text{O}$; $\text{Na}_2\text{Th}(\text{SO}_4)_3 \cdot 4$ and $12\text{H}_2\text{O}$ (Bull. Soc. Min. 1901, 24, 105; Zeitsch. anorg. Chem. 1903, 35, 424; Gazz. chim. ital. 1903, 32, ii. 523). On heating the sulphate to 55°C . with excess of water, basic sulphates,

and $6\text{H}_2\text{O}$ are formed (Barré, Compt. rend. 1910, 151, 70-72).

Thorium ethylsulphate has been described as intermediate in the production of pure thorium nitrate (Fr. Pat. 414463, 1910).

Thorium nitrate $\text{Th}(\text{NO}_3)_4$, with 5, 6, and $12\text{H}_2\text{O}$, the dodecahydrate separating in hygroscopic plates (Cleve, l.c.; cf. Zeitsch. anorg. Chem. 1897, 115; Chem. Soc. Trans. 1898, 73, 951). The commercial product, which is not a definite hydrate, but approximates to $\text{Th}(\text{NO}_3)_4$ with $4\text{H}_2\text{O}$, contains sulphate equivalent to 1 to 2 p.c. H_2SO_4 , and swells considerably on heating, leaving a finely divided residue of snow-white thorium. Commercial thorium nitrate should contain a minimum of 48 p.c. of ThO_2 .

Thorium nitrate unites with the nitrates of univalent and divalent metals, forming complex nitrates, having respectively the general formulae $\text{R}_2\text{Th}(\text{NO}_3)_6$ and $\text{R}'\text{Th}(\text{NO}_3)_8 \cdot 8\text{H}_2\text{O}$, which correspond with the double nitrates containing quadrivalent cerium. Similar double nitrates (and sulphates) are formed with organic bases (Zeitsch. anorg. Chem. 1901, 27, 359; 1908, 60, 123).

Complex thorium carbonates. Normal thorium carbonate is not known, but complex carbonates are prepared by adding soluble carbonates to thorium solutions until the pre-

cipitate first formed redissolves or by dissolving thorium hydroxide in aqueous alkali bicarbonate, saturated with carbon dioxide, and precipitating with alcohol or by the interaction of thorium and carbon dioxide under pressure (Compt. rend. 911, 153, 66-68). *Sodium thorium carbonate* $\text{Na}_2\text{Th}(\text{CO}_3)_2 \cdot 12\text{H}_2\text{O}$ separates in prismatic crystals; the thallous salt $\text{Tl}_2\text{Th}(\text{CO}_3)_2$ is precipitated as a crystalline powder on adding a soluble thallous salt to a solution of ammonium thorium carbonate (Cleve, l.c.; cf. Zeitsch. anorg. Chem. 1903, 35, 424). For the thorium chromates, see H. T. S. Britton, Chem. Soc. Trans. 1923, 123, 1429.

Thorium molybdate $\text{Th}(\text{MoO}_4)_2$, obtained by fusing partly dehydrated thorium chloride with excess of anhydrous sodium molybdate, forms tetragonal crystals, $a : c = 1 : 0.73565$, $d^{75} 4.92$, which exhibit mutual miscibility in the solid state with cerous molybdate (Ferruccio Zambonini, Atti R. Accad. Lincei, 1923, [v.] 32, i. 518-524; cf. A. 1916, ii. 249).

Thorium formate $\text{Th}(\text{HCO}_2)_4 \cdot 3\text{H}_2\text{O}$ and **thorium acetate** $\text{Th}(\text{CH}_3\text{CO}_2)_4$, crystallising respectively in leaflets and needles, are produced by dissolving thorium in the corresponding acids; interaction between thorium salts and soluble formates and acetates leads to basic salts $\text{Th}(\text{OH})_2(\text{HCO}_2)_2$ and $\text{Th}(\text{OH})_2(\text{CH}_3\text{CO}_2)_2 \cdot \text{H}_2\text{O}$ (Haber, Monatsh. 1897, 18, 687).

Thorium oxalate $\text{Th}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$ is precipitated completely by adding oxalic acid to thorium solutions even in the presence of considerable proportions of mineral acid (Brauner, Chem. Soc. Trans. 1898, 73, 951). Complex oxalates such as $\text{K}_4\text{Th}(\text{C}_2\text{O}_4)_6 \cdot 4\text{H}_2\text{O}$ and $\text{Na}_4\text{Th}(\text{C}_2\text{O}_4)_6 \cdot 6\text{H}_2\text{O}$ are produced by dissolving thorium oxalate in concentrated solutions of alkali oxalates (Cleve, l.c.; and Brauner, l.c.). The existence of double oxalates with ammonium oxalate $2\text{Th}(\text{C}_2\text{O}_4)_2 \cdot (\text{NH}_4)_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ and $7\text{H}_2\text{O}$ is established by solubility curves (James, J. Amer. Chem. Soc. 1914, 36, 1853-1856).

Complex chloro-oxalates, e.g.

have been described (Compt. rend. 1913, 156, 1075-1076; *ibid.* 1913, 156, 1907-1909).

Thorium acetylacetonate $\text{Th}(\text{CH}(\text{CO}\cdot\text{CH}_3)_2)_4$, m.p. 171° , soluble in alcohol or chloroform, is prepared by adding acetylacetonate dissolved in aqueous ammonia to 13 p.c. thorium nitrate solution. This salt can be distilled *in vacuo* (Urbain, Bull. Soc. chim. 1896, [iii.] 15, 1338; Biltz, Annalen, 1904, 331, 334; Zeitsch. anorg. Chem. 1904, 40, 218).

Thorium tartrates and complex tartrates, v. Cleve, l.c.; Haber, l.c.; Rosenheim, Zeitsch. anorg. Chem. 1903, 35, 424.

Thorium salts of other organic acids, v. Morgan, Pharm. J. 1904, [iv.] 19, 472; and Karl, Ber. 1910, 43, 2068.

Thorium olate has been employed therapeutically in ointment form for carbuncles and other skin troubles (Martindale, Extra Pharmacopoeia).

Pharmacological action of thorium, v. Solimann and Brown, Amer. J. Physiol. 1907, 18, 426.

Thorium compounds are used to render the internal organs opaque to Röntgen rays (D. R. P. 223375, 1909).

Biological action of thorium.—Elemental thorium inhibits the growth of certain micro-organisms and algae without endangering the life of higher organisms (*Amphioxus*, *Zeitsch. Elektrochem.* 1911, 17, 816; *Arch. Sci. Phys. Nat.* 1911, [iv.] 32, 347); the salts inhibit the growth of cholera vibrio (*Compt. rend.* 1914, 159, 410-413).

Industrial application of Thoria v. Gas Mantles. Gas mantles are generally woven in cotton or preferably ramie fibre, but artificial silk has also been employed, and formerly the thorium-cerium solution was added to the dissolved cellulose before it was spun into thread. The present practice, however, with viscose artificial silk is to impregnate the woven stocking just as in the case of ramie or cotton fibre. The rare earth nitrates may be replaced by the corresponding acetates or formates and, with artificial silk, the impregnated stocking is treated with ammonia or some volatile alkali such as hydrazine or tetraethyl-ammonium hydroxide in order to produce within the fibres the hydroxides of thorium and cerium. Hydrogen peroxide may also be employed as the precipitant. In either case, the stockings are washed free from soluble salts (ammonium nitrate, &c.) or acid; the head is hardened with a solution of magnesium, aluminium, zirconium, glucinum or chromium salt, and the mantle 'burnt off' and 'seasoned' as in the case of the ramie fibre.

From a kilogram of thorium nitrate 600 to 800 mantles can be made; hence each mantle contains about 0.5 gram of thoria.

Although in most instances the optimum effect is attained by mixing the thorium and cerium salts in such proportions that the mixed oxides of the mantle consist of 98.8 p.c. of thoria and 1.2 p.c. of ceria, yet owing to the yellow colour of the light produced by this amount of ceria in inverted mantles, it is customary in this form of illumination to reduce the proportion of ceria to from 0.5 to 0.7 p.c.

According to R. L. Swan (*J. Chem. Soc.* 1924, 125, 780) the catalytic activity of mixtures of ceria and thoria on the combination of hydrogen and oxygen at 450° reaches a maximum when the mixtures contains 1 p.c. of ceria (Welsbach mixture). The activity of pure thoria is the same as that of a mixture containing 9 p.c. ceria. The light-giving powers of these are also equal. The author considers that the Welsbach mixture represents the best illuminant obtainable from the two oxides in question. The ceria may act as a carrier of oxygen (*cf. A.* 1907, ii. 557) or as a promoter of the electronic emission from the thoria (*Chem. Soc. Abstr.* 1924, 126, ii. 400).

A pure thoria mantle gives no emission in the visible region of the spectrum and only a slight radiation of infra-red rays of short wave-length. A cerium dioxide mantle gives a maximum radiation at the extreme red end of the visible spectrum, the intensity at first diminishes in the infra-red region and then increases again for heat rays of longer wave-length. In this mantle there is, on the whole, a relatively considerable loss of heat by radiation, the temperature remains comparatively low and consequently the emission of light rays is only feeble.

In the Welsbach mantle containing 0.5 p.c.

to 1.5 p.c. cerium dioxide, the emission of light is selective and attains its maximum in the blue region of the spectrum. On the other hand, the heat radiation is remarkably small, except for rays of comparatively long wave-length. Consequently the temperature attained by the mantle is comparable with that of the flame itself. The cerium dioxide colours the transparent ground mass of thoria so that an intense selective absorption is developed in the visible region of the spectrum and, providing that the amount of colouring oxide is small, this result is attained without any appreciable increase in the loss of heat by radiation and consequently without diminution in the intensity of illumination.

One hundred parts of thoria can hold in solid solution 6.7 parts of cerium dioxide, and as the mantle contains only about 1 p.c. of the latter oxide, it is entirely in the dissolved condition. Owing to this intimate mingling of the two oxides, a very small addition of cerium dioxide suffices to bring about the intense emission of light waves whilst the increase in heat radiation is too slight to act injuriously. If, however, the proportion of cerium is raised, the greater loss of heat by radiation leads to lowering of the mantle temperature and consequent diminution in luminosity. Cerium dioxide itself is stable in the Bunsen flame, but nevertheless the ignited mixed oxides, when treated with hydrochloric acid and potassium iodide solution liberate an amount of iodine corresponding with only a portion of the dioxide originally introduced into the mixture. This result suggests the possibility of some chemical combination between the cerium and thorium oxides which may be the chemical cause of the characteristic physical properties of the Welsbach gas-mantle (*cf. White and Traver, J. Soc. Chem. Ind.* 1902, 21, 1012; *Lewes, Chem. News.* 1905, 28, 62; *Journ. Gas Beleuchtung*, 1903, 46, 787, 974; *R. J. Meyer and Anschütz, Ber.* 1907, 40, 2639). For the testing of incandescent mantles, *see Coste and Powney, J. Soc. Chem. Ind.* 1911, 30, 65.

RADIOACTIVITY OF THORIUM.

Thorium preparations, in general, exhibit radio-activity, yielding α -rays of similar intensity but greater penetrative power than those of uranium. The long range of these α -particles was discovered by Rutherford and Wood (*Phil. Mag.* 1916, vi. 31, 379-386), who state that they have greater velocity than any α -particles previously known. The β -rays from thorium are about one-tenth as intense as those from uranium, and have less penetrating power. The γ -rays are relatively feeble but very penetrating. It has been stated that the radio-activity of thorium from monazite is due to the uranium present in this mineral, and that minerals free from uranium yield inactive thorium (*Baskerville, J. Amer. Chem. Soc.* 1904, 26, 1642; *Zerban, Ber.* 1903, 36, 3911; 1905, 38, 557). On the other hand, minerals free from radium have been found to give helium and thorium emanation (*Strutt, Proc. Roy. Soc.* 1905A, 76, 88, 312; 1907A, 80, 56; *Hahn, Ber.* 1905, 38, 2371). After allowing for uranium, a constant ratio between the radio-activity and amount of thorium was found for thorium minerals in which, probably,

thorium and radio-thorium are in equilibrium. In thorium salts, where the radio-thorium is largely removed, this constancy does not exist. Boltwood has not succeeded in obtaining inactive thorium (Amer. J. Sci. 1906, 21, 415, and 433).

Thorium hydroxide precipitated by ammonia from a solution of a thorium salt has no emanating power and only a greatly diminished α -radiation. The filtrate retains the whole of the emanating power; and the minute residue obtained on evaporation and ignition possesses the radio-activity which the precipitate has lost. The emanating power and radio-activity of this product, thorium X, disappear in the course of a month, decaying to half their original value in four days. The precipitated thorium hydroxide recovers the properties just as fast as they

disappear from thorium X, and a second treatment of its acid solution by ammonia after one month leads to the separation of another quantity of thorium X having the same activity as the first fraction. Thorium X, a short-lived radio-active product of thorium, produces gaseous thorium emanation, and this in turn gives thorium 'active deposit,' which imparts radio-activity ('induced activity') to solid objects brought into contact with this disintegration product (Rutherford and Soddy, Chem. Soc. Trans. 1902, 81, 321, 837; Phil. Mag. 1902, 4, 370, 569).

Owing to the complicated nature of the disintegration changes the radio-activity of a thorium preparation is a complex function of its age. The sequence of these changes is indicated in the annexed diagram. All thorium emanations

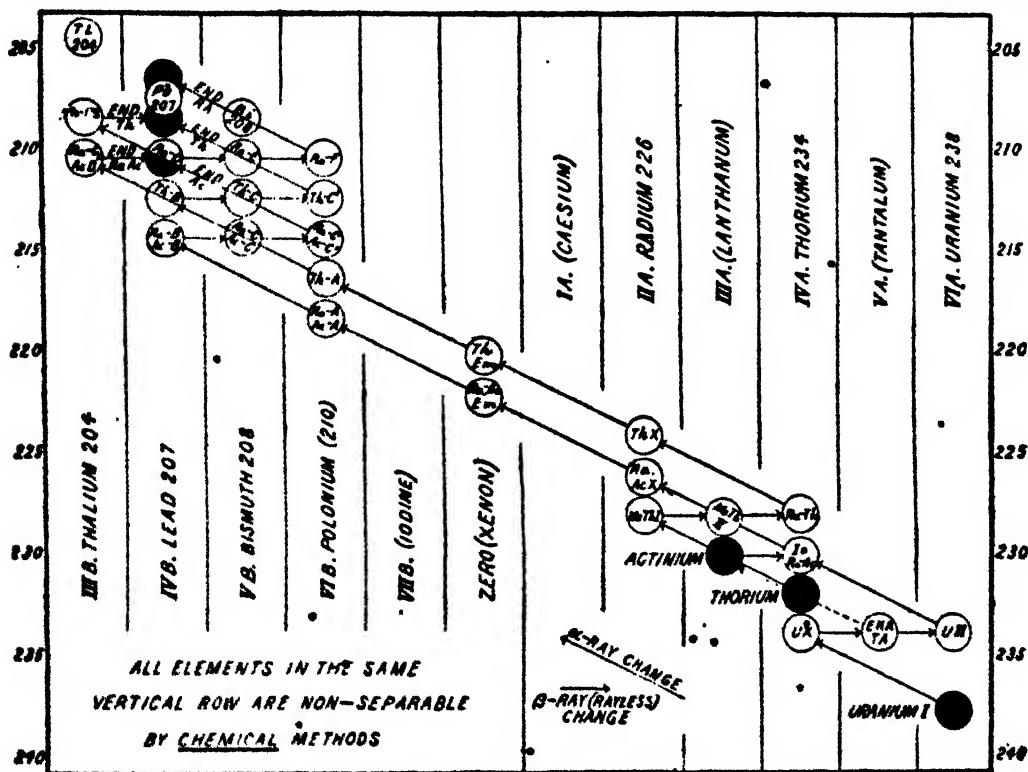

FIG. 1

are condensed at 5°C. (Fleck, Phil. Mag. 1915, 20, 337-362).

Mesothorium 1 is separated from thorianite by adding 26 grms. of barium nitrate to 1.5 litres of a slightly acid solution of 600 grms. of the mineral in nitric acid and by shaking the solution for an hour with excess of sulphuric acid when the sulphate of mesothorium 1 is co-precipitated with barium sulphate. The radioactive precipitate is reduced to sulphide by heating with carbon in a quartz crucible. Various methods are described for the reduction of this radio-active sulphate. Hahn (Ber. 1907, 40, 1462, 3304) recommends reduction with sugar carbon in a quartz crucible; Ebler (Eng. Pat. 1173, 1914), ignition with calcium carbide; and firing of a mixture of the dry sulphates and calcium hydride is suggested (Zeitsch. anorg.

Chem. 1913, 82, 149-158). The product is dissolved in hydrochloric acid. The lead is precipitated from this solution by hydrogen sulphide and traces of iron and thorium by ammonia. The radio-active chloride in the filtrate is crystallised out fractionally when mesothorium 1 is concentrated in the least soluble portions (Hahn, Ber. 1907, 40, 1462, 3304).

From monazite sand, mesothorium 1 is isolated by adding 0.1 p.c. of barium carbonate and heating the sand (400 grms.) with 800 grms. of concentrated sulphuric acid. The product is thoroughly mixed with cold water when the sediment contains practically the whole of the mesothorium 1 and radium. These two active components are concentrated from the barium sulphate precipitate by converting this product

successively into sulphide and chloride, and fractionating the latter from water when the mesothorium 1 accumulates in the least soluble crystals (Soddy, Eng. Pat. 25504, 1910; Chem. Soc. Trans. 1911, 99, 75).

In practice, the radioactive residues from monazite sand consist mainly of lead sulphate, silica, and rare earth phosphates. They may be boiled with a large excess of a mixture of caustic soda and sodium carbonate (10:1), the residue well washed, and the treatment with the preceding mixture repeated once or twice, when the silica and lead are almost completely removed and the barium, mesothorium, and rare earths left as carbonates. The residue is extracted with hydrochloric acid and the clear liquor precipitated with sulphuric acid. The crude radioactive barium sulphate may then be transformed into carbonate by boiling with excess of concentrated sodium carbonate solution several times in succession, with intervening washings (see Strong, J. Amer. Chem. Soc. 1921, 43, 440).

Another method for the separation of the radio-active constituents from monazite without the addition of barium salts is by the precipitation of these along with a small proportion of the thorium from phosphate solutions by dilution and boiling (U.S. Pat. 1084734, 1914; see also U.S. Pat. 1100743, 1914; D. R. P. 274874, 1913).

Mesothorium cannot be separated from radium by fractionation of the double barium salts, but in the fractional crystallisation of the picrates, bromates, and ferrocyanides from alcohol or acetic acid mesothorium separates before radium (Kunheim, D. R. P. 264901, 1912).

On account of this complete similarity of chemical properties all radium compounds separated from uranium minerals containing thorium contain mesothorium 1, and all mesothorium preparations include the radium present in the thorium minerals. In fact, technical mesothorium, produced from monazite sand, contains about 99 parts by weight of radium to one of mesothorium, but nearly 90 p.c. of the radiation it emits is due to the active products of mesothorium 1 (Hahn, Chem. Zeit. 1911, 35, 845).

Mesothorium 1 is rayless, and it disintegrates into mesothorium 2; its period of average life is 7-9 years, the period of half-change being 6-7 years (Phys. Zeitsch. 1918, 19, 257-263; J. Chem. Soc. Abs. 1918, ii. 347). It behaves like a metal of the alkali earths.

Mesothorium 2 reacts like a metal of the rare-earth series, and accordingly ammonia serves to precipitate it from solutions of mesothorium 1, a trace of zirconium salt being generally added to serve as a nucleus for precipitation (Hahn, Zeitsch. physikal. Chem. 1908, 9, 246; Russell and Soddy, Phil. Mag. 1911, [vi.] 21, 130). Two other disintegration products, radio-thorium and thorium X, are co-precipitated, but if the precipitation is repeated on the solution after one or two days the second precipitate will contain mesothorium 2, relatively free from radio-thorium. Mesothorium 2 has an average life period of 8.9 hours, the half-change period being 6.2 hours; it gives β - and γ -rays; the former are heterogeneous, the absorption coefficient

increasing as absorption proceeds; the γ -rays resemble those of uranium X.

Radio-thorium. Period of average life 1063 days (?), period of half-change, accurate to 1 p.c., 696 days. It is chemically identical with thorium, and is only distinguished from the latter by preparing it through mesothorium 1 and 2. Mesothorium 1 is readily separated from thorium, and when left to itself produces radio-thorium, which is separated by precipitating a solution of the two disintegration products with ammonia in the presence of a trace of zirconium salt. When first precipitated in this way the radio-thorium will contain mesothorium 2, but this decays completely in the course of 3 days, while the formation of the next disintegration product, thorium X, causes an increase in the radio-activity of the preparation over a period of 3-4 weeks. The emanating power increases with the growth of thorium X, but after a month the total activity and emanating power decay to zero.

Radio-thorium can be prepared by evaporating to dryness the nitric acid solution of the washed ammonia precipitate from solutions of thorium X, freed from barium, calcium, iron, and lead salts and phosphates. The residue is washed free from ammonium salts by a solution of sodium chloride free from carbon dioxide.

Radio-thorium preparations, especially when kept moist, are very suitable for demonstrating the properties of the thorium emanation. When the air in the tube containing a radio-thorium compound is blown between two darkened zinc sulphide screens with films turned inward, a brilliant luminescence is observed, and the decay and reproduction of the emanation can be thus illustrated (cf. Hahn, Ber. 1905, 38, 3371; Zeitsch. physikal. Chem. 1905, 51, 717; Phil. Mag. 1906, [vi.] 11, 793; Elster and Geitel, Chem. Zentr. 1906, ii. 302).

Radio-thorium emits α -rays which have a range of 3.9 cm. of air (Leslie, Le Radium, 1911, 8, 356).

Thorium X. Period of average life 5.35 days, period of half-change 3.7 days. Resembles radium, mesothorium 1, and the metals of the alkaline earths and remains in solution when thorium is precipitated with ammonia. The residue left on evaporating the filtrate gives on ignition a small amount of an intensely radioactive product, this activity being due to thorium X. If, however, thorium is precipitated by a carbonate or phosphate, thorium X is also rendered insoluble; the precipitate retains the initial radio-activity of the thorium compound, and when dissolved it exhibits the initial emanating power. The emanating power of a thorium solution is a measure of the amount of thorium X present (Zeitsch. anorg. Chem. 1909, 61, 338; 63, 197).

When fumaric or *m*-nitrobenzoic acid or pyridine is used to precipitate thorium both thorium X and thorium R are left in solution. In this way thorium hydroxide is freed from thorium X and its disintegration products. Four precipitations with *m*-nitrobenzoic acid give thorium hydroxide, having neither β -activity nor emanating power and a minimum of α -activity; the activity of this preparation then increases regularly without the initial decay characteristic of the precipitate obtained by

hydroxides and acids, are difficultly soluble in boiling water and in organic solvents, but more soluble in potassium iodide solution (Phil. Mag. 1913, 25, 330-332).

Thorium C is removed from a solution of thorium active deposit by absorption with animal charcoal when thorium B remains dissolved. Thorium C is also deposited alone when the solution is electrolysed or shaken up with metallic nickel. Zinc, however, deposits both thorium B and C, but not thorium X.

Thorium C gives two sets of α -rays having different ranges, these being attributed to the presence in this active product of the two constituents thorium C_1 and thorium C_2 ; these products have not, however, been separated, and the two sets of rays are due to concurrent changes (Hahn, Phil. Mag. 1906, [vi.] 11, 793; Ber. D. physikal. Ges. 1909, 11, 55).

Thorium C_2 . When the thorium active deposit coating a plate or wire is kept in a vacuum at the ordinary temperature, the powerful α -ray disintegrations of thorium C and C_1 , one of which is the strongest known, cause a considerable proportion of thorium C_2 to 'recoil,' i.e. to become projected from the plate or wire on to surrounding surfaces of the vacuum space, these receiving surfaces being kept negatively charged.

According to von Lerch's rule the disintegration of radio-active elements is accompanied by a regular increase in the electro-negative character of the successive products. But to this rule thorium C_2 is an exception, as it dissolves more readily in acids than the other products, and is moreover more volatile than its generators, being completely volatilised at 700°C. from an active wire placed for 30 seconds in a Bunsen flame (Sitzungsber. Akad. Wiss. Wien. 1907, 116, [11a], 1443; 1909, 118 [11a], 1575; Zeitsch. physikal. Chem. 1911, 12, 273, 378). It can be separated by volatilisation from thorium C, which sublimes at 780°C. (Wood, L.C.).

Thorium C_2 is probably non-separable by chemical methods from thallium, and like this element is co-precipitated with potassium platichloride (Chem. News, 1913, 107, 97). Barratt has found that thorium C undergoes dual disintegration into thorium C_1 and thorium C_2 (Proc. Physical Soc. 1912, 24, 112).

Thorium C_2 , which emits only β - and γ -rays is the last active member of the series; its decay is regular and complete, and the ultimate product (thorium D) is regarded as an element indistinguishable chemically from ordinary lead.

Thorium-lead, which is the stable end product from thorium C_1 (α -ray change) or from thorium C_2 (β -ray change), has the atomic weight 208, and is an isotope of ordinary lead and of the lead (206) derived from radium.

The relationship existing between radio-active elements and the ordinary elements of the periodic classification is illustrated by the diagram on p. 41, in which can be seen the connection between the degradation products of thorium and the elements non-separable from these products by ordinary processes (Soddy, L.C.).

THORN APPLE v. DATURA.

THORON. A term given to the emanation of thorium. This gas is an isotope of radon and actinon, the emanations of radium and actinium respectively. A number of springs in the Pyrenees and in the Central Plateau of France have been examined to ascertain their content of radium and thorium emanations. The former occurs in various proportions in all the waters, but thorium emanation is found in traces only in those of the Central Plateau. Even in those cases in which thorium emanation is not detectable, it is probable that the water comes into contact with this emanation, but that the time elapsing between the termination of this contact and the appearance of the water at the outlet of the spring exceeds 10 minutes, which is the duration of the life of thorium emanation (A. Lepape, Compt. rend. 1924, 178, 931; Chem. Soc. Abstr. 1924, 126, ii. 295).

THORTVEITITE. A silicate of scandium with yttrium, dysprosium, and erbium

forming monoclinic prisms, reaching a length of 35 cm., of a greyish-green colour and somewhat resembling epidote in appearance. Useful as a source of scandia. It occurs in some quantity in pegmatite at Iveland and Evje in Sætersdalen, Norway, and is remarkable in being the only mineral containing scandium (analysis I.) as an essential constituent (J. Schetelig, Centr. Min. 1911, 721; Norsk Geol. Tidsskr., 1922, 6, 233; Vid.-Selsk. Skrifter, Kristiania, 1922, No. 1, 49. In the last paper is given a history of the element scandium).

A very similar mineral, as prismatic crystals 10 cm. long and 3 cm. across, was discovered in 1920, also in pegmatite, at Befanambo, Madagascar; this gave analysis II. (Boulanger and Urbain, Compt. rend. 1922, 174, 1442) with traces of Cl , Mn , Sn , Sb , and Pb . The figure for scandia includes about 0.5 p.c. of yttrium, neoytterbium, and lutecium. The mineral is only slightly attacked by hydrofluoric acid, or by fused bisulphates, but is decomposed by repeated fusion with sodium carbonate.

The Madagascar mineral being rather richer in scandia and with zirconia in place of yttrium-earths, it is regarded by A. Lacroix (Minéralogie de Madagascar, 1923, 3, 311) as representing an end-member of the thortveitite group, and for it the name *befanamite* is proposed.

L. J. S.

THROMBOPLASTIN. An extract from the brain of cattle, dissolved in common salt solution. Used as an hæmostatic.

THSING-HOA-LIAO. A Chinese name for a cobaltiferous aluminium silicate used in the manufacture of porcelain; also applied to a cobaltiferous manganese ore used for producing a blue colour on porcelain.

THUJONE v. **KETONES.**

Probable presence of thujone in the essential oil of *artemisia herba alba*. This oil, d_{40}^{20} 0.9257, n_D^{20} +3.88°, n_D^{20} 1.4553, contains 14.4 p.c. of free, and 7.39 p.c. of combined alcohols, calculated as $C_{10}H_{18}O$. The presence of camphor has been demonstrated, and that of thujone is probable (cf. Grimal, Chem. Soc. Abstr., 1904, ii. 605; E. Alinari, Annali Chim. Appl. 1924, 14, 109; Chem. Soc. Abstr. 1924, 126, i. 754).

THULITE v. **ZOISITE.**

THULIUM. Sym. Tm. At.wt. 169.4 (James and Stewart, J. Amer. Chem. Soc. 1920, 42, 2022). The erbium sub-group of the yttrium metals contains the three elements, erbium, dysprosium, and thulium; the compounds of the last of which have been hitherto studied only by few workers owing to difficulties of isolation.

Occurrence.—Thulium is a very rare element, the best sources being euxenite, sipylite (a columbite from Northern Norway), ytterspar (Norwegian xenotime) and samarskite. It occurs in small quantities in the yttrium earths from other rare minerals.

Separation. Cleve first indicated the existence of the rare earth, *thulia* (Compt. rend. 1879, 89, 478, 521, 708; Thalén, *ibid.* 1880, 91, 376), and Lecoq de Boisbaudran, by decomposing fractionally the nitrates of the yttrium group, discovered thulium fractions between those of erbium and ytterbium (Compt. rend. 1879, 89, 516). A separation of erbium and thulium has been effected by fractional crystallisation of the ethyl-sulphates (Urbain, Ann. Chim. 1900, [vii.] 19, 184).

According to Auer von Welsbach, spectroscopic examination indicates that thulium consists essentially of three elements. Of these three thulium I. and thulium III. cannot be isolated by the present methods of purification. The salts of the former absorb rays in the extreme red down to $\lambda 700$, and show characteristic lines between 2700 and 3270 (spark spectrum). Thulium III. exhibits a characteristic spark spectrum between 2800 and 3260. Thulium II. forms an almost white sesquioxide. Its salts are pale yellowish-green in daylight and emerald-green in artificial light, and exhibit the absorption spectrum hitherto ascribed to thulium. The oxides of those fractions which are richest in thulium II. and neo-ytterbium exhibit a characteristic phenomenon in the flame; before becoming actually incandescent the oxides give out a purple light for a short time. The spark spectrum shows many strong lines between 3400 and 3800 (Monastch. 1911, 32, 373). According to Eder (Sitzungsber. K. Akad. Wiss. Vienna, IIa, 124) thulium I. contains a new element, *dansbium*; thulium II. has substantially the same spectrum as the original complex material, and *neo-thulium* is suggested as the name for the chief element present; thulium III. gave an arc spectrum containing a set of lines which are attributed to a new element, "*dubbium*" (cf. Paulson, Physikal. Zeitsch. 1915, 16, 352).

The minerals containing thulium are decomposed by hydrochloric or sulphuric acid; the rare earth oxalates precipitated, ignited, and the resulting oxides converted successively into

oxalates and sulphates. The latter salts are heated with barium bromate in aqueous solution from which the rare earth bromates are fractionally crystallised. After 15,000 operations the absorption spectrum underwent no change.

Thulium bromate $Tm(BrO_3)_3 \cdot 9H_2O$, hexagonal prism, which has been obtained in considerable amount by repeated crystallisation of the more soluble portions of the rare earth bromates, is more soluble than erbium bromate, but less soluble than ytterbium bromate. Fractional crystallisation of the bromates of the yttrium earths gives a fairly rapid separation of thulium from its associates (C. James, Chem. News, 1908, 97, 61; 1911, 104, 73; J. Amer. Chem. Soc. 1910, 32, 517; 1911, 33, 1332).

Thulium salts are pale bluish-green, but their colour is readily masked by small quantities of erbium, the hue changing to yellowish-green, yellow, white, and finally pink as the amount of this impurity increases.

Thulium oxide (*thulia*), Tm_2O_3 , a dense white powder with a greenish tinge, is prepared by igniting the oxalate; it is the least basic of the oxides of the erbium sub-group and dissolves slowly in strong acids. It exhibits a reddish incandescence on heating.

Thulium hydroxide is a white precipitate filtering readily even in the cold.

Thulium chloride $TmCl_3 \cdot 7H_2O$, deliquescent crystals very soluble in alcohol or water.

Thulium sulphate $Tm_2(SO_4)_3 \cdot 8H_2O$ is precipitated by alcohol from an aqueous solution of thulium chloride and sulphuric acid.

Thulium nitrate $Tm(NO_3)_3 \cdot 4H_2O$, deliquescent crystals obtained from solution in strong nitric acid.

Thulium oxalate $Tm_2(C_2O_4)_3 \cdot 6H_2O$, a greenish-white precipitate, soluble in aqueous alkali oxalates to form double oxalates.

Thulium acetylacetonate

crystallises from an alcoholic solution of thulium hydroxide in acetylacetone; the absorption spectrum of this compound differs appreciably from that of the inorganic salts, nitrates, chlorides, &c. Other organic salts of thulium have been described by James and his co-workers.

Absorption spectrum, v. Cleve, *l.c.*, and Forsling, Bit. Sv. Vet. Akad. Handl. 1899, 24, 1, No. 7). G. T. M.

THUNDERITE. An explosive consisting of a mixture of ammonium nitrate, trinitrotoluene, and flour.

THURINGITE. A member of the chlorite group of minerals of some importance as an ore of iron. The best crystallised members of this group and those containing the least iron have the composition $H_2Mg_4Al_2Si_2O_{12}$, as in clinocllore and penninite. The magnesium is, however, isomorphously replaceable by ferrous iron and the aluminium by ferric iron; when this replacement is complete the formula would be $H_2Fe''_4Fe'''_2Si_2O_{12}$ with Fe 50.7 p.c. Depending on differences in composition and in physical characters, a large number of species and varieties have been distinguished by special names. Those forming distinct crystals or plates are grouped as *orthochlorites*, whilst those forming compact masses composed of minute scales or fibres are

called *leptochlorites*. Like the micas, the chlorites crystallising in the monoclinic system often with pseudo-rhombohedral forms; and they have a perfect micaceous cleavage parallel to the basal plane. The characteristic colour is dark green to blackish-green, hence the name, from *χλωπῖτις*, a green stone. They are quite soft (H. 2-3) and often greasy to the touch; sp.gr. 2.6-3.5, depending on the amount of iron; decomposed by hydrochloric acid with separation of silica. They are of abundant occurrence as alteration products of silicate minerals of almost all kinds; and are found in igneous rocks, metamorphic rocks (e.g. chlorite-schist), and as beds in sedimentary rocks. In the last case they frequently present an oolitic structure (compare glauconite and greenalite). The following are the leptochlorites, all closely allied to thuringite, that have been worked as ores of iron.

Thuringite $H_2Fe''(Al,Fe''')_2Si_2O_{11}$ is compact with a fine scaly or granular structure and an olive-green to blackish-green colour; sp.gr. 3.15-3.19. It occurs as beds in clay-slates of Lower Silurian age near Schmiedefeld in eastern Thuringia (anal. I). The main ore-bed is 15-20 metres in thickness, and the ore, consisting of thuringite with chalybite and oolitic chamosite, yields 32-40 p.c. of metallic iron. Thuringite occurs abundantly amongst the iron ores of the diabase and schalstein zone between Sternberg in Moravia (anal. Ia) and Bennisch in Silesia. It is also met with in the Lake Superior iron mining district, and in the French Creek mines in Pennsylvania.

Chamosite or **Chamosite** (anal. II) is compact or oolitic with a greenish-grey or greenish-blue colour; sp.gr. 3-3.4; Fe 28-37 p.c. It forms thick beds in strata of Jurassic age at Chamoson in Canton Valais, and also at the Windgällen in Canton Uri in Switzerland. A chamosite ore is also extensively mined in Silurian rocks at Nučič in Bohemia. Identical with chamosite is the so-called *berthierine* (anal. III, by P. Berthier, 1827), which occurs with chalybite in Jurassic strata at Hayanges in Dept. Meurthe-et-Moselle and in Lorraine, and which by its alteration gives rise to the important *minette* (q.v.) ores of this district. Another similar oolitic ore is the *bavilite* in the Lower Silurian rocks of Brittany and Normandy.

Stilpnomelane $H_2(Fe,Mg)_2(Fe,Al)_2Si_2O_{11}$ is present in the ores of the diabase and schalstein zone between Sternberg in Moravia and Bennisch in Silesia. From this district several other closely allied minerals have been described by F. Kretschmer (1905, 1906, 1918), including *moravite* $H_2(Fe,Mg)_2(Al,Fe)_2Si_2O_{11}$, and *stilpnokhlorane* $H_2(Ca,Mg)(Al,Fe)_2Si_2O_{11}$ (anal. IV). The latter forms shining yellow scales and results from the alteration of thuringite; it is found in the iron mines at Gebitzgau near

Sternberg. **Viridite** $H_2Fe_2''Si_2O_{11}$; and *mücken-sile* $H_2Fe'''_2Si_2O_{11}$, he regards as end-members of the thuringite series.

Cronstedtite $H_2Fe''_2Fe'''Si_2O_{11}$ (anal. V) is found in some quantity in mineral-veins at Kuttenberg and Příbram in Bohemia, and in Cornwall. L. J. S.

THUS AMERICANUM v. RESINS.

THUYA OCCIDENTALIS. *Thuya occidentalis* (Linn.).—In 1858 Rochleder and Kawaler (Wien. akad. Ber. 29, 10) isolated from the green portions of the *Thuya* (*Thuja*) *occidentalis* a glucoside *thujin*, which, when hydrolysed, gave a yellow colouring matter *thujetin*.

Thujin $C_{20}H_{22}O_{12}$. The plant is extracted with alcohol, the extract when cold filtered from wax, and evaporated to a small bulk. The residue is diluted with water, a few drops of lead acetate solution added, the precipitated impurities removed, and the clear brown filtrate treated with lead acetate. The yellow lead compound is collected, extracted with dilute acetic acid, and basic lead acetate now added to the solution. The bright yellow precipitate is suspended in water, decomposed with sulphuretted hydrogen, the lead sulphide removed, the filtrate treated with carbon dioxide in order to free it from sulphuretted hydrogen and evaporated *in vacuo* over sulphuric acid. Crystals gradually separate, and these are crystallised repeatedly from dilute alcohol until when treated with ammonia a green coloration is no longer produced.

Thujin is described by these authors as citron yellow microscopic prisms sparingly soluble in cold water. The alcoholic solution becomes yellow on treatment with alkalis, whereas with ferric chloride a dark green coloration is produced. When thujin is digested in alcoholic solution with dilute hydrochloric or sulphuric acid it is hydrolysed with formation of glucose and *thujigenin*, apparently an intermediate product, which readily takes up a molecule of water, with formation of *thujetin*—

Thujigenin.

Thujetin.

Thujetin $C_{14}H_{14}O_8$, forms yellow crystals, and is characterised by the fact that its alcoholic solution is coloured blue-green with ammonia, and green coloured by potassium hydroxide solution.

With lead acetate it gives a deep red precipitate. When thujetin is digested with boiling baryta water it is converted into *thujetic acid* $C_{14}H_{22}O_{13}$, which consists of yellow microscopic needles, sparingly soluble in water, readily soluble in alcohol.

Thujigenin $C_{14}H_{12}O_8$, crystallises in fine yellow needles, soluble in alcoholic ammonia, with a blue-green coloration.

The quantity of thujin which is present in the plant is very small; thus, from 240 lbs. Rochleder and Kawaler were successful in isolating a few grams only.

Perkin (Chem. Soc. Trans. 1914, 105, 1408), who re-examined this subject and employed methods almost identical with those of Rochleder and Kawaler, found that the glucoside corresponding to *thujin* possessed the formula $C_{21}H_{22}O_{11}$, melted and when

hydrolysed gave rhamnose and quercetin and was identical with the *quercitrin* of quercitron bark. The plant also contained a small amount of quercetin, and this also, prepared by the hydrolysis of the glucoside which, evidently corresponds to the thujetin of Rochleder and Kavalier, dissolved in alkaline solutions with a pale green tint, but failed to give the blue-green coloration with ammonia described by these authors. During a preliminary investigation of this plant (Chem. Soc. Trans. 1899, 75, 829), the sample then examined gave a trace of yellow colouring matter soluble in alkalis with a strong green coloration, the acetyl compound of which after frequent recrystallisation melted at 205°-206°. It thus seems probable that the thujin of Rochleder and Kavalier consisted of quercitrin contaminated with a second glucoside, possibly that of myricetin. The quantity of this latter present in the plant may possibly vary according to its environment or with the season of the year.

THYMACEOL. Condensation product of acetone and o-thymic acid.

THYMATOL. Trade name for thymol carbonate.

THYME CAMPHOR *v.* CAMPHOR.

THYMEGOL. Trade name for the mercury potassium salt of thymol-p-sulphonate.

THYME OIL *v.* OILS, ESSENTIAL.

THYMINES *v.* PYRIMIDINES.

THYMOL *v.* CAMPHORS; also PHENOL AND ITS HOMOLOGUES.

According to Howards & Sons, Ltd., and John William Blagden (Eng. Pat. 200151) *m*-cresol is condensed with isopropyl alcohol in the presence of phosphoric acid at a temperature of 70°-80°. If the reaction temperature is higher (e.g. 150°), a condensation product melting at 114° and possessing antiseptic properties is obtained (J. Chem. Soc. 1923, 123, 124, i. 1006).

p-Cymene isolated from the crude oil obtained from the sulphite spruce pulp mill, after purification, is nitrated and the nitro-cymene reduced to cymidine by means of iron powder and hydrochloric acid. Sulphonation of cymidine gives a mixture of *o*- and *p*-cymidine sulphononic acids, which, by diazotisation and subsequent treatment with ethyl alcohol and copper powder, are successively converted into the corresponding diazocymenesulphonic acids and the same cymene 3-sulphonic acid, the sodium salt of which yields thymol on fusion with sodium hydroxide (Max Phillips and H. D. Gibbs, J. Ind. Eng. Chem. 1920, 12, 733-734; see also J. Amer. Chem. Soc. 1923, 45, 1489-1493).

Thymol in oil of thyme may be determined by extracting the phenols by repeated shaking with sodium hydroxide solution. On adding strong hydrochloric acid to an aliquot part of the extract the phenols separate. The thymol is obtained by crystallisation and weighed after collection and drying (Mastbaum, Anal. Fia. Quim. 1922, 20, 501; J. Soc. Chem. Ind. 1923, 244 A).

THYMOLIN. Trade name for a mixture of naphthalene, camphor, and thymol.

THYMOLOPHORE *v.* SYNTHETIC DRUGS.

THYMUS CAPITATUS OIL. The flowers and leaves of *Thymus capitatus*, grown in Sicily, yield on distillation about 1.5 p.c. of an oil,

d_{20}^{15} 0.9582, n_D^{20} = 1.5106, α_D^{22} = -0.70°, which contains 73-84 p.c. by volume of phenols (carvacrol) and shows a corresponding high solubility in dilute alcohol. These results agree moderately well with those given by Pellini (Z. 1923, 858 A), and show that the figures given by Schimmel und Co. (Bericht, 1889, ii. 36) refer to an oil other than that of *Thymus capitatus* (F. C. Palazzo and C. Lutri, Annali Chim. Appl. 1924, 14, 103; J. Soc. Chem. Ind. 1924, 43 B. 537).

THYRESOL. Syn. for santalol methyl ether.

THYROGLOBULIN, THYROIDIN, THYROXIN *v.* THYROID GLAND.

THYROID GLAND. *Glande thyroïde*, Fr.; *Schilddrüse*, Ger. In 1891 Murray introduced the oral administration of thyroid gland in diseases where the natural secretion is defective (myxœdema, cretinism), and the subsequent success of the remedy has been one of the greatest triumphs of organotherapy. Baumann (Zeitschr. physiol. Chem. 1895, 21, 381) discovered the iodine content of the gland and obtained, by boiling with dilute sulphuric acid, an impure amorphous substance, iodothyron (thyroidin), containing 9-10 p.c. of iodine, and Oswald (*ibid.* 1899, 27, 15) separated a protein (thyroglobulin), also containing iodine.

The active constituent has been isolated by E. C. Kendall (J. Biol. Chem. 1915, 20, 501; Proc. Amer. Soc. Biol. Chem., J. Biol. Chem. 1917, 29, 29; Endocrinology, 1917, 1, 153; 1918, 2, 81; Proc. Amer. Physiol. Soc., Am. J. Physiol. 1918, 45, 540; J. Amer. Med. Assoc. 1918, 71, 871). It is obtained by hydrolysis of the gland with alcoholic sodium hydroxide and fractional solution in various organic solvents. It represents that half of the iodine containing substances of the gland which is insoluble in acids; the other half, soluble in acid, is also organic, but physiologically inert. Kendall has named the hormone thyroxin (from thyroxindol) and assigned to it the formula $C_{11}H_{10}(O)_2NI_2$ and the subjoined constitution:

Thyroxin forms crystals, m.p. 220°, soluble in alcohol, ether, water, acids and sodium carbonate, readily soluble in dilute sodium and ammonium hydroxides, with opening of the lactam ring. It is perhaps closely related to the important amino acid tryptophan and is extraordinarily active. On cretinism and myxœdema it has the full action of the entire gland, in daily doses of a fraction of a milligram. A dose of 10 mg. per day increases the basal metabolism of an adult by 30 p.c., and the total quantity present in the human body is estimated at 23 to 50 mg. The iodine content of the thyroid has generally been regarded as some measure of its activity. Hunt (Amer. J. Physiol. 1923, 23, 257) has recently found a close parallelism between iodine content and activity as tested by his acetonitrile method (see below), but on the other hand, Romeis (Arch. f. Entwicklungsgemech. d. Organ. 1922, 50, 410)

prepared from thyroid a crystalline iodine-free substance, which accelerates the development of tadpoles. The estimation may be carried out by Baumann's process (fusion with sodium hydroxide and colorimetric comparison in chloroform solution; cf. Riggs, J. Amer. Chem. Soc. 1909, 31, 710; 1910, 32, 692; Seidell, *ibid.* 1909, 31, 1326). Hunter's method (J. Biol. Chem. 1910, 7, 321; Seidell, *ibid.* 1911, 10, 95) appears to be preferable and has been adopted by the United States Pharmacopœia. One gram of the dried gland (corresponding to about 5 grms. of the fresh organ) is mixed in a nickel crucible of 125 c.c. capacity with 15 grms. of a mixture of anhydrous sodium and potassium carbonates and potassium nitrate in the molecular proportion of 1 : 1 : $\frac{1}{2}$ respectively. Five grms. of the salt mixture is spread on top; the mass is fused, dissolved in 150 c.c. water in a half-litre conical flask and mixed with 50 c.c. of sodium hypochlorite solution containing 2.4 p.c. Cl by weight. Syrupy phosphoric acid, diluted with an equal volume of water, is added until the yellow colour of free chlorine appears. Then 10 c.c. of the phosphoric acid solution is added in excess, the solution is diluted with an equal volume of water and boiled down to 150 c.c. or for half an hour, to expel the excess of free chlorine. After cooling 10 c.c. of 1 p.c. potassium iodide solution is added, and the liberated iodine (corresponding to 6 times that originally present, which was converted into iodic acid) is titrated with N/200 thiosulphate, of which 1 c.c. = 0.01058 mg. iodine present in the gland. *Thyroideum siccum*, U.S. P., should contain 0.17-0.23 p.c. iodine. (= about 0.034-0.046 p.c. in the fresh gland) and should contain not more than 6 p.c. of moisture. It is also official in the B. P. Seidell and Fenger (J. Biol. Chem. 1913, 13, 517) state that the glands of the sheep, ox, and pig contain from June to November about three times as much iodine as in the rest of the year. Aldrich (Amer. J. Physiol. 1912, 31, 152) finds the ratio for these three animals as 5 : 7 : 9 respectively. The amounts found by Seidell and Fenger were for sheep, ox, and pig respectively 0.08-0.24, 0.03-0.33, and 0.16-0.44 p.c. of dry weight. They remark that a standard of 0.2 p.c. could only be obtained with sheep's thyroids in the United States during a small part of the year. In English sheep the amount apparently does not fall so much in winter.

The physiological estimation of the hormone is more satisfactory but complicated. Quantitative experiments on the rate of metabolism are best, but very laborious. In a simplified form they may be carried out on tadpoles, which, in a solution containing very little of the hormone, have their normal growth retarded and their metamorphosis (loss of tail and development of hind limbs) greatly accelerated (Gudernatsch. Arch. f. Entwicklungsmech. d. Organ. 1912-13, 35, 457; cf. e.g. Rogoff and Marjé, J. Pharm. exp. Therap. 1916, 9, 57).

This method has been proposed for the commercial standardisation of thyroid preparations. Reid Hunt (J. Amer. Med. Assoc. 1907 [ii.] 240; J. Biol. Chem. 1905, 1, 33) finds that as little as 0.1 mg. of the gland may double the resistance of mice to poisoning by acetonitrile. On account of its effect on metabolism thyroid may be useful in reducing the weight of the constitu-

tionally corpulent, who are incapable of sufficiently oxidising fat. G. B.

THYROXIN. See **THYROID GLAND.**

TIEMANNITE. Mercury selenide, HgSe, crystallised in the cubic system with tetrahedral hemihedrisms, and isomorphous with metacinnabarite (HgS). Compact granular material is more usual than crystals. Greyish-black colour with metallic lustre; sp.gr. 8.19-8.47; H. 2 $\frac{1}{2}$. It occurs in some quantity with barytes, calcite, and manganese oxide in a vein in limestone near Marysville in Utah; and large masses have been found in the mercury districts in Lake, Orange, and Santa Clara counties, in California. Other localities are near Clausthal in the Harz, and the Sierra de Umango in Argentina.

TIGLIC ACID v. **OILS, FIXED, AND FATS.**

TIGLIC ALDEHYDE, TIGLIC ANHYDRIDE v. *Guvaiacum*, art. **RESINS.**

TIKITIKI. A preparation of rice-polishing extract used in the treatment of beriberi. It contains a high percentage of antineuritic vitamin, and is a cure for infantile beriberi. For a method of preparing it, see A. H. Wells, Philippine J. Sci. 1921, 19, 67 (in abstract J. Soc. Chem. Ind. 1922, 41, 77 A).

TIL or **TEEL OIL** v. **SESAME OIL.**

TILE ORE v. **CUPRITE.**

TILIACORA ACUMINATA (Miers). The dried powdered bark by exhaustive treatment with alcohol yields quercitol, fumaric acid, an alkaloid, *tiliacorum* (C₂₂H₃₂N₂O₅, m.p. 260°-261° (decomp.), $\alpha_D^{20} = +105.3^\circ$, a phytosterol, a solid fatty acid, m.p. 47°, a mixture of unsaturated acids containing oleic and linolenic acids, with some linolic acid, a resin, and dextrose. Tiliacorum contains two methoxyl groups, but no methyl imide, or methylene oxide group; no acetyl or methyl derivative could be obtained. A solution of the alkaloid in sulphuric acid becomes first blue, and then green on treatment with oxidising agents (Van Itallie and Steenhauer Pharm. Weekblad. 1922, 59, 1381; J. Soc. Chem. Ind. 1923, 159 A).

TIMA. A medicinal preparation imported from Tampico as a remedy for phthisis. Is prepared as a syrup by boiling the fruit of *Parmentaria edulis* (DC.) with sugar, and mixing the product with almond oil (Arch. Pharm. [iii.] 107, 375).

TIMBER AND DRY ROT. E. H. Ellis (Chem. News, 1923, 127, 402) describes the fungus *Merulius lacrymans*, to which this disease is due, its method of growth and action upon timber, and the means adopted for its extermination. This fungus is rarely, if ever, found upon living trees, but is common upon worked timber, the term 'dry rot' referring to the condition of the wood upon which it grows and not to the infecting organism. Infection of the wood often occurs in the timber yard, but is rarely caused by the spores, which, although remaining alive for several years, appear to develop upon sound timber with difficulty. During dry weather the protoplasm of the fungal spawn (*mycelium*) breaks up into small bodies (*oidia*), which are easily scattered and readily germinate, thus leading to re-infection. Development of the fungus proceeds by the growth of a fine

network (*mycelium*) within the wood, followed by the well-known growth upon the surface, the form of which depends upon conditions such as moisture, temperature, &c. Various enzymes are produced by the *mycelium*, which cause the breakdown of certain constituents of the wood to water and carbon dioxide, whilst the lignin, tannin, and calcium oxalate remain as a spongy skeleton of the original timber.

Under favourable conditions the fungus is capable of penetrating mortar, thus spreading infection to distant wood. Various human diseases have been attributed to the growth of this fungus, but the impossibility of this is shown by the fact that 'dry rot' is killed at blood heat (98°F.). Infection of timber may be prevented by avoiding contact with infected material, the selection of well-seasoned timber, and storage of the wood both before and after use in dry and well-ventilated situations. In dealing with existing infection, timber may be impregnated with various antiseptics, among which the best are sodium fluoride, boric acid, magnesium silico-fluoride, creosote and tar, but the process is costly. Treatment with potassium or sodium dinitrophenates or dinitro-cresylates is effective, and kiln-drying of the wood is also recommended. In cases of serious infection all damaged timber should be removed, the exposed surfaces treated with formalin, followed by coating with an antiseptic, and precautions should be taken to avoid future access of damp (J. 1923, 29, 344; J. Inst. Brewing Abstr. 1924, 30, 123).

TIMBER FIRE-PROOFING. In the fire-proofing of wood the methods of impregnation are closely similar to those used in applying wood preservatives (see Chem. Trade Journal and Chem. Engineer, Oct. 5th, 1923, 39). The pressures applied will depend on the structure of the wood, as an excessive pressure will tend to crush the cells. Too high a temperature during drying may lead to brittleness. In order to assist penetration, an initial vacuum may be applied, followed by injection under about 170 lb. pressure. In the application of water-glass and its subsequent precipitation with hydrochloric acid, salt is left in the wood. To obviate this, it has been proposed to utilise pure silicic acid, prepared and impregnated by electro-osmotic methods (Eng. Pat. 101205 of 1917). Many fibres, such as kapok, have cuticles which are penetrated with difficulty by soluble salts. To facilitate penetration in such cases the material may be treated with alcohol or other volatile solvent or with a dilute solution of hydrofluoric acid (2 parts of the commercial acid in 100 parts of water). Coating with metal by electro-deposition is suggested as a method of fire-proofing aircraft linen without loss of tensile strength (Eng. Pat. 149745 of 1919).

For most practical purposes, the direct method of testing the efficacy of a fire-proofing treatment—that is, by applying a flame—should be sufficient. In certain cases, notably for aircraft fire-proofing, some method of testing the comparative protective action is necessary. Very little information is available, however, with regard to the inflammability of fire-proofed fabrics, although some results of comparative tests with unproofed materials have been made public (Aeronautical Advisory Committee

Report, No. 573 of 1918; Pharm. J. 1924, 112, 692).

Magnesium ammonium phosphate, which decomposes on heating into magnesium pyrophosphate and ammonia, has been patented by the Du Pont Company of America for reducing the inflammability of cellulose-ester and oil-varnish films. In the latter case the boiled linseed oil is incorporated with about one-third its weight of the phosphate (U.S. Pat. 1316881 of 1919).

For fire-proofing and preserving wood, the material may be impregnated with a solution of the double ammonium magnesium sulphate or with cuprammonium sulphate. In order to lower the melting-point of the magnesium sulphate, sodium or potassium sulphates may be added, preferably in quantity to form the eutectic mixture—that is, the mixture with the lowest melting-point (D. R. P. 306600 of 1914). Calcium sulphate or barium carbonate may be deposited in the body of the wood, the former by impregnation with ferrous sulphate followed by treatment with calcium chloride, the latter by treatment with a solution of barium sulphide and subsequent injection of gaseous carbon dioxide (U.S. Pat. 1346287 of 1920; Pharm. J. 1924, 112, 691).

TIMBO. The name of a narcotic medicine, the root rind of a variety of *Conchocarpus*. The rind appears in the form of tubes or rolls, is bright reddish-brown on the outside* and yellowish on the inside. The outer and middle rind break off short, but the inner rind has a long fibrous fracture and the interior colour is whitish. It possesses a weak aromatic taste somewhat like cascarilla bark, but has no special odour. A cross-section shows an interrupted yellow zone near the outer side, whilst the inner rind is faintly streaked in radiating lines. Some of the cells contain crystals of calcium oxalate (Chem. Zeit. 11, 315; J. Soc. Chem. Ind. 6, 560).

TIN. Sym. Sn. At.wt. 118.71. Atomic number 50. According to Aston, ordinary tin is a mixture of isotopes—eight in number, and of atomic masses 120, 118, 116, 124, 119, 117, 122, 121. The average atomic weight, in proportion to the intensities of the lines of the positive rays, agrees well with the accepted value (Nature, 1922, 109, 813). The molecular weight of tin at different temperatures has been studied by Jouniaux (Bull. Soc. chim. 1925, [iv] 37, 67; Chem. Soc. Abstr. 1925, ii. 489). *Tin was known and prized in the earliest historic ages, for it is mentioned without comment as one of the common metals in the days of Moses (Numbers xxxi. 22), and was an important commodity in the fair at Tyre; numerous bronze instruments of very early date have also been discovered in Assyria, and, particularly by Layard, in the ruins of Nineveh. Many of these bronzes are now preserved in the British Museum. The tin so employed was obtained by the Phœnicians from Cornwall and the Scilly Isles in this country, and from the mountains of Spain, and there is no evidence of the occurrence of tin in those countries in which, in ancient times, the metal was most largely used. Pliny appears to have been familiar with tin, and states that it occurs in grains, in alluvial soil, from which it is obtained by washing. These grains, the further

states, are black, and their metallic character can only be recognised by their great weight. Though tin was regarded by the ancients as one of the baser metals, its cost was greater in the days of Homer and Pliny than at present, for in the days of the latter of these writers an avoirdupois pound of tin cost 8s. 7½d. sterling, or about four times its present value. The uses of tin among the Romans were similar in many respects to those of the present day. It was chiefly employed in the form of an alloy with copper, on account of the hardness imparted to the alloy by a comparatively small proportion of tin, and some of the very earliest known bronzes agree closely in composition with those used for similar purposes at the present day. Tin was also used with lead by the Romans for the production of solder, and for tinning the inside of copper and brass vessels, in which art the Roman workmen appear to have attained considerable skill. Alloys containing more tin, corresponding somewhat to the modern *speculum metal*, were used by the ancients for mirrors, but the art of tinning iron does not appear to have been discovered until a much later date.

Occurrence of tin.—Tin occurs in comparatively few localities, never in the native state, and in but few forms of chemical combination. The most important one is *tinstone* or *cassiterite*, tin dioxide (SnO_2), which is met with in two principal forms, crystallised and massive. The crystals are of the regular prismatic or tetragonal system, isomorphous with those of rutile, and are frequently well formed and of large size. Tinstone in the usual or massive form is a dark reddish-brown or slaty-coloured very heavy mineral, which occurs in Cornwall in veins usually running nearly east and west, and in which the tin ore is associated with arsenical pyrites, copper sulphide, wolfram, and a great variety of other minerals. Tin usually occurs in plutonic or metamorphic rocks, such as granite, felspar, porphyry, or clay slate, but by the action of denudation on these older rocks grains of tinstone are frequently met with in the neighbouring alluvial deposits, and this variety of ore, which is of special purity and now almost entirely exhausted in this country, is known as 'stream tin.' The metal also occurs in small quantities as *tin pyrites* (SnS_2). The largest quantities of tin are now produced in the island of Banca ('Straits tin'). Smaller though considerable quantities are met with in Britain, Germany, Siberia, China, South Australia, New South Wales, Nigeria, and Bolivia. Among the newer sources of tin may be mentioned the Waterberg district, to the north of Pretoria, in the Transvaal, the present monthly output of which is valued at about £30,000, and is likely to increase. Cassiterite has been met with over an area comprising Helderberg, between Stellenbosch and Somerset West, and the Kuits River Mills in the Koeberg District of South Africa. The Malay States are the chief producer, contributing over 36 p.c. of the world's output; then follow Bolivia and the Dutch East Indies, with about 20 and 15 p.c. respectively. At present the production and consumption of tin appear to balance. Normally the United Kingdom imports about 35,000 tons of tin ore, about 8000 tons being from British possessions, and 40,000 tons of metal, which, with the excep-

tion of 2000–3000 tons, is derived from British possessions. The re-exports in a normal year are about 3000 tons of ore, and 40,000 tons of unwrought tin. The balance, about 32,000 tons of tin ore, together with the domestic production, which in 1913 was 8355 tons, was apparently sufficient to meet the domestic requirements of the United Kingdom. Few new sources of tin have been discovered in recent years, although it appears probable that the Belgian Congo is likely to become an important producer in the not far distant future. It would seem that unless really extensive deposits are discovered, tin will be one of the first base metals to be exhausted. The smelting of tin ore is concentrated in few hands, although the tin-smelting capacity of the world is well in excess of the annual supplies of ore. In this respect the Straits Settlements heads the list with a capacity of about 58,000 tons of metal, Great Britain following with a capacity of about 34,000 tons, and the United States with a capacity of 30,000 tons, the total world smelting capacity being about 175,000 tons per annum (Sir R. Redmayne, *J. Soc. of Arts*, 1923; *J. Soc. Chem. Ind.* April 27, 1923, 425). Promising reports are received in connection with tin mining in Texas. In parts of Nigeria tin occurs distributed over wide areas, but in relatively small proportions. The present world's output of tin is about 115,000 tons per annum.

Production of tin.—The metallurgy of tin is in its main features simple, but the mechanical preparation of the ore involves more skill and labour than is the case with any of the other common metals. So much, in fact, is this true that success in the extraction of tin frequently depends more upon the captain of the mine, who superintends the dressing of the ores, than upon the smelter. On account of the high price of tin, and the relatively high density of tinstone, it is found practicable to work ores which in the first place contain comparatively little tin, ores which contain only 0.5 p.c. of tinstone being sometimes profitably worked. The principle adopted in the mechanical separation of tinstone is very simply illustrated in the operation of 'vanning,' which is frequently used in Cornwall and elsewhere as an approximate test of the richness of an ore. A quantity of the crushed material is placed in a miner's shovel of special shape, known as a vanning shovel, water is added, and then by means of a circular motion which is imparted to the shovel by the hands, aided by a peculiar jerk of the wrist, the ore is ultimately almost completely separated from the earthy matter, and can be dried and weighed. On the large scale the ore is first picked and assorted, and then broken by suitable stone breakers and rolls. The roughly-powdered ore is carefully assorted, and then fed into a mill containing a battery of stamps, of which there are many varieties in use. Each stamp weighs 3 cwt. or upwards, the face of the stamp being either steel or chilled cast iron. By means of suitable cams on a revolving wheel the stamp is raised at regular intervals, and allowed to fall upon the ore which is contained in the box or coffer of the stamp. A supply of water flows through the boxes and escapes through perforations, carrying away the finely-crushed ore, while the larger pieces remain in the box to be further crushed by the stamp.

The finely-powdered ore now passes to some form of buddle, or to a concentrating table, which more or less completely separates the earthy matter. Probably the simplest form of such apparatus, of which there is an endless variety, is the inclined plane with ridges or 'riffles' placed at right angles to its length. On such a plane the heavier particles naturally remain, the richer fragments being deposited principally at the upper part of the buddle, whilst the earthy matter, with some ore, passes away. But such a simple form of buddle is now seldom used, and a considerable number of improvements have been from time to time adopted. Thus the inclined plane is made movable, and either a jerking or a rocking motion is imparted to it, and this is found to give better results than the fixed form. But buddles of a circular shape have met with considerable favour in late years, one form (Borlase's) being a circular concave buddle fed from the outside and discharging the slimes from the middle; but the variety generally preferred in Cornwall is that of a very flat cone, the water and ore being distributed either by a revolving spout, near the apex of the cone, or by means of a smaller and more acute distributing cone. The waste liquid from the buddle is led into a succession of tanks or pools, where it is allowed to settle in order to recover the finer portion of the ore, which would otherwise be lost, and the slimes thus obtained are worked over again in order to recover the finely-divided tin ores.

In dressing tin ores it is important that they should not be too finely crushed, or the gangue will be removed with greater difficulty. The ore should be, as far as possible, separated into parcels, the fragments in each being of uniform size, and the method of treatment is varied with the fineness of the material; in no case should the ore be crushed more than is necessary to separate the matrix. These facts form the basis of all successful ore dressing.

Reduction of tin.—From the point of view of the tin smelter, ores of tin may be divided into two classes, first those of tolerable purity, which may be directly smelted in the furnace, and secondly a less important class of ores, which from the fact that they contain notable proportions of copper, arsenic, sulphur, or tungsten, require to be further treated, after dressing, before smelting. Ores which contain arsenic or sulphur are roasted at a low temperature, usually in calciners with a bed which is mechanically rotated in a horizontal plane, and which is supplied with mechanical rabbles. The greater part of the arsenic and sulphur is thus removed. The mass is then withdrawn, and, after being exposed for some time to the action of the atmosphere, is washed to remove the oxide of iron and other lighter matters from the heavy oxide of tin. Ores which contain much tungsten are heated with sodium sulphate or carbonate in a reverberatory furnace, by which means soluble sodium tungstate is produced, and can be removed by washing from the unaltered oxide of tin. This process (Oxland's) is not carried on now to any considerable extent. The ore having been purified by one or other of these processes is ready for smelting in the ordinary way. The reduction of the metal from the ore is always accomplished by heating

with carbon, which operation may be performed either in a reverberatory furnace, as is the custom in this country, or in small blast furnaces such as are used to a limited extent in Germany. Shaft furnaces also are used in China, Sumatra, Nigeria, and by natives in many other localities.

Tin smelting in England.—The furnace employed for the smelting of tin in this country, and in fact pretty generally elsewhere, is a reverberatory, with a fireplace at one end and a stack at the other. At the front is a single working door, while at the back is a tapping hole which is closed during the smelting, but which when the operation is concluded serves to convey the metal into a 'float' or circular iron pot lined with clay. The bed of the furnace is about 18 ft. long by 9 ft. broad, and slopes to the tapping hole. The fireplace is about 2 ft. broad, and the firebridge is of firebrick and some 14 ins. high. The roof is low, and slopes uniformly from the firebridge to the stack.

The charge of ore, which weighs 20–25 cwts., is mixed with rather less than one-fifth of its weight of anthracite powder, and spread uniformly over the furnace bottom. If the ore is refractory, a little fluorspar or lime is added as a flux. The door is then closed and luted up, and the temperature gradually raised for 5–6 hours, when the door is opened, the mass rabbled, and a quantity of powdered anthracite or 'culm' is thrown on the surface of the charge. After heating for about another hour, and a further rabbling, the metal is tapped. Part of the slag produced is thick and is raked out of the furnace, while the remainder is more fluid, flowing out with the metal, and is called 'glass' by the smelter. The slag consists essentially of ferrous silicate, and as it frequently contains a considerable amount of tin it is melted again when the furnace is at liberty.

As tin is a valuable metal any considerable loss in smelting would result in commercial failure. The boiling-point of tin is high, in the neighbourhood of 2000°C., so the loss by volatilisation is very small. Practically the chief source of loss, in the smelting process, is in the slags. Tin oxide readily passes into solution in fused silicates yielding enamels. Hence the slag should be as small in quantity as possible, and should not be oxidised. The first requirement is met by employing ores of high concentration, and by mixing them so that the basic gangue of one will neutralise the acid gangue of another, so far as possible. Thus the use of fluxes is kept at a minimum, and the bulk of slag diminished. The slags are collected, and are generally smelted in a water-jacketed blast furnace, for the recovery of the tin they contain.

Small blast furnaces, which were previously used in Cornwall, have survived longer in southern Germany, and are also employed by the natives of India. The waste of metal is much greater than in the reverberatory furnace, whilst the cost of fuel (charcoal) is also greater than in England, but the tin obtained is stated to be of excellent quality.

Refining.—The refining process consists of two parts, a preliminary liquation, and the refining proper. The liquation is conducted in a furnace of similar shape to the reverberatory furnace above described, and about 10 tons are

operated upon at once. The temperature is carefully regulated so as just to melt the purer tin, which gradually flows away into a separate pot or 'kettle,' while the impurities, consisting of iron, arsenic, sulphur, and traces of many other elements, together with some 20 p.c. of tin, remain in the form of a hard, brittle, white, semi-metallic mass known as *hard-head*. For the composition and properties of hard-head, see Levy and Ewen, *Trans. Inst. Min. & Metallurgy*, 1908-9, 466. The purer metal which has collected in the kettle (which is heated by a small separate fire) is now refined by plunging billets of green wood under the surface of the melted tin. A quantity of gas is evolved from the wood, and violently agitates the metal, gradually separating a scum which contains the impurities originally present in the crude tin. The same result is sometimes attained by 'tossing' the melted metal in ladles from a height of several feet and allowing it to fall into the kettle; in this way the metal is also exposed to atmospheric influences, and a scum separates as before. The refined metal is sold as *grain*, *refined*, or *common tin*, according to its quality, though all tin met with in commerce has been more or less refined. For *refined tin* purer ores are employed, the refining is continued longer, and after polishing the metal is allowed to stand some time, and only the upper or purer portions are used. The second or ordinary quality, when cast in suitable moulds, is known as *block tin*. A simple test of the commercial quality of tin is to melt the metal at a moderate temperature, and to pour it into an ingot mould. The ingot, if of good quality, should be smooth, bright, and rounded, and should retain this appearance on solidification; if impure it will have more or less sharp edges, and will 'frost' over on solidifying, while very impure metal will be tinged with yellow or purple, according to the amount and nature of the impurities. *Grain tin* is produced by heating blocks of refined tin to a temperature a little below the melting-point of the metal, at which point it becomes very brittle, and is broken either by dropping from a height or by a blow of a hammer. For further particulars of the properties and metallurgy of tin, see H. Louis, *Metallurgy of Tin*, London, 1911.

Electrolytic refining of tin.—After liquida- tion, to remove iron, crude tin has been successfully refined on the large scale by electrolysis in solutions containing (a) 20 p.c. of hydrofluosilicic acid, 0.1 p.c. of sulphuric acid, and 6 p.c. Sn; (b) 5 p.c. of hydrofluosilicic acid, 8 p.c. of sulphuric acid, and 3 p.c. Sn; (c) 8 p.c. of sulphuric acid, 4 p.c. of cresol- or phenol-sulphonic acid, and 3 p.c. Sn; (d) 13.7 p.c. of sulphuric acid, 21.2 p.c. of crystallised sodium sulphate, and 1.5 p.c. Sn. The electrolysis is preferably carried out at 35° with a current of 10 amp. per sq. ft. at 0.3 volt. With electrolytes (a), (b), (c), which contain the tin as a stannous salt, an emulsion of 1 lb. of glue and 8 lb. of cresylic acid is added per ton of metal deposited, to assist in producing smooth deposits, and 0.3 p.c. of hydrochloric acid is added to bring about uniform corrosion of the anode and to make the slimes soft and porous. Electrolyte (d) contains the tin as stannic sulphate, and 0.2 p.c. of Cuprasol slimes is added to obtain

a smooth deposit. The slimes from Bolivian crude tin containing 97 p.c. Sn usually assay about 20 p.c. Pb, 5 p.c. Cu, 3 p.c. As, 5 p.c. Sb, 20 p.c. Bi, and 30 p.c. Sn, together with 130 ozs. Ag per ton, and traces of Au. Two methods of treating this material have been used: the first involves fusion of the slime with sodium hydroxide under oxidising conditions to obtain a lead-bismuth-silver bullion, which is refined electrolytically, and a soda slag from which crude tin is again obtained by reduction. In the second process the slimes are melted and reduced to metal, which is cast into anodes: these are electrolysed in 18 p.c. hydrochloric acid, which dissolves 90 p.c. of the tin and bismuth, 45 p.c. of the antimony, and 35 p.c. of the copper. The bismuth is precipitated by crude tin and refined by fusion with soda and sulphur, and the tin is precipitated by lime. The slimes are smelted to give a base lead bullion, which is softened and desilverised (J. R. Stack, *Trans. Amer. Electrochem. Soc.* 1924, 45, 279; *J. Soc. Chem. Ind.* 1924, 43, B. 521).

Brands of tin. In 1911 a committee of the London Metal Exchange drew up a new form of contract for the purchase of tin. This provided for the recognition of two classes of tin: Class A. includes Straits or Australian tin of good merchantable quality, and also refined tin of good merchantable quality, assaying not less than 99.75 p.c. of tin. Class B includes common tin of merchantable quality, and assaying not less than 99 p.c. of tin. The official brands include the following: Straits, Australian, Banca, Billiton, English, German, and Chinese. In connection with this classification a number of brands and descriptions were assayed, and tabulated analyses prepared.

It will thus be seen that some of the best brands of commercial tin are of remarkable chemical purity.

Properties of tin. Tin is a white lustrous metal which exhibits a fibrous structure, and when bent emits a creaking sound owing to its crystalline character. When melted and allowed partially to solidify, and the still liquid portion poured away, needle-shaped crystals are formed in the remainder. The metal is deposited in tetragonal prisms when stannous chloride is decomposed by a weak electric current. Tin is capable of existing in different allotropic forms depending upon the temperature. At ordinary temperatures it is in a metastable condition, but on exposure to great cold it falls to pieces forming a coarse grey powder. Between 18° and 170° the stable form of tin is tetragonal, above 170° it is rhombic. Tin has a sp.gr. of 7.312 and melts at 232° (Heycock and Neville). It expands 2.8 p.c. during melting. The change of density of melted tin with temperature may be represented by the formula

$$d = 7.01 - 0.00074(t - 232)$$

(Hogness, *J. Amer. Chem. Soc.* 1921, 43, 1621). Tin suffers little change when exposed to air, either dry or moist, at ordinary temperatures. When melted it slowly oxidises to the dioxide. It is readily attacked by acids: hydrochloric acid converts it into stannous chloride with evolution of hydrogen, nitric acid forms meta-stannic acid. It dissolves in aqueous solutions

of the alkalis with evolution of hydrogen, forming meta-stannates.

For passive tin, see Steiner (Z. Elektrochem. 30, 279, June, 1924; Sci. Abstr. 1924, 27, 832).

Uses of tin.—The manufacture of tin plates absorbs more tin than any other industry, and of this a separate account will be given. Tin is also largely used for alloying with copper to produce bronze, bell metal, and speculum metal, while in combination with other metals tin produces a number of useful alloys, to be afterwards described, among which may be mentioned pewter, Britannia metal, plumber's (or soft) solder, Queen's metal, type metal, fusible metal, &c. Though tin is comparatively brittle at ordinary temperatures, it becomes very malleable at about 100°, and can then be rolled into thin sheet or foil, for which there is a considerable application, and which was formerly much used, in the form of an amalgam, for the 'silvering' of mirrors.

Tin foil containing small quantities of aluminium gradually becomes brittle, owing to the slow oxidation of the aluminium. On account of its power of resisting atmospheric influences and the action of vegetable acids, tin is also used for the manufacture of pipes for brewers, distillers, and other purposes. For similar reasons lead pipes are sometimes tin-lined. Pots, pans, kettles, and other culinary utensils are frequently *tinned* inside. The process is very ancient, and extremely simple. The surface of the vessel to be tinned (which may be of copper, brass, or iron) is carefully cleaned and brightened, and a little ammonium chloride (patented for this purpose by John Bootie in 1768) is often rubbed over the surface. Some tin and a little powdered resin is now melted in the vessel, and is wiped over the surface with tow. By this means a skilful workman rapidly produces a uniform coating of tin, which resists considerable wear, and yet weighs, according to the experiments of

Bayen, less than a milligramme per square inch of surface. No wonder that Pliny states, with surprise, that copper when tinned 'does not increase in weight! Tin salts are also used for tinning brass and copper wire, and as mordants in dyeing.

Alloys of tin. The alloys of tin are of great practical importance, and have naturally attracted considerable attention, although accurate information is still wanted in respect of many of their physical and other properties. For convenience of study the alloys of tin may be divided into two classes, the first in which the properties of the resulting alloy are entirely different from the mean of the constituents, while the second class includes those alloys some of the most important properties of which agree very closely with what might be anticipated from the properties of the constituent metals. The first class is typically represented by the alloys of copper and tin, which include the important alloys known as *brasses*, *gun metal*, *bell metal*, &c.

Tin itself is weak, soft, readily fusible, and of a nearly white colour, while copper is strong, tough, moderately hard, and of a characteristic red colour. On adding tin to copper, however, in gradually increasing proportions a succession of alloys is obtained with properties which are utterly different alike from those of each other and from their constituent metals. Thus an addition of about 5 p.c. of tin to copper produces a tough strong alloy, which still retains a fairly characteristic copper colour, but which is much harder than copper, and is suitable for medals or coinage, but the hardening effect of tin is so great that already the practical limit has been reached for coinage purposes. On adding 5 p.c. more tin we have an alloy which is still harder, so much so that it has to be cast instead of being rolled or drawn, and the alloy possesses a rich yellow colour. With a little more tin an alloy suitable for the hardest bearings is produced, and with still more tin we have the alloy used for small bells, and which is

sonorous, but shows considerable brittleness when cold, but though it be worked at a low red heat. With still more tin an alloy suitable for the largest bells is obtained; brittleness is more marked, and the fracture is dull earthy grey, and it is only when the metal has been worked or burnished that a yellow colour is visible. But on continuing the addition of tin, which is one of the softest of the common metals, the alloys become more and more brittle, until with about 33 p.c. the alloy can easily be pounded in a mortar, and possesses a white colour, with a more or less pronounced blue shade. This alloy is thus utterly different alike from its constituents and from either of the other alloys previously mentioned. As examples of the second class of alloys of tin, in which the properties of the alloy are approximately what would be expected from the characters of the constituents, the combination with zinc or with lead may be taken. Tin and zinc unite in all proportions, and the colour, hardness, ductility, &c., of the alloys are what would be anticipated from a mixture of the two constituents. Tin and lead also unite in all proportions to form a series of alloys, all of which are nearly white in colour, and are soft, malleable, and readily fusible, like the metals themselves. Tin-lead alloys, however, furnish a characteristic illustration of the fact that the melting-point of mixtures or alloys is very commonly lower than the mean calculated from the melting-points of the pure substances. This rule is very generally observed, both in salt solutions, with mixtures of salts, and with mixtures of organic substances (Guthrie, *Phil. Mag.* [iv.] 59, 1, 206, 266; [v.] 1, 49, 354, 446; 17, 462; 6, 35). Common, or soft, solder is an alloy of tin and lead, the best proportions being very nearly 2 parts of tin to 1 of lead. The melting-point of this alloy, calculated from the melting-points of its constituents ($Pb=327^{\circ}$, $Sn=228^{\circ}$), would be 261° , but the lowest melting-point in this series of alloys actually observed is 180° (Turner, *B'ham. Phil. Soc.* [iv.] 318), and the composition of the alloy was very nearly 2 parts of tin to 1 of lead. A number of investigators have examined these alloys of tin and lead, including Küpffer, Pillichody, Laurie (*Chem. Soc. Trans.* 1889, 678), and more recently Rosenhain and Tucker (*Phil. Trans. Series A.* 1908, 89), and the results of the determination of the composition of the lowest melting-point alloy vary from about 60 to 65 p.c. of tin (62.93 p.c. tin, Rosenhain and Tucker). There appears to be no indication of a definite alloy of tin and lead in atomic proportions, though, on very slow cooling, there is evidence of the existence of a solid solution, at the lead end of the series. There is also an inversion at 150° with alloys containing 18–63 p.c. of tin. In addition to their use for solders the tin-lead alloys have an important application in the form of *pewter* , the toughest and hardest variety of which contains about 3 parts of tin to 1 of lead. The hardness of lead-tin alloys is altered completely by prolonged re-heating of the alloy (C. di Capua and M. Arnone, *J. Soc. Chem. Ind.* 1924, 43, B. 580; Atti R. Accad. Lincei, 1924, 33, i. 293). Alloys of tin and antimony belong to the same class as those previously mentioned, and a mixture of 4 parts of tin with 1 of antimony is used for one

kind of type metal. Tin also enters into the composition of Britannia metal, the proportions being as follows (Greenwood), *Metallurgy*, i. 211):—

	Britannia metal			Queen's metal
	For spinning	For rolling	For casting	
Tin . . .	94	90	84	75
Antimony . . .	5	7	10	8.5
Copper . . .	1	3	4	—
Bismuth . . .	—	—	2	8.4
Lead . . .	—	—	—	8.5

A Birmingham manufacturer's mixture for Britannia metals is as follows: tin, 1 cwt.; antimony, 12 lbs.; copper, $\frac{1}{2}$ lb.

Britannia metal has a somewhat considerable application on account of its white colour, and the fact that it takes a good polish and resists the influence of the atmosphere; its low conductivity for heat also renders it very suitable for some purposes. This manufacture was introduced by Jessop and Hancock about 1770.

Type metal varies considerably in composition, consisting essentially of antimony and lead; but for small type tin is commonly added, and in some cases considerable proportions of tin are employed.

The following illustrates the composition of type metal of excellent quality, and suitable for different sizes of type. It will be noted that large type is made of a softer and cheaper mixture.

	Tin	Lead	Antimony
Large type . . .	7.5	78	14.5
Medium type . . .	9.0	73	18
Small type . . .	14.5	57	28.5

From 1 to 1.5 p.c. of copper is also added in some cases to improve the wear of the type.

White bearing metals for heavy machinery contain the same constituents as type metal. At least 10 p.c. of antimony is required; with above 20 p.c. the alloy is brittle. The limit of tin, on account of price, is usually about 45 p.c. (Hague, *Bearing Metals*, South Staffs. Iron & Steel Inst. Jan. 1909; Hiorns, *Anti-friction Alloys*, Birm. Metallurgical Soc. Feb. 1909). For special purposes larger proportions of tin are employed, as shown in the following analyses (G. Hughes, *Non-ferrous Metals in Railway Work*, Journ. Inst. of Metals, Sept. 1911):—

	A	B	C
Tin . . .	82.0	11.5	80
Antimony . . .	14.0	13.5	10
Copper . . .	4.0	3.0	10
Lead . . .	—	72.0	—

Alloy B is a fairly typical soft bearing metal. A and C are harder, the former being used for bearings, &c., in steam locomotives, and the latter for high-class axle bearings on the pinion and commutator ends of electrical rolling stock.

Tin is also a constituent of the various fusible alloys, one of the best known being Wood's alloy, which consists of 4 parts of tin with 4 of lead, 8 of bismuth, and a little cadmium; it fuses at 63° .

The tin-lead-bismuth eutectic melts at 94° . It can be prepared by melting together 4 parts of tin, 8 of lead, and 13 of bismuth. The alloy with 4 of tin, 8 of lead, 10 of bismuth, and 4 of cadmium melts at about 71° .

Fusible alloys are used chiefly for taking rapid impressions of objects which would fre-

quently be injured by the use of metal melting at a higher temperature, and also for safety plugs in steam boilers, &c.

For the equilibrium of the ternary system bismuth-tin-zinc, see Sheikh D. Muzaffar (J. Chem. Soc. 1923, 123, 2341).

Hardness of tin-cadmium and tin-bismuth alloys.—The hardness of tin is increased by addition of cadmium to a maximum for about 6 p.c. of the latter. With further addition of cadmium, the hardness falls rapidly until the eutectic point is reached at 28 p.c. of cadmium, remains constant over the region 28-97 p.c. Cd, and then falls to the value for pure cadmium. This behaviour is changed markedly by annealing the alloys in paraffin wax at 150° for 330 hours, the two branches of the curve in the neighbourhoods of 0 p.c. and 100 p.c. of cadmium then revealing the solid solubility of each metal in the other; about 3 p.c. of tin dissolves in cadmium and about 8 p.c. of the latter in tin (cf. Bucher, A., 1917, ii. 211).

With tin-bismuth alloys the maximum hardness corresponds with the eutectic point, but annealing causes the disappearance of this maximum and renders the curve normal, the maximum hardness being then shown by crystals of tin saturated with bismuth, and the limit of solid solution being extended from 4 p.c. to 7 p.c. of bismuth (C. di Capua, Atti R. Accad. Lincei, 1924 [v.] 33, i. 141; Chem. Soc. Abstr. 1924, 126, ii. 414).

Tin-copper alloys. History.—Copper is one of the few metals which have been known from prehistoric periods, and, like silver and gold, is in the pure condition too soft and ductile for many useful applications. The ancients, therefore, prepared various hard copper alloys or bronzes, which were used for many purposes to which iron and steel are now applied. The elements added to give hardness were arsenic, iron, or, preferably, when obtainable, tin. A very ancient Egyptian knife-blade (1400 B.C.) examined by Dr. Percy (Metallurgy, i. 504) consisted of copper with 2.29 p.c. of arsenic and 0.43 p.c. of iron; such a material would, of course, form an indifferent cutting tool.

The Hindoos have for many centuries produced a variety of bronze for coins and statues, which was hardened by the presence of iron. Dr. Percy mentions an ancient Indian coin which contained 5.06 p.c. of iron, the remainder being copper (l.c.), while in the Birmingham Art Gallery there is one of the earliest known images of Buddha, which is believed to be 2500 years old, and which was found by Daniel Forbes to contain 91.50 p.c. of copper and 7.59 p.c. of iron. With the introduction of tin by the Phoenicians came the use of bronze in Egypt, Assyria, Greece, and all the important countries of the ancient world. Of these bronzes, numerous examples are preserved, and the composition recommended for various purposes was very similar to that which is used at the present day. Thus Pliny states (Thomson, Hist. Chem. i. 57) that the Romans made their pans for boiling from a mixture of 100 lbs. of copper and 3-4 lbs. of tin, while for statues to every 100 lbs. of copper, consisting of one-fourth old copper and three-fourths new metal, 12½ lbs. of tin was added. Brass was not known, or at all events was not in general use, until shortly before the

Christian era, and the references to brass which so frequently occur in the Old Testament have to do either with copper or bronze, and not with alloys of copper and zinc. See further on the early history of copper and copper alloys, W. Gowland, Presidential Address, Institute of Metals, 1912.

Constitution of copper-tin alloys.—Previous to the researches of Matthiessen, it was customary to regard alloys as examples of chemical combination, and most experimenters prepared and studied alloys of definite atomic proportions. An example of this method of working is to be found in the researches of Mallet on the tin-copper alloys (Brit. Assoc. Rep. ix., Construction of Artillery, p. 82). The remarkable change in properties which results when tin and copper are alloyed was used as an argument in favour of the view that definite chemical compounds were produced. The result of more recent investigations, however, tends to show that although in some cases definite atomic combinations actually do occur, still these are comparatively few (see C. H. Desch, Intermetallic Compounds, Journ. Institute of Metals, vol. i. 227); while the other alloys, which constitute the vast majority of those in use, are either solid solutions of a metal in an excess of one of the constituent metals, or are simply mixtures of the two or more metals present in the alloy. The equilibrium of the copper-tin series has been studied by Heycock and Neville, Phil. Trans. 202A, 1; Giolitti and Tavanti, Gazz. chim. ital. 1908, 38, ii. 209; Shepherd and Blough, J. Phys. Chem. 1906, 10, 630; Haughton and Turner, Jour. Institute of Metals, 1911, part ii.; Ishihara, Chem. Soc. Abstr. 1925, ii. 122; Stockdale, Chem. Soc. Abstr. 1925, ii. 973. For a discussion of the equilibrium diagram, see art. METALLOGRAPHY. In the tin-copper series there is good evidence of the existence of a definite alloy Cu_2Sn containing 61.64 p.c. of copper, while there is considerable reason to believe that Cu_3Sn , containing 68.18 p.c. of copper, also exists. Thus Calvert and Johnson (Phil. Trans. 1858), in investigating the conductivity for heat of these alloys, found a maximum conductivity corresponding to Cu_2Sn , and a minimum conductivity corresponding to Cu_3Sn . Some very interesting determinations by Riche (Compt. rend. 55, 1862, and more completely Ann. Chim. [iv.] 30, 361) show two maxima, corresponding to Cu_2Sn and Cu_3Sn . These experiments have also received strong support from the induction balance curve of Roberts-Austen (Phil. Mag. 1879, [ii.] 57), which shows two distinct breaks corresponding to Cu_2Sn and Cu_3Sn . The determination of relative electric conductivity by Lodge (*ibid.* 1879, [ii.] 554) also show a very distinct maximum at Cu_2Sn and a minimum conductivity corresponding to Cu_3Sn . Laurie examined these alloys from the standpoint of the electro-motive force produced in a standard cell, and concluded that there was very definite evidence of the existence of Cu_2Sn , but failed in this way to obtain any proof of the existence of Cu_3Sn (Chem. Soc. Trans. 1898, 109; 1899, 678).

The evidence in favour of Cu_2Sn is therefore exceedingly strong, while that in favour of Cu_3Sn , though not quite so complete, is still good, and at present there is hardly sufficient evidence

in support of any other atomic combinations. Farther evidence on this point will be found in C. H. Desch's paper on Intermetallic Compounds, *Journal Institute of Metals*, 1, 1909, 227, above cited. These facts, when considered in connection with the known characters of the two alloys in question, give a key to the peculiar characters of the useful tin-copper alloys. The two definite alloys are white, hard, and brittle, and practically all the alloys used in the arts, except speculum metal, contain more copper than $\text{Cu}_3\text{Sn}=68.18$ p.c. Cu. Hence the useful bronzes may be regarded as mixtures of one of two definite alloys with an excess of a solid solution of tin in copper, and these tend to separate more or less completely during solidification. This separation is particularly marked with large castings rich in copper, as in *gun metal*, which was in former times largely used for ordnance. Microscopical examination shows clearly that at the copper rich end of the series of alloys the first constituent to separate out on cooling the fluid alloy is a solid solution of tin in copper. This forms a dendritic, or fir-tree like structure, giving cores which increase in tin from the centre outwards. This copper-rich solid solution is called the α constituent, and is relatively soft and ductile; as the proportion of tin increases harder constituents separate out, the first of them being designated by the symbol β . It is harder and more brittle than α .

Copper retains a maximum of 13.9 p.c. of tin in solid solution, but tin can retain only traces of copper. The compound Cu_3Sn exists in two modifications: the α -form is stable up to 676° , above which the β -form is the stable modification and melts unchanged at 720° . The existence of the compound Cu_3Sn has been definitely proved, and a new compound, Cu_5Sn_3 , has been found in and isolated from alloys containing more than 60 p.c. of tin. It is stable below the eutectic point at 225° in all alloys containing more than 61 p.c. of tin (cf. *J. Soc. Chem. Ind.* 1923, 42, 227A) (O. Bauer and O. Vollenbruck, *Z. Metallk.* 1923, 15, 119-125, 191-195; *J. Chem. Soc.* 1923, 124, ii. 640).

The production of bronze castings requires special precautions, which cannot be described here. For details, see Mallet On the Construction of Artillery, 1856; also Reports of the United States Chief of Ordnance, 1880, 126, 189; 1884, 369. These latter reports contain some important observations with regard to this variety of bronze. It is stated that the best proportion for such purposes is 91 of copper to 9 of tin. This is best cast in a mould or 'chill' of cast iron, and 100 tests of metal so prepared gave an average tensile strength of 21.9 tons per square inch, the maximum being 24.8 tons and the minimum 16.5 tons. It should be mentioned that these values are higher than those usually obtained in this country, where the metal is generally cast in sand moulds.

Composition of principal tin-copper alloys.—The following list is based on that given by Holtzapffel (*Mechanical Manipulation*, i. 270).

Tin, 0.5 p.c. A small quantity of tin is sometimes added to copper for engraver's purposes to give crispness. About 5 p.c. was used by the Romans for pans, and for ancient flexible bronze nails. A similar alloy is now used for bronze coinage and medals, often with

a little of the tin replaced by zinc; also for engineers' soft gun metal or 'brasses.'

7 p.c. Slightly harder alloy; suitable for mathematical instruments, &c.

8.5 p.c. Rather harder; fit for wheels to be cut with teeth.

8-12 p.c. Soft bronze statues of the ancients. These alloys are harder than the preceding, and mark the extreme limit for coinage purposes. Also used for brass ordnance, 9 or 10 p.c. of tin being preferred. Medium engineers' 'brasses' contain 10-12 p.c. of tin.

12-14.5 p.c. Hard bronze of the ancients, used for weapons and tools. These proportions are also used for engineers' hard bearings.

16 p.c. Soft musical bells.

18-20 p.c. Chinese gongs and cymbals.

20 p.c. Small house bells; Indian gongs.

22 p.c. Large house bells.

24 p.c. Limit for large church bells.

About 33 p.c. Speculum metal (v. Phil. Trans. 1840, 503).

About 66 p.c. 'Temper,' an alloy used for addition to tin and lead to harden pewter.

It has already been mentioned that the addition of a small quantity of tin to copper prevents it rolling well when hot, and the addition of a little more tin destroys its malleability when cold. Bronze is tempered by an exactly opposite process from that used in the case of steel, namely, the alloy is heated to redness and then rapidly cooled in water.

Admiralty bronze consists of 88 parts copper, 10 zinc, and 2 tin. It is a very useful and important alloy, which has received considerable attention in recent years. Its properties are largely influenced by temperature of casting and rate of cooling (see Carpenter and Elam, *J. Institute of Metals*, 1918, xix. 155).

For the majority of purposes bronze is melted in crucibles of fireclay or plumbago, the charge being about 90 lbs. For large castings a reverberatory furnace is often employed, though such work is sometimes performed by means of a large number of crucibles. It is recommended that the copper should be well melted and kept in fusion for some time before the tin is added, if strong castings are required. Founders also prefer to use some new metal in every charge, and not merely to re-melt scrap. The oxidation which takes place during melting removes some 3 or 4 parts of copper to 1 of tin; the result is, therefore, that the alloy, which contains about 9 parts of copper to 1 of tin, tends to get poorer in tin by remelting, and due allowance must be made for this loss, even though it may appear to be slight, as small differences in composition often exert a most important influence in tin-copper alloys.

Bronze bearing metal.—According to Dudley (*Jour. Franklin Inst.* 133, 81, 161; *J. Soc. Chem. Ind.* 11, 460), the following composition is very suitable for bearings for locomotives and similar purposes: copper, 77; tin, 8; lead, 15. The presence of lead in bearings very much diminishes the loss of metal caused by wear, and also reduces the local heating of the journals. Phosphor bronze and other varieties of bearing metal for similar purposes to the above often contain about 10 p.c. of lead, and the wearing properties of the alloy is chiefly connected with the proportion of copper and tin to lead. The presence

of tin is necessary in order to obtain a uniform alloy, as lead and copper alone do not unite well. With too much tin the alloy wears more rapidly and becomes more heated. The presence of phosphorus and arsenic gives solidity to the castings, but with suitable proportions of tin and lead, as above, alloys are obtained which wear even better than standard phosphor bronze with the following composition: copper, 79.7; tin, 10; lead, 9.5; phosphorus, 0.8 p.c.

Phosphor bronze is an alloy containing copper and tin in various proportions, and which also contains a small quantity of phosphorus, introduced in the form of phosphor tin. Occasionally small quantities of zinc or lead are also added. The phosphorus varies from a mere trace, added chiefly to ensure soundness in casting, to about 1.75 p.c. with hard alloys. The results of the analyses and mechanical tests of 99 samples of phosphor bronze, as received by the British Admiralty, have been given by A. Philip, *Journ. Inst. of Metals*, 1, 164, while the constitution and microstructure have been dealt with by O. F. Hudson and E. F. Law, *Journ. Inst. of Metals*, iii. 1910, 161. This alloy has met with considerable favour where special power of resisting wear (as with gears and bearings for quick-running machinery) is required. Similar alloys containing manganese, which is added in the form of ferro-manganese, have also met with considerable application, and are known as *manganese bronzes*. **Silicon bronze**, made by the addition of copper silicide, is used for conductivity wire, though many of these so-called bronzes contain very little or no tin. They are usually alloys which closely resemble Muntz metal in composition, and contain about 60 p.c. of copper, 38 p.c. of zinc, and the remainder of specially added elements, such as manganese, and impurities.

The structure of a tin amalgam corresponding approximately with the formula $HgSn$ is found to consist, like that of tin bronzes, of large granules which are built up of a crystalline skeleton solidifying at a higher temperature and of a component still liquid at the ordinary temperature. The crystalline skeleton consists of acicular, tabular, and granular particles, which are comparatively loosely united and are composed of very small crystalline granules. Centrifugation of the amalgam allows of the separation of the liquid component from the crystalline skeleton (F. Hauser, *Zeits. f. Physik*, 1923, 13, 1 and 2, 1-6; *Sci. Abstr.*, 1923, 26, 680-681).

Detection of tin and mercury by means of a spot test.—A black stain is produced if a mercuric chloride test paper is treated with one drop of a solution containing stannous tin and then with one drop of aniline. The stannous ion is the only cation in the five analytical groups that will reduce mercuric chloride to metallic mercury in the presence of aniline, and the test can therefore be used in the presence of any of the ordinary metals. If the tin is present in the stannic condition, it is first reduced to the stannous form by means of magnesium and hydrochloric acid. By using a test paper soaked in a solution of stannous chloride, the same reaction serves for the detection of mercury (Tananaev, *Zeitach. anorg. Chem.*, 1924, 133, 222; *Chem. Soc. Abstr.*, 1924, 19, 871).

Dry assay of tin ores.—Hofman finds that Winkler's method of assaying black tin stone gives results averaging 65.96 p.c., or 1.88 p.c. too low, the figures disagreeing amongst themselves up to over 3 p.c. The process consists of reducing together 5 grms. each of cassiterite and cupric oxide with 15 grms. of black flux, 1.25 grms. of borax, and a little salt as a cover. A similar experiment is conducted without the cassiterite, and the copper obtained in the one case deducted from the alloy in the other gives the amount of tin. The following modifications of this method were tried: increasing the amount of charcoal, using chalk-lined crucibles, omitting the salt and increasing the potassium carbonate, and Rickett's modification of adding argol; but they all gave worse, and in some instances very variable, results.

The iron method—reduction with hæmatite, charcoal, and potassium cyanide or fluorspar—gave unsatisfactory results. The same may be said when a mixture of ferrocyanide and cyanide was used, and also when any of the Cornish methods were employed. So far, with fairly pure cassiterite only two methods have proved satisfactory, viz. the German and the pure cyanide methods. Hofman has attempted to prove which of these two methods gives the best results when the cassiterite is mixed with those minerals likely to be naturally associated with it. The minerals used were quartz, felspar, mica, tourmaline, garnet, and columbite. Mixtures of the purified cassiterite ore with varying proportions of each of these minerals were assayed by both methods, the percentage of tin being calculated on the cassiterite ore present. The charges were so regulated that the flux in the German assay was always equal to three times the quantity of ore plus the mineral, and in the cyanide assay to six times the quantity. In the latter case 4 parts of cyanide were mixed with the ore; 1 part was used to coat the crucible bottom, and 1 part as a cover. In all cases the cyanide method gave more concordant, and less prejudicially affected, results than the other. The results of the German assays fluctuated greatly as the amount of mineral present increased. Thus, in the case of quartz and albite the results were lower as the quantity of mineral was increased, the respective figures being, with 37.5 p.c. of each mineral, 60.7 and 60.2 p.c.; the corresponding cyanide figures being 63.90 and 65.30 p.c. (the real percentage of tin was 67.84). The tin buttons, moreover, in the German assay with albite contained iron, while those by the cyanide process were free, the temperature of fusion being too low to cause decomposition of the albite.

With muscovite, tourmaline, garnet, and columbite the results with the German method were very unreliable, being sometimes too high and very ferruginous, and sometimes too low, varying from 82 p.c. with 50 p.c. of garnet to 46 p.c. with 44 p.c. of tourmaline. The cyanide method gave fairly good results in all the above cases, very little iron getting into the buttons, except in the case of garnet, when the result was 69.89 p.c., with 37.5 p.c. of mineral present. With the same quantity of muscovite, tourmaline, and columbite the assays were respectively 63.3, 64.7, and 66.0 p.c. Consequently, where anything like a true result is

required the cyanide assay is by far the most to be relied upon, and should be employed in cases of buying and selling, although in concentration works, where comparative results and large numbers of assays are required, the question of cost must be considered, and the cheaper German method might be adopted.

Hofman emphasises the importance of properly preparing the ore for assay, and states that the ordinary method of grinding the whole sample to a uniform size is not suited to the tin ores of the Black Hills, chiefly on account of the preponderance of mica. Hence a preliminary sizing is advantageous. The ore while being pulverised is screened through a series of sieves Nos. 20, 40, 60, and 80, the different-sized screenings being then washed. This method gives purer concentrates, and necessitates less loss of cassiterite, as the material has been washed without excessive grinding, which in the present process reduces the brittle cassiterite to a slime, while some of harder associated minerals are only converted into sand. The subsequent treatment of the concentrates mentioned in the first part of the paper is recommended, as the roasting renders the cassiterite more friable and more readily reducible, the assays in some cases showing a difference of 0.5 p.c. between the raw and roasted ores in favour of the latter (Part II, H. O. Hofman, Technol. Quarterly, 3, 261-280; J. Soc. Chem. Ind. 9, 1154; v. Rennie and Derrick, *ibid.* 1892, 662).

For analysis of tin ores by wet methods, cf. Craig, J. Ind. Eng. Chem. 1919, 11, 750; Analyst, 1919, 359.

The following figures, issued by the Imperial Mineral Resources Bureau, show the world's production of tin ore in terms of metal and the world's smelter production of tin in 1921:—

	Output of tin ore. Long tons.	Smelter output of tin. Long tons.
United Kingdom . . .	679	14,000
Nigeria . . .	5,057	—
Swaziland . . .	234	—
Union of South Africa . . .	720	—
Southern Rhodesia . . .	—	4
India . . .	1,362	172
Straits Settlements . . .	1	41,917
Federated Malay States . . .	34,490	—
Unfederated Malay States . . .	1,611	—
Australia . . .	2,650	2,985
Bolivia . . .	18,804	60
Germany . . .	—	4,000 ²
United States . . .	—	10,305
China . . .	11,200	6,134
Siam . . .	6,181	—

² Estimated.

In the volumetric determination of tin, stannous chloride solutions may be titrated directly with potassium bichromate, using diphenylamine sulphate as internal indicator, the end-point being marked by the development of a blue colour; or indirectly in a similar manner after addition of excess of ferric chloride (J. G. F. Bruce, Chem. News, 1924,

184, 273; J. Soc. Chem. Ind. 1924, 43, B. 540; Analyst, 1924, 49, 402).

The small quantities of tin present in canned foods are determined volumetrically by titration with standard iodine after preliminary ignition to remove organic matter and precipitation as sulphide. A special apparatus is used in which the tin is reduced to stannous chloride by zinc and hydrochloric acid and titrated as such in an atmosphere of carbon dioxide. By means of an arrangement of three flasks and three 2-way taps the reduced liquid is blown by the carbon dioxide into another flask containing starch solution, the reducing flask is rinsed out by water saturated with carbon dioxide, and the wash-water driven as before to the main solution, which is then titrated with standard iodine, the solution being kept mixed by means of the gas content (E. J. B. Willey, J. Soc. Chem. Ind. 1924, 43, 70 T.; J. Soc. Chem. Ind. 1924, 43, B. 273).

T. T.

COMPOUNDS OF TIN.

According to Paneth and Fürth (Ber. 1919, 52, [B] 2020) an alloy of tin and magnesium Mg_2Sn when acted upon by dilute hydrochloric or sulphuric acid evolves minute quantities of a gaseous *hydride of tin* which is decomposed on passing through a heated glass tube. The gas can be condensed by liquid air and re-evaporated without decomposition.

Oxides. A monoxide, *stannous oxide* SnO , and a dioxide, *stannic oxide* SnO_2 , each of which gives rise to a distinct series of salts, are known, the former acting as a base and the latter acting as either base or acid. Oxides of the composition Sn_2O_3 , $SnO \cdot 3SnO_2$, $2SnO_2 \cdot H_2O$, SnO_2 , and others have also been said to exist, but it is probable that, with the exception of SnO_2 , they are mixtures of the other two oxides.

Stannous oxide SnO is obtained as an olive-brown anhydrous powder, when stannous oxalate is heated out of contact with the air; or as a white precipitate of the composition $2SnO \cdot H_2O$, with evolution of carbon dioxide, when stannous chloride and an alkaline carbonate or hydroxide are mixed in solution. If the precipitate is washed with air-free water, and the lixiviated product is heated in the absence of air, nearly pure dark grey stannous oxide is obtained (Enequist, Eng. & Mining J. 1895, 219; see also Hantzsch, Zeitsch. anorg. Chem. 1902, 30 289).

It may also be obtained as a bluish-black anhydrous powder by heating a mixture of 4 parts of stannous chloride with 7 of sodium carbonate, and lixiviating the resultant mixture of stannous oxide and sodium chloride (Sandall, J. exp. Chem. [i.] 254). The anhydrous oxide may also be obtained from the hydrated form as follows: (1) as a black powder by heating it out of contact with the air; (2) in minute cubes by digestion with acetic acid at 56°; (3) of a brilliant scarlet colour, which becomes brown on rubbing, by evaporating a dilute solution of ammonium chloride containing stannous chloride in solution until the chloride commences to crystallise (Fremy, Berz. J. 24, 133; 5, 172; Ann. Chim. [iii.] 12, 460); (4) as small black shining crystals, which, when heated to 58°, decrepitate and swell up, with production

of soft olive-green laminae, by prolonged digestion with a weak solution of caustic potash at the ordinary temperature (Fremy, *l.c.*). A stronger solution dissolves the oxide and ultimately deposits it in crystals, the deposit from a solution of 4 parts of potassium hydroxide in 10 of water containing potassium stannate and tin, the former produced by absorption of atmospheric oxygen. Fremy also describes various red, black, brown, and other forms of this oxide.

The following method is given by Fraenkel and Snipischsky (Zeitsch. anorg. Chem. 1922, 125, 235): Stannous chloride is dissolved in the least possible amount of hot concentrated hydrochloric acid and sodium hydroxide solution added gradually until the solution reacts alkaline towards phenolphthalein; the resulting milky liquid is then kept boiling in a bath of saturated sodium chloride solution. In a few hours a blue lustrous powder is obtained which is washed and dried (J. Soc. Chem. Ind. 1923, 101 A).

Stannous oxide becomes incandescent, and forms stannic oxide, when heated in the air. It is violently oxidised by nitric acid, and other oxidising agents. Carbon or hydrogen reduces it to metal at a red heat. It dissolves in acids, with production of stannous salts, and in caustic potash or soda, but not in ammonia. The soda solution is employed in calico printing and dyeing under the name *sodium stannite*, and is prepared as described under *sodium stannate*.

Stannous oxide and tin salts are used as reserves under pararosaniline red and other diazo colours (Bull. Soc. Ind. Mulhouse, 1900, 45).

Stannous oxide is sometimes recommended for use in glass and enamel manufacture, but it is too costly, and the results are not very satisfactory.

A so-called *sesquioxide* Sn_2O_3 is obtained as a slimy grey precipitate by the action of recently-precipitated ferric hydroxide on a solution of stannous chloride (v. Fuchs, Kastner's Archiv. für Chemie und Meteorologie, 23, 368; J. pr. Chem. 5, 318; and Berzelius, Pogg. Ann. 28, 443; Berz. J. 13, 110).

This substance is readily soluble in ammonia and in concentrated hydrochloric acid. It does not appear to form definite salts. Its hydrochloric acid solution acts like a mixture of stannous and stannic chlorides. An orange-yellow oxide of the composition $\text{SnO} \cdot 3\text{SnO}_2$ is obtained by digesting metastannic acid in cold aqueous stannous chloride (Fremy, J. Pharm. [ii.] 1, 344).

Hydrated stannous oxide, according to Ditte (Ann. Chim. 1882, [v.] 27, 145), is prepared by adding the hydroxides of sodium or potassium to a solution of stannous chloride, and was described as a brownish-yellow powder of the formula $\text{SnO} \cdot 2\text{H}_2\text{O}$ (cf. Schaffner, Annalen, 1844, 51, 168). According to Bury and Partington (Chem. Soc. Trans. 1922, 121, 1998) the more probable formula is $3\text{SnO} \cdot 2\text{H}_2\text{O}$. It is stable at 110° and slowly loses water on standing under water, forming stannous oxide.

Stannic oxide SnO_2 occurs as *caesilerite* or *stannos*, varieties of which are known as *stream tin*, *wood tin*, *toad's eye*, &c. Daubrée (Ann. Mines, 20, 65) has pointed out that, with the exception of quartz, the minerals most frequently associated with tin ore are fluorine compounds.

Stannic oxide is obtained as an anhydrous

white powder of sp.gr. 6.7122 at 4° (Joule and Playfair, Chem. Soc. Trans. 1849, 1, 128) when tin is heated until it burns in the air. The powder is converted into microscopic quadratic crystals resembling the native oxide when heated in a current of hydrogen chloride (Deville, Compt. rend. 1861, 53, 161; see also Abel, Chem. Soc. Trans. 1858, 119). The oxide may also be obtained in trimetric crystals, and is therefore dimorphous (v. Daubrée, Pharm. Zentr. 1849, 821; Levy and Bourgeois, Compt. rend. 94, 1365.)

It has also been obtained in oblong and rhombic plates of sp.gr. 7.0096 and approaching the form of anatase (Emich, Monatsh. 1893, 14, 345).

Metallic tin may be heated electrically or otherwise to 1700° out of contact with air, and the resulting tin vapour is then burnt in a current of air or oxygen. The stannic oxide thus produced is said to be more homogeneous and in a better state of subdivision for enamelling than the ordinary oxide (Eng. Pat. 9231, 1900).

Stannic oxide is obtained from its ores or from dross, waste, &c., by heating the ore or waste with or without an admixture of coke, chalk, or dolomite and acting upon the liberated molten tin with hot air or oxygen (Fr. Pats. 392805, 392806, 1908; 370640, 1906; 409157, 409485, 1909; also Eng. Pats. 12910, 1899; 28565, 1908; U.S. Pats. 695939, 1912; 780984, 1905; 880873, 1908; J. Soc. Chem. Ind. 1900, 448; *ibid.* 1905, 197; *ibid.* 1908, 335; *ibid.* 1909, 21; *ibid.* 1910, 352; see also *ibid.* 1904, 1239; *ibid.* 1907, 696, 1094).

The dioxide may also be formed by electrolysis a solution of sodium chloride using a tin plate as anode and a platinum plate as cathode (Lorenz, Zeitsch. anorg. Chem. 1896, 12, 436).

Stannic oxide is reduced to metal when heated with hydrogen, carbon monoxide, carbon, potassium, or sodium (Doeltz and Graumann, Metallurgie, 1907, 4, 420). It dissolves in fused potassium disulphate, but separates from the mass when treated with water. When fused with sulphur, stannic sulphide is formed, with evolution of sulphur dioxide.

The anhydrous oxide is insoluble in acids, except in concentrated sulphuric acid, with which it forms a syrup decomposed by dilution, with precipitation of the oxide. It dissolves in aqueous or fused alkalis, with formation of stannates.

Treated with hydrochloric acid in presence of tin both stannous and stannic oxides form stannous chloride, and this is used as a method for the recovery of tin from the waste liquors of the dye house (Vignon, Textile Colourist, 18, 333; J. Soc. Chem. Ind. 1893, 762).

With chloroform stannic oxide chiefly reacts thus:

(Renz, Ber. 1906, 39, 249).

When heated with hypophosphorous acid over a Bunsen flame for 30 mins., *stannous phosphate* or *pyrophosphate*, is formed; since these are readily soluble in hydrochloric acid, stannic oxide can thus be separated from silica which is not affected by this treatment (Dott, Pharm. J. 1908, 81, 585).

Stannic oxide, in the form of *pure powder*,

which is a mixture of tin and lead oxides, or a stannate of lead, is used as a polishing material for glass. To avoid any possibility of danger from the use of this powder it has been recommended to mix 1 part of putty powder with 2 of metastannic acid (Gueroult, *Compt. rend.* 1892, 115, 757). Stannic oxide is an important factor in the manufacture of glazes and of enamels, the latter assuming an intensely white colour on the addition of a small quantity of the oxide. It is also the best material known for making opaque glaze or glass, and is employed in glaze brick and tile manufacture (Enequist, *l.c.*; Burt, *Trans. Amer. Ceramic Soc.* 1902, 4, 139).

Tin oxide is also said to be useful for the purification of water (*J. Soc. Chem. Ind.* 1894, 56).

Perstannic oxide SnO_5 . W. Spring (*Bull. Soc. chim.* [iii.] 1, 180) has obtained a substance of the composition $\text{H}_2\text{Sn}_2\text{O}_7$, probably a hydrate of this oxide, by dialysing the turbid solution obtained by adding hydrated barium peroxide in excess to a solution of stannous chloride in hydrochloric acid, and evaporating the solution of the colloid on the water-bath.

Stannic acids. Two isomeric stannic hydroxides are known, each of which behaves as an acid and exists in various degrees of hydration between the limits H_2SnO_3 and H_4SnO_4 . They are both colloidal modifications of hydrated stannic oxide, only differing in the size of their particles, the α -acid consisting of relatively small, the β -acid of relatively large particles (Mecklenburgh, *Zeitsch. anorg. Chem.* 1909, 64, 368; 1912, 74, 207; 1914, 84, 121; *see also* Fremy, *Ann. Chim.* 1844, [iii.] 12, 466; *ibid.* 1848, 23, 385; Musculus, *Compt. rend.* 1867, 65, 961; Vignon, *ibid.* 1889, 103, 1049; *ibid.* 109, 372; Kleinschmidt, *Monatsh.* 1918, 39, 149; Kreis, *Schweiz. Chem. Zeit.* 1919, 389; Tian, *Compt. rend.* 1921, 172, 1402; Collins and Wood, *Chem. Soc. Trans.* 1922, 441).

Stannic acid, α - or ortho-stannic acid H_2SnO_3 , is obtained by precipitating stannic chloride with ammonia, or by addition of calcium or barium carbonate to a solution of stannic chloride in quantity insufficient to precipitate the whole.

It is also formed by treating an alkali stannate with a mineral acid (Kühl, *Pharm. Zeit.* 1908, 53, 49) and by electrolysis of an alkali chloride, nitrate or sulphate solution, using platinum as cathode and tin as anode (Lorenz, *Zeitsch. anorg. Chem.* 1896, 12, 436), and by other methods (Engel, *Compt. rend.* 1897, 125, 851; Neumann, *Monatsh.* 12, 518; Coppadoro, *Chem. Zeit.* 1907, 31, Rep. 336).

Its composition varies with its mode of drying, and it is converted into anhydrous SnO_2 at 630°–655°. It forms a gelatinous substance, or white voluminous, amorphous precipitate, slightly soluble in water and of acid reaction. When dried spontaneously, it forms translucent lumps, resembling gum arabic.

When boiled with phenosafranine in the presence of sodium sulphate, stannic acid forms an intense red lake; metastannic acid under the same conditions only forms a pale rose tint (Vignon, *Compt. rend.* 1891, 112, 580).

A colloidal stannic acid is known (*v. Graham, Phil. Trans.* 151, 213; Van Bemmelen, *Rec. trav. chim.* 7, 87; Schneider, *Zeitsch. anorg.*

Chem. 1894, 5, 83; *ibid.* 1900, 23, 111; Lottermoser, *J. pr. Chem.* 1899, [ii.] 59, 489; Biltz, *Ber.* 1902, 35, 4431). It can be prepared by the dialysis of an alkali solution of tin chloride or of a hydrochloric acid solution of potassium stannate. Colloidal stannic acid is the most important constituent of purple of Cassius (*v. GOLD PURPLE*).

Stannic acid forms a large and important series of salts, most of which are crystalline. The alkaline stannates are soluble, and may be prepared by dissolving the precipitated oxide in the alkaline hydroxide. The others are mostly insoluble, and are best obtained by double decomposition. The potassium and sodium salts are the only ones of technical importance. The stannates have been investigated by Fremy (*Ann. Chim.* 1844, [iii.] 12, 462; 1848, [iii.] 23, 393), Moberg (*J. pr. Chem.* [i.] 28, 230), Marignac (*Ann. de Mines*, [iii.] 15, 277), Ordway (*Amer. J. Sci.* [ii.] 40, 173), Ditte (*Compt. rend.* 1882, 94, 1114; 1883, 96, 701), and Bellucci and Parravano (*Atti R. Accad. Lincei*, 1904, [v.] 13, ii. 324, 339; *ibid.* 1905, 14, i. 457).

According to the last-mentioned authors they are isomorphous with the plumbates and platinates.

Sodium stannate Na_2SnO_3 usually occurs in six-sided tables of the composition $\text{Na}_2\text{SnO}_3 \cdot 3\text{H}_2\text{O}$ (Moberg, Marignac, Ordway, *l.c.*), which are less soluble in hot than in cold water. According to Ordway, 100 parts of water dissolve 67.4 parts at 0°, and 61.3 parts at 20°.

According to Bellucci and Parravano, the water is present not merely as water of crystallisation but in a more intimate form, namely, as $\text{Na}_2\text{Sn}(\text{OH})_6$.

Crystals of the above composition are deposited from a hot alkaline solution, but the salt may also be obtained with 8, 9, or 10 molecules of water. The form crystallising with 9 molecules is said to be obtained in oblique rhombic prisms by recrystallising the commercial salt (Jonas, *Chem. Zentr.* 1865, 607); while, according to Haefely (*Dingl. poly. J.* 144, 66), crystals of the composition $\text{Na}_2\text{SnO}_3 \cdot 3\text{H}_2\text{O}$ are deposited from hot concentrated solutions of 1.3 sp.gr., but re-dissolve on cooling to a solution of 1.35 sp.gr., from which crystals containing 8 molecules of water are gradually deposited.

Copper is readily tinned by immersion in a solution of the salt.

Sodium stannate is largely used, under the name of 'preparing salt,' as a mordant in dyeing and calico-printing, the fabric being first passed through a solution of the stannate, and then through weak sulphuric acid, which precipitates the hydrated oxide on the fibres.

For preparing this salt on the large scale, the original processes patented by J. Greenwood, J. Mercer, and J. Barnes (*Eng. Pat.* 10757, 1845), J. Young (*Eng. Pats.* 12359, 1848; 12744, 1849), and Haefely (*Eng. Pat.* 603, 1854), are still used with some modifications. A number of other processes are mentioned in the list of patents relating to tin salts (*infra*).

The process of Greenwood, Mercer, and Barnes consists in heating 22 lbs. of caustic soda in an iron crucible until evolution of water ceases, and then adding 8 lbs. of sodium nitrate and 4 lbs. of sodium chloride, followed, when the mass is nearly fused, by 10 lbs. of feathered

tin, with constant stirring until deflagration ensues. The mixture then becomes white hot, and pasty, and is wholly converted into the stannate.

For preparing sodium 'stannite' a mixture of 4 lbs. of sodium chloride, 1 gallon (13.5 lbs.) of caustic soda, 1 lb. of sodium nitrate, and 4 lbs. of tin is heated in an iron crucible, and the dry powder finally obtained is stirred so long as ammonia is evolved.

Young's processes—most of which are described below—consist mainly in the preparation of the stannate directly from the ore, thus avoiding the cost of obtaining and re-oxidising the metal.

By one process the native or prepared oxide is boiled in an iron pot with a quantity, varying with the tin value of the ore, of 22 p.c. soda lye, the temperature being gradually raised to about 600°F., at which combination takes place. When the operation is completed, which is ascertained by removing a portion and seeing how much dissolves, the mass is cooled in another vessel and is dissolved, filtered, or decanted, and recrystallised or sold in solution.

In another process, the ore is heated to redness with one and a half parts of sodium nitrate in a current of steam with constant stirring. The stannate is produced, with evolution of nitrous fumes and nitric acid. The nitrate may be replaced by 1 part of salt, hydrochloric acid being then obtained as the by-product.

'Stannite' of soda is obtained by heating the metal with its own weight of caustic soda, with constant stirring, or by electrolysis a concentrated solution of sodium hydroxide, using a rotating tin anode and a platinum cathode. The current must not be too strong, and the solution must be protected from oxidation by a stream of hydrogen (Goldschmidt and Eckardt, *Zeitsch. physikal. Chem.* 1906, 56, 385). The solution of the stannite may be used in dyeing and printing operations as it is, or it may be converted into stannate, with precipitation of tin as a black powder, by boiling.

The stannate may be obtained direct from the metal by heating a mixture of 20 parts of tin, 16 of sodium hydroxide, and 3 of manganese dioxide to redness, with constant agitation and free exposure to the air. The dioxide appears to act as a carrier of oxygen, and is obtained unchanged at the end of the operation.

In another process, calcium stannate is obtained by roasting in a reverberatory furnace a mixture of the ore with slaked lime. The product is treated with sufficient hydrochloric acid to precipitate the tin as oxide, but not to redissolve any of it, and the precipitate is dissolved in boiling soda lye. The salt may also be obtained by boiling barium stannate, obtained similarly to the lime salt, with sodium sulphate, until all the barium is converted into sulphate.

Haeffely's process consists in the preparation of a solution of 'plumbate of soda' by dissolving 54 lbs. of red lead or 70-80 lbs. of litharge in a solution of 45 lbs. of caustic soda of 70°Tw. The solution is diluted, and 16 lbs. of tin is suspended in it while boiling, so that in 4 or 5 hours the lead is obtained as a deposit, which may be readily oxidised for re-use, while sodium stannate remains in solution.

The following process has also been employed (*Chem. Zeit.* 9, 851):—Ten boilers, arranged in horseshoe form, and each having a central tube, the lower end of which forms a perforated funnel, are almost filled with granulated tin, and six of them are charged with soda lye of 15°Bé. The liquor is drawn off from each, after a suitable amount of boiling, through a siphon passed into the central tube, and is passed from boiler to boiler until of 30°Bé, when it is allowed to settle in a tank. For preparing 'sodium stannate liquor' enough common salt is dissolved in the solution to reduce the proportion of tin to 5 p.c.; and for producing the solid the liquid is evaporated and calcined, and mixed with enough sodium chloride to reduce the tin to 42 p.c.

Sodium stannate is used in order to render cotton goods, such as flannelette, fireproof (W. H. Perkin). The flannelette is impregnated with a solution of sodium stannate of about 45°Tw., squeezed, dried on heated copper drums, passed through a solution of ammonium sulphate of about 15°Tw., in order to precipitate tin oxide, again squeezed, dried, and finished in the usual manner. The tin oxide is probably present in actual combination with the fibre, for the fire-proofing is not destroyed by repeated washing with hot water and soap.

A sodium arsenio-stannate

occurring in shining needles, is sometimes used instead of the ordinary stannate, and is said to give brighter colours and to be more economical. It is prepared by adding nitric acid to a boiling solution of sodium stannate and sodium arsenate, and treating the resulting precipitate of $2\text{SnO}_2 \cdot \text{As}_2\text{O}_3 \cdot 10\text{H}_2\text{O}$ with excess of soda (v. Haeffely, *Dingl. poly. J.* 140, 290; J. Mercer and W. Blythe, *Eng. Pat.* 12807, 1849). In the latter process a sodium phospho-stannate is also employed for the same purposes. Another sodium arsenio-stannate

has been obtained by Prandtl (*Ber.* 1907, 40, 2133).

Potassium stannate K_2SnO_3 is obtained similarly to the sodium salt, and is sometimes employed in dyeing and calico-printing. It crystallises from spontaneously evaporated solutions in transparent oblique rhombic prisms of the composition $\text{K}_2\text{SnO}_3 \cdot 3\text{H}_2\text{O}$ (Marignac, *Ann. de Mines*, [v.] 15, 277; Moberg, *J. pr. Chem.* [i] 28, 230; Ordway, *Amer. J. Sci.* [ii.] 40, 173). It becomes anhydrous when heated to redness.

Potassium stannate is insoluble in alcohol, but dissolves in water to an alkaline solution, 100 parts of water dissolving 106.6 parts at 10° and 110.5 parts at 20° (Ordway, *l.c.*).

Cupric stannate CuSnO_3 has been employed as a green pigment. It is prepared for this purpose by precipitating sodium stannate with copper sulphate, or by addition of a solution of 118 parts of tin in *aqua regia* to a solution of 250 parts of copper sulphate, with subsequent addition of sodium hydroxide in excess.

Chromium-tin compounds. A so-called chromium stannate or 'pink colour' used for producing a blood-red colour in pottery glass,

is prepared by heating a mixture of 10 parts of stannic oxide, 34 parts of calcium carbonate, parts of silica, 1 part of alumina, and 3-4 part of crystallised potassium chromate for several hours in a closed crucible. The red compound produced gives a fine rose-coloured product when washed with dilute hydrochloric acid.

A substance known as *mineral lake*, possessing a fine lilac colour, is used in colouring paper-hangings and for oil painting. It consists of mixture of chromium oxide and excess of stannic oxide, and can be prepared by igniting together 1 part of the former with 50 of the latter (Leykauf, J. pr. Chem. 1892, 19, 127), or by dissolving potassium chromate in 5 or 6 parts of water, and adding this solution to a solution of stannous chloride until precipitation ceases. The damp, washed precipitate is ground with half its volume of nitre, and dried, and the finely-powdered mixture is thrown in small portions into crucible heated to redness and containing some potassium nitrate. After pouring off the supernatant fused salt, the pale-yellow residue is washed free from alkali, and is calcined at a strong heat in a luted crucible until it becomes dense and acquires the desired colour.

A series of 'pinks' have been prepared by moistening equal portions of calcium stannate or mixtures of tin dioxide and whiting with varying proportions of a solution of ammonium dichromate. The mixtures are then dried, fired, cooled, and washed with hot water. The products all contain a more or less constant quantity of chromium, and it is probable that they consist of the colouring agent, chromium oxide, resting on a base of stannic oxide (Lethbridge, Trans. Engl. Ceramic Soc. 1903-1904, 9; see also Hull, Trans. Amer. Ceramic Soc. 1902, 4, 230).

Stannates of many other metals and thio-stannates have also been obtained.

The powdery product of oxidation of tin with hot nitric acid, commonly described as metastannic acid, is a nitrate of metastannic acid, which on washing with water gives rise to metastannic acid as a secondary hydrolytic product. Metastannic acid obtained by the action of nitric acid (sp. gr. 1.40) on tin and careful washing with water, dried in air at ordinary temperature, has the composition $5\text{H}_2\text{SnO}_3 \cdot 4\text{H}_2\text{O}$. It loses its water *in vacuo* over sulphuric acid. It is an amorphous powder, combining with hydrochloric and sulphuric acids with development of heat forming easily hydrolysable compounds. The action of hydrochloric acid on metastannic acid yields a stannyl chloride $5\text{SnO}_2 \cdot 2\text{HCl} \cdot 3\text{H}_2\text{O}$ or $\text{Sn}_2\text{O}_3(\text{OH})_2\text{Cl}_2$. According to Weiser (J. Phys. Chem. 1922, 26, 654), stannic and metastannic acids are not acids, but are hydrated stannic oxides, the composition and properties of which are determined by conditions of formation. There are no definite hydrates of stannic oxide. Hydrated stannic oxide adsorbs colloidal gold, silver, and platinum, forming purple masses, the most common of which is the purple of Cassius.

Application to purple of Cassius of Debye and Scherrer's X-ray method yields an impression, analysis of which shows that this substance does not contain gold in chemical combination, but consists of a mixture of colloidal gold and colloidal stannic acid (A. Huber, Phys. Zeits. 1924, 25, 35; Sci. Abstr. 1924, 27, 457).

It is also obtained by the ready isomerisation of stannic acid, as when a hydrochloric or hydrobromic acid solution of the latter is allowed to stand (Lorenz, Zeitsch. anorg. Chem. 1895, 9, 376).

It is insoluble in ammonia, except when freshly precipitated from a cold solution of a metastannate by an acid, but dissolves in alkaline hydroxides and carbonates, with formation of metastannates.

A colloidal metastannic acid is known (v. Graham, Phil. Trans. 151, 213; Van Bemmelen, Rec. trav. chim. 7, 87; Liebschutz, Chem. News, 1910, 102, 213; Kreis, Schweiz. Chem. Zeit. 1919, 389.)

The meta-acid is said to have a tendering effect on silk fibres (Heermann, Färber-Zeit. 1908, 19, 318; Bayerlein, *ibid.* 1908, 18, 241).

The salts of metastannic acid appear to indicate that the acid has the formula

The metastannates are difficultly crystallisable. When strongly heated, they decompose into stannic oxide and the base. Potassium metastannate $5\text{SnO}_2 \cdot \text{K}_2\text{O} \cdot 4\text{H}_2\text{O}$ is a strongly alkaline salt obtained by dissolving the acid in potash. It is precipitated from aqueous solution by a neutral alkaline salt or by ammonium chloride. Sodium metastannate

is a slightly soluble granular salt obtained like the potassium salt. A hard gummy precipitate of the composition $\text{Na}_2\text{Sn}_2\text{O}_7 \cdot 8\text{H}_2\text{O}$ is obtained by addition of caustic soda to a solution of the above compound of hydrochloric acid and metastannic acid.

Thiometastannates are also known.

Perstannic acid $\text{HSnO}_4 \cdot 2\text{H}_2\text{O}$ is formed when stannic acid is treated with excess of 30 p.c. hydrogen peroxide and the mixture heated to about 70° . On heating to 100° it yields the acid $\text{H}_2\text{Sn}_2\text{O}_7 \cdot 3\text{H}_2\text{O}$. The alkali stannates when similarly treated form the salts corresponding to these acids (Tanatar, Ber. 1905, 38, 1184). When concentrated alkali stannates are electrolysed at low temperature with a low current density they also form perstannates (Coppadoro, Gazz. chim. ital. 1908, 38, i. 489, and *l.c.*).

Salts of tin with oxyacids. These salts, although numerous, are of little technical importance, but a number of solutions containing them are used in dyeing and calico-printing. Stannous sulphate SnSO_4 is obtained as a crystalline powder by evaporating *in vacuo* a solution of tin or stannous hydroxide in dilute sulphuric acid. Stannic sulphate $\text{Sn}(\text{SO}_4)_2$ is obtained as a white salt, soluble in dilute sulphuric acid but mostly precipitated on dilution, by dissolving the hydroxide in sulphuric acid. According to Litte (Compt. rend. 1887, 104, 172), a solution of stannic hydroxide in warm dilute sulphuric acid (1-8) deposits, on concentration, first radiating needles, then rhomboidal lamellae, and finally hexagonal prisms, all colourless and all possessing the composition $\text{Sn}(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$. He has obtained the same product by the action of sulphuric acid on metastannic acid. The crystals deliquesce to a clear liquid. The solution is decomposed, on dilution, with precipitation of the hydroxide. A number of double tin sulphates are known (Weinland and Köhl, Ber.

1906, 39, 2951; *Zeitsch. anorg. Chem.* 1907, 54, 244). *Stannous nitrate* $\text{Sn}(\text{NO}_3)_2$ is obtained by dissolving tin or stannous hydroxide in dilute nitric acid (R. Weber, *J. pr. Chem.* [ii.] 26, 121; Walker, *Chem. Soc. Proc.* 1893, 114; *Engel. L.c.*; Kleinschmidt, *Monatsh.* 1918, 39, 149).

Metastannic nitrate $5\text{SnO}_2 \cdot 2\text{HNO}_3 \cdot 3\text{H}_2\text{O}$ or $\text{Sn}_2\text{O}_5(\text{OH})_2(\text{NO}_3)_2$ is prepared by the action of hot nitric acid on tin; the compound obtained from tin and cold nitric acid consists of a mixture of stannyl nitrate $\text{SnO}(\text{NO}_3)_2$ and metastannic nitrate.

A basic salt of the composition $2\text{SnO} \cdot \text{N}_2\text{O}_5$ is obtained as a white crystalline precipitate by adding a solution of sodium carbonate to the neutral salt in quantity insufficient for complete precipitation. It may also be obtained by digesting the normal salt with stannous hydroxide. It deflagrates at 100° , or on friction. *Stannic nitrate* $\text{Sn}(\text{NO}_3)_4$ crystallises in silky tablets from a solution of stannic hydroxide in nitric acid.

It is also formed by dissolving tin in 70 p.c. nitric acid (Montemartini, *Gazz. chim. ital.* 1892, 22, 384). Even at the ordinary temperature it slowly changes into the meta-salt, and for this reason the white bulky precipitate which it yields with aqueous sodium hydroxide may not dissolve completely in an excess of the reagent; at 45° the change in the stannic nitrate is so rapid that the solution suddenly gelatinises; the transformation is complete by prolonged heating at 100° .

The so-called 'nitrate of tin' or 'physic' used by dyers is a mixture of stannous and stannic chlorides (*v. Stannous chloride, infra*). A solution of tin in nitric acid is, however, also used in dyeing (*v. Crookes, Handb. of Dyeing and Calico Printing*, 1874, 527).

Stannous sulphide SnS is obtained as a tough, crystalline, bluish-grey fusible mass by heating tin with sulphur, or in crystalline scales by fusing the sulphide so obtained with stannous chloride and treating the product with dilute hydrochloric acid. The crystalline sulphide may also be obtained by heating the amorphous form in the electric furnace (Mourlot, *Compt. rend.* 1897, 124, 768). It is obtained as a brown powder, which blackens on drying, by precipitating stannous chloride with sulphuretted hydrogen.

Stannous sulphide is insoluble in normal ammonium sulphide, but dissolves in the yellow sulphide and in alkaline polysulphides (*v. Ditte, Compt. rend.* 1882, 94, 1419), and, with evolution of sulphuretted hydrogen and formation of stannous chloride, in hot hydrochloric acid. Hydrogen chloride acts similarly on the warmed, but not on the cold, sulphide (Ditte, *ibid.* 1883, 97, 42).

Stannous sulphide is sometimes soluble, at other times insoluble, in sodium hydroxide, the cause of this variation being unknown (Perkin, *J. Soc. Chem. Ind.* 1901, 425).

Pure stannous sulphide has m.p. 880° (Pélabon, *Compt. rend.* 1906, 142, 1137). It is slightly radioactive (Campbell, *Proc. Cambridge Philos. Soc.* 1906, 13, 282).

Orthorhombic crystals of stannous sulphide are occasionally met with in tin furnaces, and were supposed at one time to be an allotropic form of tin (*cf. Spencer, Min. Mag.* 1921, 19, 113).

Stannic sulphide SnS_2 cannot be prepared by simply heating tin and sulphur together, because the heat generated is sufficient to reduce the disulphide to monosulphide, but it may be so obtained when sufficient ammonium chloride or other volatile substance is present to moderate the action. Woulfe (*Phil. Trans.* 1771, 61, 114; also Gmelin's *Handbook*, 5, 79) describes a number of methods of preparing this compound, which is used as a bronze powder for bronzing articles of gypsum, wood, &c.

Various mixtures of tin chloride and sulphur, or tin, sulphur, and ammonium chloride, or tin amalgam or tin sulphide with sulphur and ammonium chloride, are heated in retorts or covered crucibles, at first gently for a few hours, then more strongly, but not quite to redness. On cooling the greater portion of the sulphide is at the bottom, but the purer and finer crystals are found sublimed at the top.

Crystalline stannic sulphide, sp.gr. 4.425, is often known as 'Mosaic gold,' *aurum mosaicum*, or *musivum*. For a reddish shade, 50 grms. of 50 p.c. tin amalgam, 25 of crystallised stannous chloride, 35 of ammonium chloride, and 35 of sulphur are finely powdered together and ignited gradually in a glass retort covered with asbestos, in the flame of a large blow-pipe, which is moved about periodically. During the operation the colour of the mass should be dark brown. If it becomes black owing to the formation of stannous sulphide, the flame should be lowered. For yellowish shades, 50 grms. of crystallised stannous chloride and 25 grms. of flowers of sulphur are employed. The yield is 57 p.c. of the theoretical (Langutt, *Zeitsch. angew. Chem.* 1897, 557). V. GOLD, MOSAIC.

When heated, stannic sulphide sublimes, with partial decomposition into sulphur and stannous sulphide. It dissolves readily in alkalis, but not in acids, except *aqua regia*. It fuses in a current of chlorine, and absorbs 6 molecules of the gas, forming a yellow crystalline compound of the composition $\text{SnCl}_4 \cdot 2\text{SnCl}_2$ (Rose, *Pogg. Ann.* 42, 517). When heated with iodine in a current of carbon dioxide it gives a brown, crystalline, fusible mass of the composition $\text{SnS}_2 \cdot \text{I}_2$ (Schneider *J. pr. Chem.* [i.] 79, 419).

The dirty-yellow precipitate obtained by passage of sulphuretted hydrogen through a solution of a stannic salt consists of a mixture of stannic sulphide and stannic hydroxide; this dissolves in alkaline sulphides, with formation of thiostannates (Kühn, *Annalen*, 1852, 84, 110), and also in alkalis and hydrochloric acid. Ditte (*Compt. rend.* 1882, 95, 641) describes several double sulphides or thiostannates and also seleniothio-stannates.

Hydrogen chloride or bromide convert the sulphide into the corresponding halide (Kelley and Smith, *Amer. Chem. J.* 1896, 18, 1096).

When stannic sulphide is allowed to remain in contact with ammonia, filtered, and the filtrate acidified, a white mass of an amorphous stannic sulphide is formed. It dissolves readily in ammonia to an orange-red solution, and becomes yellow on drying (Schmidt, *Ber.* 1894, 27, 2739; *Chem. Zentr.* 1907, i. 397; *Materne, ibid.* 1906, ii. 557; Lang and Carson, *J. Soc. Chem. Ind.* 1902, 1018). When dried in air it loses a little sulphur and becomes dark brown, hard, and brittle. This sulphide behaves like a

colloidal sulphide. Colloidal stannic sulphide has been obtained (Spring, Ber. 1883, 16, 1142; Schneider, Zeitsch. anorg. Chem. 1894, 5, 83; see also Biltz, Chem. Zentr. 1904, i. 1040).

Tin sesquisulphide Sn_2S_3 is obtained by gentle ignition of 3 parts of stannous sulphide and 1 of sulphur in a retort. It forms a yellowish-grey mass of metallic lustre (Antony and Niccoli Gazz. chim. ital. 1892, 22, ii. 408). A sub-sulphide, Sn_3S_2 , of a grey colour, and crystalline, has been observed to occur (Epprecht, Chem. Zeit. 1915, 39, 341).

Stannous selenide SnSe is obtained with incandescence when selenium is heated with tin as a light-grey lustrous body of crystalline fracture, not reducible by hydrogen. It is obtained as a dark-brown precipitate, which becomes nearly black on drying, by passing seleniuretted hydrogen into stannous chloride solution. It dissolves in alkalis and alkaline sulphides (v. Uelsmann, Annalen, 1860, 116, 124; Pélahor l.c.).

Stannic selenide SnSe_2 is obtained by passing seleniuretted hydrogen into stannic chloride solution as a yellowish-red precipitate which dries to a brown powder, soluble in caustic alkalis and alkaline sulphides, and forming stannous selenide when heated in hydrogen.

According to Little (Annalen, 1859, 112, 213), it is obtained as a tin-white, lustrous, easily-fusible mass, unaffected by hydrochloric acid, but readily decomposed by nitric acid, by heating tin in selenium vapour. Ditte (Compt. rend. 1882, 95, 641; *ibid.* 1887, 104, 174) describes some double selenides corresponding with the thiostannates (v. *Stannic sulphide*).

A telluride is also known.

Stannous chloride SnCl_2 is obtained in the anhydrous condition by heating tin in hydrogen chloride, or by heating a mixture of equal weights of 'feathered' (i.e. granulated) tin or filings and mercuric chloride; and in monoclinic prisms of the composition $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ (O. Henry, J. Pharm. 12, 134) by evaporating a solution of tin in hydrochloric acid.

Stannous or stannic chloride may be obtained as desired by the following process: Stannous chloride, formed by the action of a solution containing chlorine on tin, is subjected to the action of a gaseous or fluid mixture containing free chlorine, hydrochloric acid, and air or oxygen (Young, J. Amer. Chem. Soc. 1901, 23, 119, 450). Stannic chloride is thus formed which when made to react with tin reforms stannous chloride (U.S. Pats. 810454, 810455, 810456, 810897, 1906; Df. R. P. 184494). For other methods, see D. R. PP. 176456, 176457, 181876, 188018.

The crystals melt at 40° , and at 100° lose most of their water, together with a little hydrochloric acid. When dried *in vacuo*, or over sulphuric acid, they become anhydrous.

The anhydrous chloride fuses at 249.3° to an oil which boils at $617^\circ\text{--}628^\circ$ (Carmelley and Carleton Williams, Chem. Soc. Trans. 1879, 563), or, according to Biltz and V. Meyer (Ber. 1888, 21, 22), at 606.1° . The anhydrous chloride is sometimes called 'butter of tin,' although that term is usually applied to the hydrated tetrachloride. Stannous chloride is soluble in water and alcohol. On dilution, the aqueous solution becomes turbid, from precipitation, with separation of hydrochloric acid, of a basic chloride

$2\text{SnO} \cdot \text{HCl} \cdot \text{H}_2\text{O}$, which is also formed when the clear solution is exposed to the air. Mallet (Chem. Soc. Trans. 1879, 524) has observed a gelatinous deposit of the composition $\text{SnO}_2 \cdot \text{HCl}$, to which he has applied the term *chlor-stannic acid*, in a solution of stannous chloride after long standing. Donath (Rep. Anal. Chem. 7, 77) considers that this compound is produced, together with stannic hydroxide, by the action of light on aqueous stannous chloride.

Keller (J. Amer. Chem. Soc. 1917, 39, 2354) found a crystalline deposit of $\text{SnCl}_2 \cdot \text{SnO}$, in cavities in a piece of tin found in an aboriginal cemetery in Florida.

R. Engel (Compt. rend. 1888, 106, 1398) has obtained a compound of the composition

which he calls *chlorostannic acid*, by passing chlorine over the hydrate $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$. The crystals fuse to a clear liquid having the above composition, and depositing, when cooled to -40° , slender silky needles which melt at about -27° . According to Ditte (*ibid.* 1883, 97, 42), however, the liquid contains a chloride of the composition $\text{SnCl}_2 \cdot \text{H}_2\text{O}$, which is also formed by the action of concentrated hydrochloric acid on the chloride $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$.

Other basic stannous chlorides are

(Carson, J. Amer. Chem. Soc. 1919, 41, 1969).

When stannous chloride is electrolysed crystalline tin can be obtained (Saposhnikoff, J. Russ. Phys. Chem. Soc. 1905, 37, 153).

Stannous chloride forms crystalline double chlorides with the alkalis (v. Benas, Chem. Zentr. 1884, 957, forming salts of the composition $\text{SnCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O}$ and $\text{SnCl}_2 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$). Similar compounds are formed with NH_4Cl (Rimbach and Fleck, Zeitsch. anorg. Chem. 1915, 94, 139). It absorbs dry ammonia, with formation of a compound of the composition $\text{SnCl}_2 \cdot \text{NH}_3$, and also $\text{SnCl}_2 \cdot 2\text{NH}_3$ (Naumann, Ber. 1910, 43, 313).

A third compound, $3\text{SnCl}_2 \cdot 2\text{NH}_3$, is formed by the action of gaseous ammonia on stannous chloride between 120° and 300°C . It is a crystalline mass of reddish-brown colour, powerfully double-refractive, and appears to be the most stable of the compounds of ammonia and stannous chloride (Sofianopoulos, Compt. rend. 1911, 152, 865).

Stannous chloride is soluble in alcohol and in ether, the latter solution gives a brownish-red ring when added to hydrochloric acid containing 1/50 mgrm. of arsenious acid (Jong, Zeitsch. anorg. Chem. 1902, 41, 596).

Like other stannous salts, stannous chloride is a strong reducing agent and is employed as such, both for the reduction of organic and inorganic compounds. It is also used in the analysis of a number of substances (Henriet, Compt. rend. 1901, 132, 966; Weil, *ibid.* 1902, 134, 115).

A small quantity of stannous chloride is said to increase the yield of alcohol in fermentation processes; it also accelerates the revivification of the yeast sown in must, and cultures taken from the yeast so formed retain a similar property for a certain length of time (Gimel, Compt. rend. 1908, 147, 1324).

Stannous chloride and other stannous salts

are largely used in dyeing and calico-printing under the name 'tin-salts' or 'tin crystals' (Dreher, *Färber-Zeit.* 7, 145; Reisz, *ibid.* 221, 222; Binder, *Bull. Soc. Ind. Mulhouse*, 1900, 92; Paterson, *J. Soc. Dyers Col.* 1906, 22, 188; Coberti, *J. Soc. Chem. Ind.* 1899, 829).

Stannic chloride SnCl_4 was first prepared by Libavius in 1605, who obtained it by distilling a mixture of tin or its amalgam with excess of mercuric chloride; he termed the product *Spiritus argenti vivi sublimati*. It may also be prepared by the action of chlorine (Lorenz, *Zeitsch. anorg. Chem.* 1895, 10, 44; Beckmann and Geib, *ibid.* 1906, 51, 96); or phosphorus pentachloride on tin (Goldschmidt, *Chem. Zentr.* 1881, 489); or by the action of chloroform on stannic oxide (Renz, *Ber.* 1906, 39, 249). Technically, it is generally prepared by the action of chlorine or hydrochloric acid on tin-plate waste or tin waste residues from dye works and a large number of patents have been registered for this purpose (see *Fr. Pats.* 371067, 1906; 392615, 401125, 405851, 406300, 1909; Heermann, *Färber-Zeit.* 1907, 18, 34; *U.S. Pats.* 884756, 877261, 877248, 1908; 976990, 958986, 1910; *D. R. P.* 222838; *J. Soc. Chem. Ind.* 1907, 253; *ibid.* 1908, 160; *ibid.* 1909, 21, 1087; *ibid.* 1910, 424, 1105; see also *U.S. Pats.* 883140, 883141, 1908; *Fr. Pats.* 386594, 388089, 1908).

Stannic chloride may also be prepared by the action of sulphur dioxide upon stannous chloride in presence of strong hydrochloric acid

(Smythe and Wardlaw, *Proc. Durham. Phil. Soc.* 1914, 5, 187).

The chloride distils over as a colourless mobile liquid, boiling at 113.89° at 760 mm. pressure (Thorpe, *Chem. Soc. Trans.* 1880, 37, 331), and solidifying at -33° to small white crystals (Besson, *Compt. rend.* 1889, 109, 940).

The liquid has sp.gr. 2.2788 at $0^\circ/4^\circ$ (Thorpe, *l.c.*), and, owing to its high refractive index, presents a very brilliant appearance.

When exposed to the air, it emits dense white fumes, and is finally converted into a crystalline hydrate $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$ (Lewy, *Compt. rend.* 1845, 21, 369), which is also obtained, with evolution of heat, by mixing stannic chloride with one-third its weight of water. This hydrate is sometimes known as 'butter of tin,' or, by the dyers, as 'oxymuriate of tin.' Hydrates of the composition $\text{SnCl}_4 \cdot 3\text{H}_2\text{O}$ and $\text{SnCl}_4 \cdot 8\text{H}_2\text{O}$ are also known. For the sp.gr. of various solutions of this salt, see Heerman (*Chem. Zeit.* 1907, 31, 680).

On hydrolysis, it first forms the intermediate compound SnCl_3OH , and then stannic acid; by alcoholysis it gives the compound SnCl_3OEt (Pfeiffer, *Ber.* 1905, 38, 2466; von Biron, *J. Russ. Phys. Chem. Soc.* 1906, 37, 963).

Stannic chloride forms crystalline double chlorides, sometimes called *chloro-stannates* or *stannichlorides* with the alkaline chlorides (Bellucci and Parravano, *Atti R. Accad. Lincei*, 1904, v. 13, ii. 307; von Biron, *J. Russ. Phys. Chem. Soc.* 1904, 36, 489, 933; *ibid.* 1905, 37, 963, 994, 1036; Weinland and Bames, *Zeitsch. anorg. Chem.* 1909, 62, 250; Druce, *Chem. News*, 1918, 117, 193); thus, $\text{SnCl}_4 \cdot 2\text{KCl}$ and

the latter forming the 'pink salt' formerly much used by dyers.

Stannic chloride dissolves phosphorus and iodine, and mixes with bromine and carbon disulphide. It converts mercury into calomel, and is itself decomposed by nitric acid, with precipitation of metastannic acid. Among the substances produced by direct combination with other compounds may be mentioned $\text{SnCl}_4 \cdot 2\text{NH}_3$, a soluble volatile solid (Rose, *Pogg. Ann.* 16, 63); $3\text{SnCl}_4 \cdot 2\text{PH}_3$, a yellow fuming solid (Rose, *ibid.* 24, 159); $\text{SnCl}_4 \cdot \text{N}_2\text{O}_5$, a yellow amorphous mass; $\text{SnCl}_4 \cdot \text{SO}_2$, a white solid (Rose, *ibid.* 44, 320); $\text{SnCl}_4 \cdot \text{PCl}_5$ and $\text{SnCl}_4 \cdot \text{POCl}_3$ (Casselmann, *Annalen*, 1852, 83, 257); $\text{SnCl}_4 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$, a white crystalline compound (Coldridge, *Phil. Mag.* [v.] 29, 383, 480). A yellow crystalline substance $\text{SnCl}_4 \cdot 2\text{SCl}_2$, fusing below 30° , is obtained by the action of chlorine on stannic sulphide (Rose, *Pogg. Ann.* 42, 517).

When a cooled solution of stannic chloride in chloroform is treated with nitric peroxide, the compound $3\text{SnCl}_4 \cdot 4\text{NOCl}$ is formed (Thomas, *Compt. rend.* 1896, 122, 32), whilst if such a solution is treated with nitrogen sulphide dissolved in chloroform, red crystals of the substance $\text{SnCl}_4 \cdot 2\text{N}_2\text{S}_2$ are deposited (Davis, *Chem. Soc. Trans.* 1906, 1576).

Stannic chloride absorbs large quantities of chlorine at low temperatures, with considerable increase in volume and lowering of the melting-point (Besson, *Compt. rend.* 1889, 109, 940).

Stannic chloride is used in dyeing as a mordant, and silk is weighted with it before dyeing (Froenkel and Fasal, *J. Soc. Chem. Ind.* 1898, 148; *ibid.* 1904, 899). Its use for this purpose is said to have been discovered by the Dutch chemist, Drebbel, in 1630, who found that cochineal gives a permanent brilliant red dye in the presence of dilute stannic chloride.

A patent was taken out in England as early as 1748 by O. Pawl (Specification No. 630, 1748) for the use of tin dissolved in *aqua fortis*, with addition of ammonium chloride, for dyeing scarlet.

The older methods of preparing tin salts for this purpose, whereby tin is dissolved in excess of hydrochloric acid, and the solution is oxidised by means of chlorates, have the disadvantage of producing a very impure product. The mordanting and weighting is due only to the stannic chloride and the impurities tend to weaken the fibres, to make the latter more sensitive to light, and to bring about the gradual deterioration in the strength of the material. To avoid this, Sperry has devised a special apparatus whereby pure anhydrous stannic chloride may be prepared by the treatment of impure tin-bearing materials with ordinary commercial chlorine (*J. Soc. Chem. Ind.* 1908, 312, 404, 628, 749, 978; *Eng. Pat.* 389188; *U.S. Pats.* 882354, 887538, 885391. For Fig. and description of apparatus, see *J. Soc. Chem. Ind.* 1908, 313). From the pure stannic chloride thus prepared all the compounds of tin needed by dyers may be obtained in pure condition.

According to Fiehler and Müller (*Arch. Sci. phys. nat.* 1916, [iv.] 42 123), the weighting of silk by steeping it in a solution of stannic chloride is due to a true chemical combination between the stannic chloride and the fibroin and its component amino-acids, followed by hydrolysis

during the washing process. After the hydrolysis the stannic acid is precipitated in the silk and the fibroin is regenerated and is capable of taking up more stannic chloride.

A solution consisting of stannic and stannous chloride, obtained by dissolving tin in *aqua regia*, is used in the preparation of fuchsine under the name 'nitrate of tin' or 'physic' (see above).

It is now more usual, however, to employ the crystalline pentahydrate $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$.

A solution consisting of stannic chloride, containing more or less stannous chloride, and used in dyeing under the name 'oxychloride of tin' or 'pink cutting liquid,' is prepared by adding 1 part of stannous chloride to $1\frac{1}{2}$ parts of nitric acid of sp.gr. 1.31 in portions, with constant stirring, to prevent boiling over from the violence of the action; or by dissolving 337 parts of stannous chloride in 300 parts of hydrochloric acid (20°Tw.), with the aid of a minimum of water, and adding gradually 58 parts of potassium chlorate.

In small quantities stannic chloride may be added to the sizing mass for cotton warps in order to prevent the too rapid decomposition of the size (Textile Colorist, 1893, 15, 7).

For the detection of tin in mordanted cloth, see Paterson (J. Soc. Dyers, 1906, 22, 189); Silbermann (Bull. Soc. chim. Mulhouse, 1906, 76, 357).

A rapid and delicate method for detecting sodium chloride in commercial stannic chloride, consists in precipitating the former with 99.5 p.c. alcohol saturated with hydrogen chloride (Heermann, Chem. Zeit. 1907, 31, 27).

Stannous bromide SnBr_2 is obtained in solution by dissolving tin in hydrobromic acid (Balard, Ann. Chim. 1826, [ii.] 32, 337). It may be obtained as an anhydrous, pale-yellow, crystalline mass by heating tin in hydrobromic acid vapour and re-distilling the product (Freyer and Meyer, Zeitsch. anorg. Chem. 1892, 2, 1).

According to Rayman and Preis (Annalen, 1884, 223, 323), it melts at 215.5° to a pale-yellow oily liquid, of sp.gr. 5.117 at 17° . According to Carnelley and Carleton Williams (Chem. Soc. Trans. 1879, 564), it melts at 259° , and boils at 617° – 634° .

A hydrate $\text{SnBr}_2 \cdot \text{H}_2\text{O}$ separates in needles or thin plates from the greenish solution of tin in warm concentrated hydrobromic acid. It loses its water in dry air, or when heated to 70° – 80° . It dissolves in a little water, but is decomposed by excess, with precipitation of a gelatinous precipitate (v. Benas, Chem. Zentr. 1884, 957).

A hydrate $\text{SnBr}_2 \cdot 2\text{H}_2\text{O}$, crystallising in large monoclinic tables, is also obtained from the solution of tin in hydrobromic acid (Benas, l.c.).

Benas, Rayman and Preis have also described compounds of stannous bromide with potassium and ammonium bromides.

Stannic bromide SnBr_4 was discovered in 1826 by Balard (Ann. Chim. [ii.] 32, 337). It is obtained by adding bromine drop by drop to strips of tin, the temperature being kept between 35° and 59° (Lorenz, Zeitsch. anorg. Chem. 1895, 9, 366); or preferably, on account of the violence of the action with pure bromine, by gradually adding the tin to a solution of bromine in carbon disulphide, or by passing

the vapour of bromine over heated tin (Carnelley and O'Shea, Chem. Soc. Trans. 1878, 55).

Stannic bromide forms a white iridescent deliquescent mass, which, by distillation, is obtained in small, well-formed, highly lustrous crystals, melting at 30° and boiling at 210° (uncorr.) (Carnelley and O'Shea, l.c.), or at 203° (corr.) (Rayman and Preis, Chem. Zentr. 1882, 773), and having a sp.gr. of 3.349 at 3.5° (Rayman and Preis, l.c.).

It fumes in the air, and dissolves readily in water. The solution deposits stannic hydroxide on heating or after standing. A hydrate $\text{SnBr}_4 \cdot 4\text{H}_2\text{O}$ is obtained in colourless transparent, fuming crystals, by exposing the anhydrous bromide to moist air, or by dissolving in a little water and evaporating over sulphuric acid. Oxybromides $\text{Sn}_2\text{Br}_2\text{O} \cdot 12\text{H}_2\text{O}$ and $\text{SnBr}_2\text{O} \cdot 10\text{H}_2\text{O}$, obtained from stannic bromide, and a compound $\text{SnBr}_4 \cdot 2\text{NH}_3$, obtained by absorption of ammonia by the warmed bromide, are also known (Rayman and Preis, l.c.).

Stannic bromide unites with ether to form a deliquescent crystalline body $\text{SnBr}_4(\text{C}_2\text{H}_5)_2\text{O}$ (Nickles, Compt. rend. 1861, 52, 869). By evaporating solutions of the mixed bromides, Raymond and Preis (l.c.) have obtained the following double bromides or stannibromides: $2\text{NaBr} \cdot \text{SnBr}_4 \cdot 6\text{H}_2\text{O}$, in pale-yellow, soluble crystals; $\text{CaBr}_2 \cdot \text{SnBr}_4 \cdot 6\text{H}_2\text{O}$, in slender deliquescent needles; $\text{MgBr}_2 \cdot \text{SnBr}_4 \cdot 10\text{H}_2\text{O}$, in pale-yellow, deliquescent tables; $\text{MnBr}_2 \cdot \text{SnBr}_4 \cdot 6\text{H}_2\text{O}$, in large, pale-yellow, deliquescent crystals; $\text{FeBr}_2 \cdot \text{SnBr}_4 \cdot 6\text{H}_2\text{O}$, in greenish, granular crystals; $\text{NiBr}_2 \cdot \text{SnBr}_4 \cdot 8\text{H}_2\text{O}$, in apple-green, granular, deliquescent crystals; and

in yellowish-red, deliquescent tablets (see also Leteur, Compt. rend. 1891, 113, 540).

Stannous iodide SnI_2 is obtained by dissolving tin in concentrated hydriodic acid. At the ordinary pressure solution is extremely slow, but it proceeds more rapidly in a sealed tube at 120° – 150° (Wöhler and Dünhaupt, Annalen, 1853, 86, 374). It may also be obtained in yellowish-red needles, slightly soluble in water, and readily soluble in solutions of alkaline chlorides and iodides, and in hydrochloric acid, by addition of potassium iodide in slight excess to a concentrated solution of stannous chloride (Warden, Pharm. J. 1897, 58, 61). The aqueous solution is decomposed by much water, with separation of hydriodic acid and a yellow, insoluble body the composition of which varies with the amount of water present (Personne, Compt. rend. 1862, 54, 216).

The formation of the iodide may be used as a delicate test for tin. One c.c. of the solution to be tested is treated with 0.5 c.c. of 5 p.c. potassium iodide solution and 0.5 of strong sulphuric acid added through a pipette reaching to the bottom of the test-tube. In presence of tin a yellow precipitate is produced at the plane of contact of the two layers (Heller, Zeitsch. Chem. 1922, 61, 180).

Stannous iodide melts at 316° (Carnelley and Carleton Williams, Chem. Soc. Trans. 1879, 564) and volatilises at a red heat. It absorbs dry ammonia, with formation of a white body having the composition $2\text{NH}_3 \cdot \text{SnI}_2$ (Rammelsberg, Pogg. Ann. 48, 169; Ephraïm and Schmidt,

Ber. 1909, 42, 3856). It unites with other metallic iodides, with hydrogen iodide (Young, J. Amer. Chem. Soc. 1897, 19, 851), and with stannous chloride.

Stannic iodide SnI_4 is obtained in yellowish-red octahedra by heating tin filings, preferably moistened with carbon disulphide or tetrachloride, with iodine to a temperature above 50° .

It has sp.gr. 4.696 at 11° (Bödeker, Die Beziehung zwischen Dichte und Zusammensetzung, &c., Leipzig, 1860), m.p. 146° and b.p. 295° (Personne, J. 1862, 172), m.p. 143° , b.p. 341° (corr.) (Emich, Monatsh. 1904, 25, 907). It sublimes at 180° .

It dissolves in carbon disulphide, carbon tetrachloride, alcohol, chloroform, and benzene. Water decomposes it into stannic hydroxide and hydriodic acid.

Its formation under certain conditions may be used as a delicate test for tin (Mazuir, Ann. Chim. anal. 1919, [ii.] 2, 9).

By the action of ammonia on stannic iodide, dissolved in carbon disulphide, a white substance $\text{SnI}_4 \cdot 8\text{NH}_3$, insoluble in water, is formed (Ephraim and Schmidt, l.c.).

Stannous fluoride SnF_2 is obtained in small, opaque, white, monoclinic tables of sweetish astringent taste, by evaporating a solution of stannous hydroxide in hydrofluoric acid.

Stannic fluoride SnF_4 is obtained in aqueous solution by dissolving the hydrated dioxide in hydrofluoric acid; or as a hygroscopic, white crystalline substance by the action of anhydrous hydrofluoric acid on stannic chloride (Ruff and Plato, Ber. 1904, 37, 673). It has sp.gr. 4.78 at 19° , b.p. 705° , but sublimes below this temperature. It combines with other fluorides forming a characteristic series of crystalline double salts, the *stannifluorides*, which are isomorphous with the corresponding fluorides of titanium, germanium, zirconium, and silicon (Marignac, J. 1859, 110; Emich, Monatsh. 1904, 25, 907; Ruff and Albert, Ber. 1905, 38, 55; Hall and Smith, Chem. Zentr. 1905, ii. 1462).

A number of mixed halogen compounds, such as SnCl_2Br , SnCl_2I , SnBr_2I , &c., have been described (Besson, Compt. rend. 1897, 124, 683; Lenormand, J. Pharm. Chim. 1898, [vi.] 8, 249; *ibid.* 1899, 10, 114). According to Anger (Compt. rend. 1909, 149, 860), most of these compounds are only mixtures, thus, $2\text{SnBr}_2\text{I} = \text{SnBr}_4 + \text{SnI}_4$, &c.

Phosphides.—Tin combines directly with phosphorus, forming a series of phosphides, which are used for the production of phosphor-bronze (Emmerling, Ber. 1879, 12, 155; Natanson and Vortmann, *ibid.* 1877, 10, 1460; Künzel, Dingl. poly. J. 1888, 270, 166; D. R. P. 103966; Stead, J. Soc. Chem. Ind. 1897, 206).

Tin phosphide Sn_3P_2 has a silver-white colour, crystallises in spangles, sp.gr. 5.18, and begins to dissociate at 480° .

The phosphide SnP is also a crystalline substance, sp.gr. 4.10. It has a metallic appearance, begins to dissociate into phosphorus and Sn_3P_2 at 415° , and is attacked violently by fuming nitric acid (Jolibois, Compt. rend. 1909, 48, 636). Other phosphides have also been described.

Tin hydride.—According to Vaubel (Chem. Zeit. 1924, 48, 351), a 5 p.c. solution of acetic

acid or a 1 p.c. solution of oxalic acid in contact with tin-plate containing rusty spots causes the evolution of tin hydride. The same effect is produced with pure tin in contact with metallic Zn , but the amount of hydride formed is much smaller. It is suggested that the formation of tin hydride in solution may account for cases of poisoning by eating tinned foods that show rust-spots (J. Soc. Chem. Ind. 1924, 43, B. 560).

Tin hydride is formed invariably when nascent hydrogen is liberated in the presence of tin; its production when tin is dissolved rapidly in hydrochloric acid accounts for the peculiar odour of the gas (Kastner, 1821).

The compound obtained by the action of tin hydride on silver nitrate solution has approximately the composition SnAg_4 .

During the dissolution of polished tin in hydrochloric acid, a black powder is deposited which dissolves only very slowly even in the concentrated acid; it is suggested that this is a peculiar modification of the metal which is produced by the reduction of stannous chloride by nascent hydrogen (W. Vaubel, Ber. 1924, 57, (B) 515; cf. Paneth and Fürth, Chem. Soc. Abstr. 1923, 124, ii. 41; 1924, 126, ii. 414; Paneth and Rabinovitch, Ber. 1924, 57, [B] 1877; Chem. Soc. Abstr. 1925, 128, ii. 59).

An unstable tin carbonate Sn_2CO_3 is also known (Deville, Ann. Chim. 1852, [iii.] 35, 4, 48; see also Moissan, Compt. rend. 1897, 125, 840).

Quadrivalent tin and trivalent arsenic in dilute sulphuric or hydrochloric acid may be completely separated by treatment with hydrogen sulphide after the addition of a little hydrofluoric acid. The separation is effected by treating the solution in a platinum dish with 2.5 c.c. of 48 p.c. hydrofluoric acid, heating for a few minutes, and when cold diluting to 300 c.c. The solution is then treated with a rapid stream of hydrogen sulphide for 30 minutes, when arsenious sulphide alone is precipitated. The separation is both rapid and quantitative (Le R. W. McCay, J. Amer. Chem. Soc. 1923, 45, 1187–1191; J. Soc. Chem. Ind. 1923, 42, 680 A.).

ORGANIC COMPOUNDS OF TIN.

Stannous acetate, oxalate, citrate, and tartrate are employed in dyeing and calico-printing, being generally prepared by addition of an alkaline salt of the acid to a solution of stannous chloride, or by dissolving the precipitated hydroxide in the acid. Liechti and Schwitzer (Mittheilungen des Tech. Gew. Museums, 1886, 41) have indicated the value of some of these as mordants (Platsch, Zeitsch. anorg. Chem. 1899, 20, 308; Rosenheim and Aron, *ibid.* 1904, 39, 171; Paterson, l.c.; Henderson, Orr, and Whitehead, Chem. Soc. Trans. 1899, 555).

The ancient Egyptians are believed to have used basic tin citrates (prepared by the action of lemon juice or citric acid on tin), as a mordant, in dyeing the tapestries discovered in the tombs of Antinoë (Gillieron, Bull. Soc. Mulhouse, 1907, 77, 148). Basic tin citrate forms a very efficient mordant for yellow dyes on wool, giving pure intense colours.

Stannous formate is prepared by dissolving precipitated stannous hydroxide in dilute formic acid. It forms white anhydrous crystals, which decompose above 100° (Goldschmidt, Chem. Zeit. 1907, 31, 608).

Tin forms a number of alkyl derivatives of the type SnR_4 , $\text{SnR}^1\text{R}^2\text{R}_2$, &c. (Letts and Collie, Chem. Soc. Proc. 1886, 166; Pope and Peachy, *ibid.* 1903, 290; Polis, Ber. 1889, 22, 2915; Pfeiffer and Schnurmman, *ibid.* 1904, 37, 319; Werner, Zeitsch. anorg. Chem. 1898, 17, 99; Pfeiffer, *ibid.* 1910, 68, 102).

Methyl-stannic acid or methyl-stannoxylic acid $\text{MeSnO}\cdot\text{OH}$ is formed when a mixture of methyl iodide, stannous chloride, and potassium hydroxide is allowed to stand for a day or two and the alkali is then removed by passing carbon dioxide into it. It can also be obtained pure by treating methyl-stannic bromide or iodide with ammonia. It is an odourless white powder, insoluble in water and organic solvents, but soluble in mineral and some organic acids, and in alkali hydroxides. With hydrobromic acid it yields *methyl-stannic bromide* or methyl stannibromoform SnMeBr_3 , m.p. 53° , which has also been obtained by other methods. The corresponding *iodide* or *iodoform*, MeSnI_3 , m.p. 86° , and the compounds SnMe_2Br_2 ; SnMe_2O ; SnMe_2SH and methyl-stannichloroform, m.p. 105° – 107° , b.p. 179° – 180° , have also been prepared (Pfeiffer and Lenhardt, Ber. 1903, 36, 1054, 3027; Pope and Peachy, Proc. Roy. Soc. 1903, 72, 7; Chem. Soc. Proc. 1900, 42, 116; Pfeiffer, Ber. 1904, 37, 4618; Shukoff, Ber. 1905, 38, 2691).

The potassium salt of *ethylstannic acid* is formed by the interaction of stannous chloride, ethyl bromide, and potassium hydroxide:

On treatment with dilute hydrochloric acid ethylstannic acid is formed as a white amorphous gelatinous substance, becoming yellowish-brown, transparent and horny on drying. For its salts, see Druce, Chem. Soc. Trans. 1921, 760).

The tin halogen compounds form a number of double compounds with aliphatic and aromatic amines (Cook, Amer. Chem. J. 1899, 22, 435; Richardson and Adams, *ibid.* 446; Slagle, *ibid.* 1898, 20, 633).

Pyridine stanni-iodide $(\text{C}_5\text{H}_5\text{N})_2\text{H}_2\text{SnI}_2$ is formed when an alcoholic solution of pyridine hydriodide is added to stannic iodide dissolved in alcoholic hydrogen iodide. It forms bluish-black glistening needles. The analogous *quinoline salt* $(\text{C}_9\text{H}_7\text{N})_2\text{H}_2\text{SnI}_2$ forms black needles. Both these compounds decompose gradually, liberating iodine (Rosenheim and Aron, Zeitsch. anorg. Chem. 1904, 39, 170). Similar chlorides, bromides and alkyl derivatives have also been prepared (Pfeiffer, Annalen, 1910, 376, 310; see also Hayes, J. Amer. Chem. Soc. 1902, 24, 360).

A number of other organic compounds of tin have also been prepared (Fischer, Monatsh. 5, 426; Werner and Pfeiffer, l.c.; Thiele and Dimroth, Annalen, 1899, 305, 102; Pfeiffer and Lenhardt, l.c.; Dilthey, Ber. 1903, 36, 925; Rosenheim and Levy, *ibid.* 1904, 37, 3662; Rosenheim and Schnabel, *ibid.* 1905, 38, 2777; Weinland and Barnes, l.c.; Pfeiffer, Annalen, 1910, 376, 285; Druce, Chem. Soc. Trans. 1921, 758; Chem. Soc. Abstr. 1925, i. 798; Kraus and Gress, Chem. Soc. Abstr. 1925, i. 1394; Kraus, *ibid.* 1925, i. 1253, 1254; Vorländer, *ibid.* 1925, i. 1256).

According to Miak (Compt. rend. 1923, 176, 138) tin exists normally in the human organism; the liver has the highest content, followed by the stomach, kidneys, lungs, and brain. 0.03–0.04 grm. in 100 grms. of human viscera is not excessive in amount.

TINCAL v. BORAX.

TIN MORDANTS v. DYING.

TIN PLATES. *History.*—Although the art of tinning brass and copper was well known to the Romans (*v. supra*), the production of sheet iron coated with tin, or 'tin plate,' is of a considerably later period. The art was probably of German origin, and existed in Bohemia prior to 1620. About this time the manufacture was introduced into Saxony, and speedily developed into a thriving industry. Unsuccessful attempts, with which M. Réaumur was connected, were made to introduce the manufacture into France. About 1670 an English company was formed to start a tin-plate works in this country, and Mr. Yarranton was sent to Germany to learn the art. Works were started at Pontypool, and met with some success, but were stopped, owing to the grant of a patent for the manufacture to E. Hemming in 1691. Works were, however, once more started in 1720 at Pontypool, and these were gradually followed by others, particularly in South Wales, which gradually became the most important seat of the manufacture in the world. In the earlier processes of manufacture the plates were hammered by hand from iron made in the charcoal hearth, while the surface was cleaned from scale by immersion for several days in sour barley-water, instead of for a few minutes in dilute sulphuric acid, as at present.

In 1728, the *rolling* of sheets was introduced by Hanbury, of Pontypool, while sulphuric acid was substituted for barley-water in 1806. The rolling of tin plates as they leave the tin pot, which saves metal and improves the surface, was introduced by Morewood (who took out many patents for coating metals) in 1866, since which time a great variety of machines have been introduced for use in the tinning process.

Pickling, machines have superseded hand labour, while iron made in the old-fashioned open-hearth refinery (or puddling furnace for second qualities) has been generally replaced by steel. Siemens' steel was used about 1875, Bessemer steel about 1880, and basic steel was introduced a few years later (*v. P. W. Flower, Origin and Progress of the Manufacture of Tin Plates, J. Iron and Steel Inst.* 1886; C. Vogel, Stahl und Eisen, 29, 1097).

The M'Kinley Tariff, which came into force on July 1, 1891, led to a rapid development of the tin-plate industry in the United States, and a corresponding depression in South Wales. Other markets for Welsh tin plates were, however, gradually found, so that the industry has more than made up for the ground lost.

Production of tin plate.—The metal used for rolling into sheets was formerly, as above stated, wrought iron of special quality, which was made in refineries using only charcoal. At present very mild steel is employed, Siemens' steel being in most demand for this purpose. The bars are cut into suitable lengths, and each length is heated to redness, and then passed through 'chilled' rolls until its length is about

doubled; the plate is then folded across the middle, re-heated, and again rolled. The reheating, folding over, and rolling is repeated until a sheet of the proper thickness is obtained, sometimes as many as thirty-two thicknesses being rolled together as one piece in this way. The sheets are then cut to size with shears and separated, when they should part readily if the operation thus far has been successfully conducted. The 'rough black plates' so produced should be free from streaks or 'spilly' places, and should be uniformly coated over with a black scale of oxide. This is now removed by 'pickling' in warm dilute sulphuric acid for about 20 mins., and by subsequent washing and rubbing with sand and water. The sheets are next annealed in wrought-iron boxes, which are usually about 2 ft. square, but vary in size; the upper part is in the form of a bell for ready removal, and to prevent the entry of air the joint is stopped by being covered with sand. The annealing requires about 10 hours, and is conducted in a large furnace maintained at a cherry-red heat. The pots are then withdrawn and allowed to cool, after which the sheets are cold-rolled, to improve the surface and give the smoothness and uniformity which is necessary to produce a good tin plate. The cold-rolling renders the plates somewhat hard, and they are therefore annealed once more, usually in cast-iron pots, as it is not necessary in the second annealing to use so high a temperature or as long a time as in the first case. The sheets are now finally pickled in weaker sulphuric acid then was used in the previous pickling, and after being again rubbed with sand are immersed in water preparatory to tinning.

The tinning apparatus, or 'stow,' varies somewhat with the size and quality of the plates; with very large plates the bath of tin is contained in a basin-shaped pot, while for large sizes and ordinary qualities the plates are manipulated entirely by machinery during the tinning process.

The form of apparatus which was general in S. Wales until nearly the end of the nineteenth century, and which is still occasionally employed for purposes where a specially good tin plate is required to withstand atmospheric and similar influences, consists of five baths or pots, called respectively (1) the grease pot, (2) the tin-man's pot, (3) the washing pot, (4) the dipping pot, (5) the grease pot. Formerly two other pots were used, but these have been rendered unnecessary by the introduction of rolls. The grease pot contains melted grease, such as tallow or palm oil, and in this the sheets are dipped until all moisture has been removed, and they are uniformly coated with grease. They are next dipped into the tin pot, which contains melted tin covered with a layer of grease, the latter being now usually replaced by a bath of zinc chloride or 'killed spirits.' The sheet now receives its first coating of tin, which, however, is not perfect, and to complete the tinning the sheet is dipped into the first compartment of the washing-pot, where it remains until a uniform coating is produced. The plate is now taken out and rapidly examined by the workman, who wipes over the surface with a brush, and to remove the marks of the brush rapidly dips the plate into the second compartment of the same

pot, which contains the best tin, and then transfers it to the grease pot, where it passes through a pair of rolls, which squeeze off the excess of tin and improve the surface. Formerly the plate remained for about 10 mins. in the grease pot, during which time the excess of tin drained off. The plate was afterwards transferred to the 'cold pot,' after which the lower part was inserted in the 'list' pot, which contains a little tin at a comparatively high temperature, and which rapidly removes the thick edge of tin which had accumulated at the bottom of the plate. The plates, after coating with tin, are then cleaned from grease, usually by rubbing with bran and finishing with the woolly skin of a sheep; they are afterwards separately examined for defects, and, after classification, are packed in the familiar flat wooden boxes and branded for market (*v. E. Trubshaw, J. Iron and Steel Inst. 1883, i. 252*).

For a description of the process of manufacture of tin plates in Germany, which does not materially differ from that above described, *v. Dingl. poly. J. 250, 231*.

For the method of tinning cast iron in Germany, *v. Schott, Stahl u. Eisen, 1919, 39, 119*.

In modern tin-plate works mild steel bars are reheated and rolled into 'black plates' by passing successively through two pairs of rolls for 'roughing' and 'finishing' respectively. In the United States sometimes only one pair of rolls is used; or two pairs of finishing rolls may be served by one pair of roughing rolls. The plates, after being separated, are pickled in diluted sulphuric or hydrochloric acid with the aid of pickling machines; they are then annealed under cover in iron or steel boxes, cold rolled, re-annealed at a lower temperature and again pickled, this time in weaker acid. The plates are then swilled in water and introduced, without drying, into the tinning machine. Of such machines there are various modifications. A typical form consists of two divisions connected with each other at the lower part of the pot which contains molten tin. The tin in the first division is coated with a tinning flux of zinc chloride, while that in the second division is covered with hot grease. The plate passes through the flux into and through the tin, emerging through the grease, and passing through rolls which remove the surplus tin, and give a smooth, bright, and even surface. For further details and drawings, see G. B. Hammond, *The Manufacture of Tin Plates, J. Iron and Steel Inst. 1897, 2, 24*; also papers by R. B. Thomas (*Proc. Inst. Mech. Eng. 1906, 490*) and T. L. Bailey (*J. Soc. Chem. Ind. 1918, 114 T*).

The occurrence of blisters in the thin sheets of steel used in the manufacture of tin plates is not infrequently a cause of considerable trouble. The origin of these has been studied by E. F. Law (*J. Iron and Steel Inst. 1906, 1, 134*), who concludes that oxidised steel will give rise to blistered sheets, and the defect is more likely to arise with Bessemer than with open hearth steel. Brittleness in sheets may arise from excess of sulphur or phosphorus. In metal of good chemical purity a peculiar form of weakness, sometimes called 'rectangular brittleness,' may result from annealing at an improper temperature, or for too long a time.

According to E. Mayer (*Stahl u. Eisen, 1918*)

38, 960) there is no proof that molten tin really alloys with the iron, and the time of dipping is too short to admit of diffusion of the tin into the iron. A metallographic study of tinfoil shows that there is always a sharp demarcation line between the tin and iron.

See also Chemistry in relation to Tinfoil Manufacture (H. J. Bailey, J. Soc. Chem. Ind. 1923, 362). T. T.

TITANIUM. Sym. Ti. At. wt. 48.1 (Thorpe); 47.9 (Baxter and Fertig, J. Amer. Chem. Soc. 1923, 45, 1228). Experiments to determine the ratio $TiCl_3:4Ag$ gave a mean value of 0.43957, the extremes being 0.43940 and 0.43967, which leads to the mean value 47.85 for the atomic weight of titanium, the extreme values being 47.89 and 47.78 (Baxter and Fertig, J. Amer. Chem. Soc. 1923, 45, 1228-1233; J. Chem. Soc. 1923, 124; Abstr. ii. 498). According to Aston, Titanium is simple. Titanium is not found in the free state, but occurs as oxide in three minerals of different crystalline form: *rutile*, *anatase*, and *brookite*. It is found as *titaniferous iron ore* or *ilmenite* $(FeTi)_2O_3$, and in smaller quantities as *sphenoid titanite* $CaTiSiO_6$, *perovskite* $(CaFe)TiO_3$, *schorlomite* $Ca(TiFe)SiO_6$, and *keilhaute* $CaY(TiAlFe)SiO_6$. It occurs in magnetic iron ores, and is thus frequently found in slags and pig iron; and in other minerals, in soils, clays, certain mineral waters, and in the sun's atmosphere (Barnes, J. Soc. Chem. Ind. 1896, 421; Riecke, *ibid.* 1908, 901; Becker, Zeitsch. Kryst. Min. 1903, 38, 317; Hall and Smith, Chem. Zentr. 1905, ii. 1161; H. R. Adam, J. S. Afr. Chem. Inst. 1923, 6, 3). The presence of titanium oxide in clays considerably reduces their refractibility. Titanium is said to be diffused throughout all primitive granite rocks (Dieulafoy).

It has also been found in human and in ox flesh and bone (Baskerville, J. Amer. Chem. Soc. 1899, 21, 1099); in the ash of many plants (Wait, *ibid.* 1896, 18, 402; Lippmann, Ber. 1897, 30, 3037); and in many peats (Baskerville, *l.c.* 402). It is more abundant in nature than has hitherto been supposed, but it is only within the last few years that the metal and many of its compounds have become important industrially.

Various titanium compounds have been suggested for use as pigments as far back as 1846. Ferro-titanium has been utilised in the iron industry since 1895, and titanium white, a pigment consisting essentially of titanium dioxide, is now being made.

Titanium can be extracted from its oxide by electrolyzing a solution of the latter in dry halogen salts of the alkaline earth metals heated to moderate redness. After cooling, the titanium is separated from the electrolyte by lixiviation

with water and with dilute hydrochloric acid (Fr. Pat. 344099, 1904; J. Soc. Chem. Ind. 1904, 1998; cf. also Moissan, Eng. Pat. 3073, 1895; Sternberg and Deutsch, Eng. Pat. 13117, 1893; Borschers, U.S. Pat. 930344, 1909; J. Soc. Chem. Ind. 1909, 986). In a somewhat impure form it can be obtained by the reduction of potassium titanium fluoride with sodium (Weiss and Kaiser, Zeitsch. anorg. Chem. 1910, 65, 345). Very pure titanium has been obtained in moderately large quantities by heating pure titanium tetrachloride with about half its weight of sodium in a steel bomb to a low red heat (Hunter, J. Amer. Chem. Soc. 1910, 32, 330; Lely and Hamburger, Zeitsch. anorg. Chem. 1914, 87, 209), or by passing the vapour of $TiCl_4$ over sodium hydride. Also by heating the dichloride at 1100° in hydrogen:

Titanium in a very pure state is obtained by passing the vapour of the iodide over a heated tungsten filament. Thus obtained it is ductile (van Arkel and de Boer, Zeitsch. anorg. Chem. 1925, 148, 345; Chem. Soc. Abstr. 1925, ii. 1193.)

Titanium has the appearance of polished steel. It is hard and brittle in the cold, but can be readily forged when raised to a low red heat. It has sp.gr. 4.50 and melts at 1800° - 1850° (Hunter); see also Moissan (Compt. rend. 1906, 142, 673).

For crystalline structure (hexagonal), see Patterson (Physical Rev. 1925, [ii] 26, 56; Chem. Soc. Abstr. 1925, ii. 845).

It is less ductile than thorium, zirconium, or uranium, and can be obtained in rod-form only with special precautions, owing to its ready oxidisability.

Titanium burns in oxygen, in nitrogen, and in the halogens, dissolves readily in sulphuric or hot concentrated hydrochloric acid, more slowly in nitric acid, and decomposes steam at 700° - 800° .

Titanium readily forms alloys with various metals; some of those with iron having been employed for the manufacture of pencils for arc lights (Ladoff, J. Ind. Eng. Chem. 1909, 711).

Aluminium-titanium alloys with up to 30 p.c. of the latter metal contain hard crystals of the compound Al_3Ti , m.p. 1325° , and immiscible with aluminium (E. van Erckelen, Metall und Erz. 1923, 20, 206.)

For alloys with carbon and iron, see *Tamara*, (Chem. Soc. Abstr. 1925, ii. 787).

Filaments of metallic titanium having a high melting-point and high resistance, and as used for incandescent electric lamps, are manufactured by treating titanic oxide with ammonia in the cold. The product is heated in a vacuum to 1200° , and is then mixed with an organic binding material such as a solution of casein in ammonia. The mixture is formed into threads and then heated in an electric furnace to 1300° . Finally the filament is subjected to the action of a high tension electric current in a vacuum (Trensen, Eng. Pat. 14652, 1906; J. Soc. Chem. Ind. 1906, 877).

Titanium is used in metallurgy, its addition to steel increasing greatly the transverse strength and elasticity of the steel (Ladoff, *l.c.* 642; Venator, Stahl und Eisen, 1910, 20, 666).

Its value in steel manufacture seems to be related to its power as a deoxidant. It is mainly applied in the form of 'Ferro carbon-titanium,' containing from 15-20 p.c. Ti, and consisting of microscopic particles of titanium carbide held in a matrix of grey cast iron. When added to molten steel the matrix dissolves and the titanium carbide is diffused through the mass when it reacts on the oxygen, the titanium oxide acting as a flux for silicates and other slags. (For the effect of wear on titanium treated rails, see Comstock, J. Soc. Chem. Ind. 1915, 55.)

Aluminium-titanium alloys containing up to 30.7 p.c. of titanium consist of a mixture of hard, needle-shaped crystals of Al_3Ti in a softer ground mass of aluminium. The compound Al_3Ti melts at 1325° and forms neither eutectic nor solid solution with aluminium. Addition of titanium, in amounts not exceeding 1 p.c., to aluminium removes the combined nitrogen and oxygen, and consequently improves the tensile properties; at the same time, the resistance of the metal to attack by salt solutions and by organic acids is appreciably increased (cf. J. Soc. Chem. Ind. 1923, 721 A; Eugen van Erckelens, Metall. und Erz. 1923, 20, 206-210; J. Chem. Soc. Abstr. 1923, 124, ii. 569).

A protective coating on iron and steel is said to be formed by mixing a titanium ore with 10-50 p.c. of asphalt, and if the product is to be used as a paint, adding turpentine. These coatings can also be formed by heating the metal to be treated with a layer of titanic mineral mixed with carbonaceous material in a furnace for several hours (Johnson, Eng. Pat. 15500, 1893; J. Soc. Chem. Ind. 1893, 1046).

The arc spectrum of titanium has been analysed with the object of ascertaining the regularities of this spectrum. It is shown that two different sets of multiplets of six or seven lines occur. These sets have respectively the differences 170.1 and 2.167, and are similar to the multiplets of the alkaline-earth metals. There are also multiplets of eleven to thirteen lines, with differences 42.0, 62.3, 81.7, and 100.2, similar to the multiplets of manganese, chromium, and molybdenum. The majority of the lines classified belong to King's temperature classes I. and II., although a few belong to the classes III. and IV. (Astrophys. J. 1914, 39, 139). About 10 p.c. of the arc lines of titanium are thus classified. Long tables of the classification are given in the paper (C. C. Kiess and Harriet K. Kiess, J. Washington Acad. Sci. 19; J. Chem. Soc. 1923, 124, ii. 596; 1924, 126, ii. 510; see also Behner, Zeitsch. wiss. Phot. 1925, 23, 325; Chem. Soc. Abstr. 1925, ii. 1100; Crew, Chem. Soc. Abstr. 1925, ii. 335).

Compounds of titanium.—Titanium hydride appears to exist. When the gases from a titanium electrode are passed through a heated glass tube a deposit of titanium is formed as a black metallic mirror. The gaseous hydride is colourless and tasteless, and is condensed at the aperture of liquid air. Titanium forms four oxides. The monoxide TiO forms black prisms, obtained by heating the dioxide in the electric furnace, or with magnesium powder (Winkler, Ber. 1890, 23, 3058; Moissan, Compt. rend. 1892, 115, 1034; J. Soc. Chem. Ind. 1892, 963). The sesquioxide Ti_2O_3 (Moissan,

Compt. rend. 1895, 120, 290; Braun, Min. Mag. 1892, ii. 37) is obtained by strongly igniting the dioxide in hydrogen and allowing the product to cool in this gas. In sulphuric acid it forms a violet solution, this being the characteristic colour of all the solutions of trivalent titanium compounds. The corresponding hydroxide is obtained by digesting a solution of titanic acid in hydrochloric acid with metallic copper at 20° - 40° , or by treating the trichloride with alkalis. The sesquioxide and the corresponding salts are readily oxidised to the dioxide or the trioxide and their salts (Manchot and Richter, Ber. 1906, 39, 320, 488).

Titanium dioxide TiO_2 , is the most important of the four oxides. It is trimorphous, occurring as the three distinct minerals mentioned above. It can be obtained by the decomposition of aqueous titanium chloride by ammonia or by fusing rutile with three times its weight of potassium carbonate.

Titanium oxide can be prepared by mixing crushed ilmenite or other titanium ore with carbon and heating to about 1800° . The resulting mass is crushed and the iron is removed by magnetic separation and treatment with acid (U.S. Pat. 921886, 1909; J. Soc. Chem. Ind. 1909, 657).

For the occurrence of titanium in Nile silt, see E. Griffiths-Jones (Analyst, 1923, 48, No. 568, 320).

The following results, expressed as percentage of TiO_2 , calculated on the silt dried at $100^\circ C.$, were obtained:—

	Titanium dioxide. Per cent.
Nile silt collected from the river bank at Maadi, near Cairo	2.35
Silt from the River Atbara taken 10 miles upstream from the junction with the main river—	
No. 1, a grey silt of fine texture	2.2
No. 2, a coarse sand	1.3
Silt from Nile at Hassanat Discharge site about 5 miles upstream from the junction with the Atbara—	
No. 1, fine silt; brown in colour	2.4
No. 2, fine silt, grey in colour	2.55
No. 4, fine sand, brown in colour	1.7

Amorphous titanium dioxide is a white, tasteless powder which becomes lemon yellow when gently heated, and brown when ignited strongly. It has a sp.gr. 3.89-4.25. It is insoluble in water and dilute acids, resembles silicon dioxide closely in chemical properties, and when fused with alkalis or alkali carbonates forms the titanates.

Titanium dioxide finds application as a paint material and is extracted on the large scale from a variety of ilmenite found near Egersund, Norway. The concentrated ore containing 47.5 p.c. of titanium oxide is reduced to fine powder and mixed to a paste with concentrated sulphuric acid. On heating the mineral is converted into soluble sulphates of iron and titanium. On treating with water and heating nearly to boiling-point the titanic oxide is precipitated, dried, and calcined. The product is mixed with barium sulphate, carbonate and calcium phosphate, and comes into commerce as 'titanium white.'

Titanox consists of titanium dioxide precipitated upon a base of finely divided *blanc fixe*. In colour it is far whiter than white lead, but not quite so white as French process zinc oxide or the best grades of lithopone. Its hiding power is twice that of white lead and is the greatest of any white pigment. Its inertness towards varnish liquids enables it to be used in compositions that can be kept without danger of livering or thickening. 100 p.c. titanox in oil dries very slowly to a soft film, and a fair quantity of a metallic drier should be used, while for interior work an addition of about 30-50 p.c. of zinc oxide is advantageous, this causing it to give a firm dust-resisting film. Titanox appears to be very resistant to sunlight and to all atmospheric conditions and to hydrogen sulphide fumes. Experiments on rabbits showed that titanox is non-toxic and physiologically inert (H. A. Gardner, U.S. Paint Manuf. Assoc., Govt. No. 199, Feb. 1924, 256; J. Soc. Chem. Ind. 1924, 43, B. 303).

Green pigments containing titanium were first manufactured about 1861. White titanium pigments are now chiefly made in America and Norway, and are usually sold in two forms containing 65-90 p.c. and 25-35 p.c. TiO_2 , respectively. Ilmenite ($\text{FeO} \cdot \text{TiO}_2$, containing 51 p.c. TiO_2) is now the chief raw material used for these pigments, since it is cheaper than rutile (containing 90-98 p.c. TiO_2), which was formerly used. Pure white pigments are microcrystalline, and have sp.gr. 4.0 and refractive index 2.1-2.3. White titanium pigments are only soluble in the concentrated acids and alkalis, and are inactive towards the oils and pigments used in the paint and varnish industries. The resinates and linoleates of cobalt and manganese are particularly suitable siccatives for use with titanium paints, 0.2 p.c. of manganese or 0.03 p.c. of cobalt being recommended as suitable quantities. Paints containing titanium pigments are elastic and do not crack or scale after prolonged weathering. Titanium pigments have a high covering and oil-absorption power, and a ready-to-use paint contains 52-62 p.c. of white titanium pigment and 48-38 p.c. of oil (E. O. Rasser, Chem. Zeit. 1923, 47, 460-461; J. Soc. Chem. Ind. 1923, 42, 729 A).

The following volumetric method of estimating titanium in titanium pigments is not affected by other elements likely to be present, and is convenient when a number of samples have to be analysed. The reagent used is prepared by dissolving 30 grms. of ferric ammonium sulphate in 300 c.c. of water containing 10 c.c. of sulphuric acid, adding permanganate solution drop by drop as long as the pink colour disappears, diluting to a litre, and standardising in terms of iron; 0.5 gm. of the pigment is mixed with 20 c.c. of concentrated sulphuric acid and 7 to 8 grms. of sodium sulphate in a 250 c.c. beaker, which is heated on a hot plate until fumes of sulphur trioxide are evolved and then boiled over a flame for 5 minutes or until solution is complete. The cold liquid is mixed with 100 c.c. of water and boiled, the barium sulphate and silica being filtered off and washed with 5 p.c. sulphuric acid solution. As reductor a 500 c.c. pyrex glass dispensing burette, 22 by 1 inches, is used. Into this is introduced a platinum gauze covered with a $\frac{1}{2}$ -inch mat of

fibrous asbestos supporting, in the order mentioned, a 1-inch layer of 10-mesh and a 6-inch layer of 20-mesh amalgamated zinc and a 5-inch layer of amalgamated stick zinc. The reductor is connected with a litre flask for receiving the reduced titanium solution through a 3-holed rubber stopper, which carries also an inlet tube for carbon dioxide and an outlet tube joined to the suction pump. The reductor is prepared by passing through it a little hot dilute sulphuric acid followed by hot water, sufficient of which is left to cover the zinc. The hot filtrate from the barium sulphate is now introduced, about 100 c.c. of water being drawn from the reductor into the original beaker to bring the solution to about the top of the zinc; the water withdrawn may be acidified with 10 c.c. of sulphuric acid and kept on a hot plate for washing after the reduction. The titanium solution is left in the reductor for 10 minutes, the receiving flask being meanwhile connected with the reductor and the air displaced by carbon dioxide. When reduction is complete the receiving flask is joined to the suction pump, and, with carbon dioxide still flowing, the reduced solution is drawn out and is followed by the acid washing liquor and three or four quantities of 100 c.c. of hot water, the zinc being kept covered. The suction is then gradually released and the flask disconnected, 5 c.c. of saturated potassium thiocyanate solution being added and the liquid titrated at once with the ferric ammonium sulphate solution until a brownish colour persists for at least a minute; the burette reading is to be corrected by an amount which each operator must determine by means of several blank tests. As the composition of titanium oxide is always very nearly 25 p.c. of titanic oxide and 75 p.c. of barium sulphate, the percentage of the pigment is obtained nearly enough for all practical purposes by multiplying the percentage of titanic oxide by four. If only an occasional estimation is to be made, the following gravimetric method is useful. The filtrate from the barium sulphate (see above) is treated with excess of ammonia and filtered, the precipitate being dissolved in hydrochloric acid (1:1) and again precipitated with ammonia. The precipitated titanium hydroxide is filtered off and washed with hot water, the filtrate being added to that from the previous filtration. The residue is dissolved in hydrochloric acid (1:1), the volume of the solution, which is received in a 500 c.c. beaker, being kept below 150 c.c. To the solution, heated to 50°C., ammonium hydroxide is added gradually until the precipitate formed just redissolves, ammonium carbonate solution being then added, drop by drop, until a slight permanent precipitate forms. This is dissolved in hydrochloric acid, and an excess of 2 c.c. of the acid (1:1) added, the solution being treated with sulphur dioxide gas or solution until it smells strongly, diluted to about 400 c.c. and boiled until only a slight odour remains. The liquid is filtered while hot, and the precipitate washed with hot water, dried, calcined at not lower than 900°C. for 30 minutes, and weighed as TiO_2 .

With a mixed pigment containing titanic oxide, 1 gm. is heated on a hot plate in a 400 c.c. pyrex glass beaker with 10 grms. of sodium sulphate and 40 c.c. of sulphuric acid (93 p.c.)

for 30 minutes, and then boiled for about 10 minutes, cooled, diluted to 300 c.c., boiled for 30 minutes, and filtered while hot. The residue is washed with 5 p.c. sulphuric acid solution; it contains silica, undecomposed silicates and all the lead and barium as sulphates. The hot filtrate, containing the titanium, iron, aluminium, zinc, and calcium, is treated with excess of ammonia, and filtered, the precipitate being washed with hot water, redissolved in hydrochloric acid (1:1), and again precipitated with ammonia. The precipitate is filtered off and washed with hot water, the filtrate being united with that from the first separation; if desired, this filtrate may be tested for aluminium and used for estimating the calcium and zinc. The precipitate is dissolved in dilute hydrochloric acid, and the titanium separated and estimated as described above, the filtrate being used for estimating the iron and aluminium (L. E. Barton, *Chem. Trade J.* 1923, 357, 358; *Analyst*, 1923, 48, 403).

For the volumetric estimation of titanium, see also Morley and Wood (*J. Chem. Soc.* 1924, 125, 518; *Abstr.* 1924, 126, ii. 351); Lundell and Jones (*J. Amer. Chem. Soc.* 1923, 45, 2620-2623; *J. Soc. Chem. Ind.* 1924, 43, B. 38).

Titanium oxide is used as a mordant, and in at least two cases it has an advantage over alumina; thus alizarin yellow produces with titanium as bright but a much faster colour than with alumina, whilst the scarlet obtained from alizarin orange on a titanium mordant is the fastest scarlet that can be obtained on wool.

For this purpose the titanium mordant must be freed from iron, and this can be done by dissolving freshly precipitated titanium hydroxide, containing iron, in tartaric acid, making alkaline with ammonia and precipitating the iron by the addition of the requisite amount of ammonium sulphide. The filtered solution is then warmed until most of the free ammonia has been expelled (Barnes, *J. Soc. Chem. Ind.* 1899, 15).

According to Sabatier and Mailhe (*Compt. rend.* 1910, 150, 823) the dioxide forms a very efficient catalyst in the esterification of acetic acid.

According to E. L. Nichols (*Physical Rev.* 1923, [ii] 22, 420), cathode rays but not ultraviolet light from an iron spark excite a very faint, orange-red fluorescence in titanium oxide, or, after fusion of the surface layer, a fine blue fluorescence, with rapid fatigue. A thin layer of the oxide, when heated, gave a very feeble greyish-blue fluorescence up to 425°, strong red from 425° to 677°, and strong yellow from 677° to 1000°. When the oxide is heated directly with an oxygen-hydrogen flame, two distinct phases are observed, according as the oxygen or the hydrogen is in excess (*cf.* Nichols and Wilber, *Chem. Soc. Abstr.* 1922, ii. 105; 1924, 126, ii. 81).

Like silicic acid, titanous acid forms a number of hydrates known as ortho- and meta-titanous acids (Wagner, *Ber.* 1888, 21, 960; Pfordten, *Anzeig.* 1887, 237, 218; Tamann, *Zeitsch. anorg. Chem.* 1905, 43, 370; Bornemann and Schramm, *Chem. Zentr.* 1910, ii. 1870). Many titanates are known. The two compounds $\text{Na}_2\text{TiO}_3 \cdot 2\text{H}_2\text{O}$ and $\text{K}_2\text{TiO}_3 \cdot 4\text{H}_2\text{O}$ described by Demsky in 1909 have been shown by Collenberg and Sandved not to exist (*Zeitsch. anorg. Chem.* 1923, 120, i. 1; *Chem. Soc. Abstr.* 1924, 126, ii. 52).

Tetramethyl titanate prepared from methyl alcohol, sodium, and titanium tetrachloride crystallises at 210° and boils at 243° corr. at 52 mm. Tetraethyl-, tetraisopropyl-, and tetra-*n*-butyl titanates have also been prepared (Bischoff and Adkins, *J. Amer. Chem. Soc.* 1924, 46, 256; *Chem. Soc. Abstr.* 1924, 126, i. 259).

Chloro-acetate compounds of titanium have been prepared from TiCl_4 and acetic acid (Gins and Monath, *Zeitsch. anorg. Chem.* 1925, 143, 383; *Chem. Soc. Abstr.* 1925, i. 531).

Titanium peroxide TiO_2 (Classen, *Ber.* 1888, 21, 370) resembles hydrogen peroxide very closely in its reactions in solution. Faber (*Zeitsch. anal. Chem.* 1907, 46, 277) has prepared the hexavalent acetate and phosphate

both of which are stable at low temperatures, but, particularly the acetate, are explosive on heating. Hypertitanates of potassium and sodium have also been prepared (Melikoff and Pissarjewsky, *Ber.* 1898, 31, 678).

According to Billy (*Compt. rend.* 1921, 172, 1411) all salts of the oxide TiO_2 are really complexes of hydrogen peroxide and pertitanic salts corresponding with the peroxide Ti_2O_3 .

Halogen compounds.—Titanium tetrachloride TiCl_4 can be obtained readily by passing dry chlorine over a mixture of the dioxide with carbon; by passing the vapour of chloroform over titanium dioxide (Renz, *Ber.* 1906, 39, 249), and by heating the latter with sulphur monochloride (Hall, *J. Amer. Chem. Soc.* 1904, 26, 1235; Bourion, *Ann. Chim.* 1910, [viii.] 20, 547; *ibid.* 21, 49), or by passing sulphur dioxide into a warm, strongly acid solution of titanium trichloride (Smythe and Wardlaw).

Titanium tetrachloride is best prepared from industrial ferro-titanium by treating the latter with hydrochloric acid to remove most of the iron. It is then levigated to remove titanous anhydride, and after drying the mass is introduced into a porcelain tube, heated to dull redness, and subjected to the action of a current of dry chlorine. The ferric chloride is separated by filtration, and the filtrate is fractionally distilled when the pure substance is obtained. It boils at about 136°, is colourless, and does not fume in air (Vigouroux and Arrivaut, *Compt. rend.* 1907, 144, 485).

The tetrachloride can also be prepared from rutile by igniting the latter with aluminium and then heating the mixture in a current of chlorine (Ellis; *Chem. News*, 1907, 95, 122).

It is a mobile, transparent, colourless liquid of sp. gr. 1.7604 at 0/4° (Thorpe), which solidifies at -23° and boils at 136.4° under 760 mm. pressure (Thorpe). It is decomposed by an excess of water yielding titanous acid and combines with ammonia, forming a number of solid addition compounds (Rosenheim and Schütte, *Zeitsch. anorg. Chem.* 1901, 26, 239; Stähler and Wirthwein, *Ber.* 1905, 38, 2618). When the latter are extracted with liquid ammonia, dark yellow titanamide $\text{Ti}(\text{NH}_2)_4$ is formed. Titanium tetrachloride, like stannous chloride, yields a large number of crystalline compounds with other chlorides (Rosenheim and Schütte, *loc. cit.*; Rast and Ipsen, *Ber.* 1903, 36, 1777). Is reduced to the trichloride by heating with aluminium, antimony, arsenic or tin in a sealed tube at 400°.

A solution in concentrated hydrochloric acid deposits, on evaporation in the cold over sulphuric acid, large, colourless, rhomboidal plates of $\text{TiCl}(\text{OH}) \cdot 2\text{H}_2\text{O}$, decomposed in moist air (Collenberg and Sandved, l.c.).

Titanium trichloride TiCl_3 is formed when a mixture of titanium tetrachloride vapour with hydrogen is passed through a red-hot tube (Georges and Stähler, Ber. 1909, 42, 3200; Stähler and Bachran, Ber. 1911, 44, 2906), and can be prepared by electrolysis of a solution of the tetrachloride and then evaporating the solution to the sp.gr. 1.5 at $60^\circ\text{--}70^\circ$ (Spence, U.S. Pat. 723217, 1903; J. Soc. Chem. Ind. 1903, 495, 628; D. R. P. 154542). As prepared by the latter process, it forms violet crystals of the composition $\text{TiCl}_3 \cdot 6\text{H}_2\text{O}$, which decompose into the tetra- and di-chloride on heating, the latter also being formed when the trichloride is heated in hydrogen (Georges and Stähler, l.c.). Titanium trichloride may be prepared by reduction of the tetrachloride by means of hydrogen, provided that the reaction products are quickly cooled and the hydrogen chloride is removed by means of metallic titanium. The trichloride so prepared consists of large violet crystals, which are fairly stable in the air. The reduction is not direct, but three reactions, $\text{TiCl}_4 + \text{H}_2 = \text{TiCl}_3 + 2\text{HCl}$; $\text{TiCl}_4 + \text{TiCl}_3 = 2\text{TiCl}_3$; $2\text{TiCl}_3 + 2\text{HCl} = 2\text{TiCl}_2 + \text{H}_2$, may proceed simultaneously (F. Meyer, A. Bauer, and R. Schmidt, Ber. 1923, 56, 1908–1914; J. Soc. Chem. Ind. 1923, 42, 1067 A). When titanium tetrachloride is heated with magnesium, zinc, aluminium, arsenic, or antimony it is reduced to trichloride, the reaction being accelerated by aluminium chloride. Phosphorus and sulphur reduce the tetrachloride only in presence of aluminium chloride. Reduction with aluminium and aluminium chloride in absence of air is the best method of preparing titanium trichloride. The trichloride can be sublimed at 425°C . at 1 mm. pressure. At 475°C . it decomposes into dichloride and tetrachloride. Titanium dichloride is a black powder, stable at least to 600°C . in absence of air, but catching fire at once in moist air. It decomposes water immediately with evolution of hydrogen (O. Ruff and F. Neumann, Zeitsch. anorg. Chem. 1923, 128, 81–95; J. Soc. Chem. Ind. 1923, 42, 1220 A).

Investigation of the reduction of the tetrachlorides of titanium and zirconium by sodium amalgam, magnesium, zinc, aluminium, tin, arsenic, phosphorus, etc., has shown that reduction by aluminium at about 250° affords a convenient means for the preparation of the trichlorides, from which excess of tetrachloride and aluminium chloride can be removed by distillation. Titanium trichloride thus prepared is a bright violet, non-crystalline powder subliming at $425^\circ/\text{1 mm.}$ to form dark violet, prismatic crystals; it is very sensitive to oxygen and moisture, and dissociates at 450° to form the volatile tetrachloride and a black residue of the dichloride, which is very reactive, takes fire in moist air, and decomposes water with evolution of hydrogen (O. Ruff and F. Neumann, Zeitsch. anorg. Chem. 1923, 128, 81).

The trichloride is a powerful reducing agent. It liberates sulphur from sulphurous acids, sulphites, and thiosulphates, and selenium from selenious acid, many metals, such as gold, silver

the platinum metals, mercury, and copper from solutions of their salts, and reduces nitric acid and nitrates to ammonia. It reduces ferric salts quantitatively to the ferrous condition, reacts with a gold solution like stannous chloride, producing colloidal gold, analogous to purple of Cassius, organic nitro compounds to amines, gives characteristic coloured precipitates or colorations with many organic acids or their salts. The intense violet coloration with solutions of alkali citrates is a characteristic and sensitive test, and can be employed in the analysis of many dyes (Knecht, Ber. 1903, 36, 166; Knecht and Hibbert, *ibid.* 1549; *ibid.* 1905, 38, 3318; 1907, 40, 3819; J. Chem. Soc. 1924, 125, 1537). This reducing property has also been made use of in cloth printing (D. R. P. 138503; *Frld.* 1902–4, 477). Titanium trichloride forms double compounds with the chlorides of rubidium and caesium (Stähler, Ber. 1904, 37, 4405), and also with nitrogen sulphide (Davis, Chem. Soc. Trans. 1906, 1576).

The use of titanous chloride in the titration of iron is discussed by Brandt (Chem. Zeit. 1924, 48, 265, 270; J. Soc. Chem. Ind. 1924, 43, B. 469).

The standardisation of titanous chloride solutions, using the potentiometric method, has been studied by Zintl and Rauch (Zeitsch. anorg. Chem. 1925, 146, 281; Chem. Soc. Abstr. 1925, ii. 1003; see also Tomicek, Chem. Soc. Abstr. 1925, ii. 243).

A brown polymorphic modification of titanium trichloride, obtained by the action of the silent discharge on a mixture of hydrogen and the vapour of the tetrachloride, has been described by Böck and Moser (Monatsh. 1913, 34, 1825).

Titanium dichloride TiCl_2 , prepared as above, is a hygroscopic light-brown powder.

Titanium tetrabromide (Ruff and Ipsen, l.c.), and tribromide (Stähler, l.c.), the triiodide (Stähler, l.c.), tetra-iodide and the diiodide (Defacqz and Copaux, Compt. rend. 1908, 147, 65), the tetra- and tri-fluorides (Ruff and Ipsen, l.c.; Ruff, Plato and Graf, Ber. 1904, 37, 673), and a number of alkali titanofluorides (Marchetti, Zeitsch. anorg. Chem. 1895, 10, 66; Piccini, *ibid.* 438; Ebler and Schott, J. pr. Chem. 1910, [ii.] 81, 552) have been prepared.

Titanium forms three sulphides TiS_2 , Ti_2S_3 , and TiS (Müller, Chem. Zentr. 1910, ii. 1195), and also a chlorosulphide.

Titanium sesquisulphate $\text{Ti}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ is obtained when the metal is dissolved in dilute sulphuric acid. It is decomposed by heat and forms alums and double salts with the alkali sulphates.

The electrolytic reduction of many organic compounds is greatly facilitated by the addition of a small quantity of a titanium salt, such as the sulphate (D. R. P. 168273; *Frld.* 1905–7, 115). Titanous sulphate is also recommended for detecting copper in dyed fabrics (Knecht, J. Soc. Dyers, 1904, 20, 97). The electrometric titration of chlorate, bromate, iodate, and ferricyanide with titanous sulphate is discussed by Hendrixson (J. Amer. Chem. Soc. 1923, 45, 2013; Sci. Abstr. 1924, 27, 53).

Titanous sodium sulphate $\text{Ti}_2\text{Na}_2(\text{SO}_4)_3 \cdot 5\text{H}_2\text{O}$ is obtained by electrolysis of a solution containing titanous sulphate, sodium sulphate, and sulphuric acid. The electrolysis is carried out with a

low-current density in a lead-lined vessel, the solution being finally evaporated to a sp.gr. of 1.145, when the salt crystallises out.

It is a powerful reducing agent, and can be applied in the preparation of other titanous salts (Peter Spence and Sons, D. R. P. 149602, 1904).

Titanium disulphate $Ti(SO_4)_2 \cdot 3H_2O$ forms double salts with the sulphates of the alkalis and alkaline earths (Weinland and Kühl, *Zeitsch. anorg. Chem.* 1907, 54, 253). A number of basic sulphates (Blondell, *Bull. Soc. chim.* 1899, [iii.] 21, 262; Roseheim and Schütte, *l.c.*) and titanousulphuric acid (Reichard, *Chem. Zeit.* 1904, 28, 16) have also been prepared. The preparation of solutions of titanyl sulphate $TiOSO_4$ is described by Weizmann and Blumenfeld (E. P. 209480, 210033; *J. Soc. Chem. Ind.* 1924, 43, B. 256).

Titanium forms a number of nitrides and also a chloro- and bromo-nitride (Ruff and Eiser, *Ber.* 1908, 41, 2250; *J. Soc. Chem. Ind.* 1908, 809; Ruff, *Ber.* 1909, 42, 900; Ruff and Treidel, *ibid.* 1912, 45, 1364). The mononitride Ti_2N_3 is a bronze yellow mass of sp.gr. 5.18, and is hard enough to cut rubies and diamonds (Moissan, *Compt. rend.* 1895, 120, 290).

According to Shukoff, however (*J. Russ. Phys. Chem. Soc.* 1910, 42, 40), titanium only forms solid solutions with nitrogen, but no definite compounds.

Titanium also forms a carbide (Shimer, *Chem. News*, 1887, 55, 156; Moissan, *l.c.*; and *Compt. rend.* 1897, 125, 839); a carbide of titanium, m.p. 3400° – 3500° Abs. was prepared by Friederich (*Z. Physik.* 1925, 31, 813; *Chem. Soc. Abstr.* 1925, ii. 374); Titanium forms a cyanonitride $Ti(CN)_2 \cdot 3Ti_2N_3$ (Wöhler, *Annalen*, 1850, 73; *ibid.* 34, 74, 212; Franck, *Chem. Zeit.* 1897, 21, 520; *J. Soc. Chem. Ind.* 1908, 809); and a silicide $TiSi_2$ (Hönigsamid, *Compt. rend.* 1906, 143, 224; *J. Soc. Chem. Ind.* 1909,

double double pyrophosphates of titanium and alkali are prepared by mixing together alkali pyrophosphates and basic titanium sulphate (Barnes and Spence, *Eng. Pat.* 6329, 1906; *J. Soc. Chem. Ind.* 1907, 93).

Titanium phosphide TiP forms a brittle mass with a metallic lustre. It burns when heated in air, is a conductor of electricity, is insoluble in dilute and in concentrated alkalis and acids (Gewecke, *Annalen*, 1908, 361, 79).

Titanic acid forms crystalline *thiocyanates* of the type $K_2TiO(SCN)_2 \cdot H_2O$ and double salts with pyridine (C_5H_5N), $H_2TiO(SCN)_2$, and quinine (Rosenheim and Cohn, *Zeitsch. anorg. Chem.* 1901, 28, 167).

Double fluorides of titanium, with some alkaloids are described by Schaeffer (*J. Amer. Chem. Soc.* 1906, 30, 1862).

Complex azo-salts of titanium have been prepared by Mazzucchelli and Pantanelli (*Gazz. chim. Ital.* 1910, 40, i. 666). Other titanium organic compounds are described by Dilthey 57, 588; *Annalen*, 1906, 344, 300), and Schnabel (*Ber.* 1905, 38, 2777), Gropmann (*Chem. Zeit.* 1906, 30, 907), Mazzucchelli (*Atti R. Acad. Lincei*, 1907, [v.] 16, ii 263), Pantanelli (*Chem. Soc. Trans.* 1906, 1004).

The possibility of using titanium compounds was first demonstrated by

Barnes in 1877. For the behaviour of titanic acid towards dyes, see A. M. Morley and J. K. Wood (*J. Soc. Dyers and Col.* 1923, 39, 100–105). The salts used are: the sulphate, chlorides, fluoride, oxalate, tartrate, lactates, and the double alkali derivatives of these salts. The salts for this purpose are obtained by the following process.

The ore is melted with sodium hydroxide and the mass is lixiviated with water; the residue is then washed free from alkali, dissolved in hydrochloric acid, and the solution is treated with alkali to precipitate titanium as hydroxide. The product is freed from iron by the addition of sodium sulphide, the precipitate washed and treated with sulphurous acid. It is then converted into titanium oxalate by treatment with ammonium oxalate and oxalic acid (Erban, *Chem. Zeit.* 1906, 30, 145; *cf.* also Dreher, *Eng. Pat.* 1835, 1903; *J. Soc. Chem. Ind.* 1904, 18; Spence, *ibid.* 1900, 246).

The *lactates* are conveniently prepared by dissolving titanic acid in hydrochloric acid and pouring the solution into a warm solution of an alkali or alkaline earth lactate (Dreher, *Farber-Zeit.* 1902, 13, 293; D. R. P. 149577; *Frdl.* 1902–4, 43; *J. Soc. Chem. Ind.* 1902, 988, 1245; 1903, 908).

The soluble salts of titanium, such as the oxalate, are very efficient fixing agents for the tannates of the basic colours, the results obtained being as good as, and in many cases better than, those obtained with antimony. For this purpose it is unnecessary to purify the titanium salts from iron (Barnes, *J. Soc. Chem. Ind.* 1899, 15).

Titanium tannate washed free from sulphate and chlorides, and dissolved in warm aqueous oxalic or tartaric acid, is an excellent dye for cotton, the shade varying with the sp.gr. of the solution. The solution of titanium tannate can also be employed as a further fixing and modifying bath after dyeing, the colours becoming faster and more yellow after such treatment. It also serves as an excellent fixing agent for the Janus colours which have been dyed substantively. Very good colours are also obtained with methylene blue, rhodamine, and aniline black (Barnes, *l.c.*; Kearns and Barnes, *Eng. Pat.* 8589; *J. Soc. Chem. Ind.* 1899, 491; Erban, *Chem. Zeit.* 1906, 30, 145).

A solution containing a titanium salt gives, with tannic acid, an orange precipitate; with gallic and pyrogalllic acids, orange or brownish-yellow solutions; and with salicylic acid a pale-yellow coloration: a yellow to deep orange colour is also produced by hydrogen peroxide; these colours are imparted to wool when the latter is steeped in the hot solutions (Barnes, *J. Soc. Chem. Ind.* 1896, 420; 1897, 238; *Eng. Pat.* 5712).

The oxalate, tartrate, titanium sodium oxalate, titanium tanno-oxalate, titanium sodium sulphate, and titanous chloride can be used with good results in dyeing and mordanting silk. The titanium mordants are also useful in the chrome developing colours, and in the after treatment of silk previously dyed with anthracene yellow or brown or alizarin colours. For this purpose titanium potassium oxalate or titanium sodium sulphate are best used (Hunt, *J. Soc. Dyers and Col.* 1919, 35, 58).
J. Soc. Dyers and Col. 1919, 35, 58).

Titanium salts unite with the tannin matter of leather to form on the fibre a yellowish-brown titanium tannate, which is very fast to light and to the action of soap. On account of its cheapness, potassium titanium oxalate is the most applicable. It is exceedingly soluble in hot water and can be applied to tanned leather either in the dye-bath or with a brush. The mode of application and the previous and subsequent treatment of the leather depend on the quality of the latter, whilst the shade of colour obtained, which varies from bright yellow to a reddish-brown, depends on the nature of the tannage and on the amount of titanium salt used. The basic colours especially give much fuller and richer shades with titanium than without (Lamb, J. Soc. Chem. Ind. 1901, 1111; U.S. Pat. 722857, 1903; Dreher, J. Soc. Chem. Ind. 1902, 771; 1903, 294; 1904, 71; Eng. Pats. 9556, 1901; 27597, 1902; Stiasny, J. Soc. Chem. Ind. 1902, 1329; Erben, *l.c.*).

According to Barnes (*l.c.*) titanium tannate can also be used effectively as a pigment in water-colour drawings, the colour depending upon the conditions of preparation of the pigment and varying from brick-red to almost pure yellow. Titanium salts are also said to be employed in the manufacture of artificial teeth and in colouring porcelain (Ladoff, *l.c.*; Barnes, J. Soc. Chem. Ind. 1896, 421).

See A. H. A. Robinson on Titanium, Dept. of Mines, Canada.

The titration of triphenylmethane and azo dyes with N/20 titanous chloride solution is a satisfactory method for determining the strength of commercial dyes of these classes, and has been applied to the routine analysis of about 30 members of the former and over 100 of the latter class, giving results that could be relied upon to about 0.5 p.c. The concentration of sodium tartrate and of alcohol in the solution to be titrated and the temperature of titration can be varied within wide limits without materially affecting the results obtained. In the case of the azo dyes difficulty was encountered in the intense colour of the reduced solution, which masked the end-point of the titration. It was found that this colour depends to a large extent on the nature of the solvent, and that by a judicious choice of solvents a direct titration is possible. Details are given of a direct titration method and a black titration method for use with azo dyes. In the latter method the reduction products of the dye frequently serve as an indicator, but if not a 0.1 p.c. solution of reduced methylene blue may be added. Water, alcohol, acetic acid, and mixtures of these were used as solvents. The analysis of basic brown dye-stuffs was possible by the indirect method if the titanous chloride was added at room temperature. In the analysis of chrysoidines the temperature had to be kept below 70°C. to avoid decomposition and consequent low results (W. S. Calcott and F. L. English, Ind. Eng. Chem. 1923, 15, 1042-1044; J. Soc. Chem. Ind. 1923, 42, 1122A).

TITANIUM GREEN. Titanium ferrocyanide, prepared by adding potassium ferrocyanide to a solution of hydrated titanous oxide in hydrochloric acid, has been suggested as a substitute for Schweinfurth green and other arsenical

pigments (Elsner, Dingl. poly. J. 905, 130; Gentele, *ibid.* 140, 238).

TIZA. A local South American name for ulexite (*q.v.*).

T.N.T. Trinitrotoluene *v.* **EXPLOSIVES.**

T.N.X. Trinitroxylene.

TOAD'S EYE. Native oxide of tin *v.* Tin salts and oxides, art. TIN.

TOAD VENOMS. Toads have long been known to be poisonous, and in the eighteenth century toadskins were employed as a remedy against dropsy. This application now only survives in China. A scientific basis for this therapy has been supplied by the isolation of the following crystalline active principles having a powerful digitalis-like action on the heart.

Bufotalin $C_{25}H_{38}O_8 \cdot C_2H_5O$, m.p. 148°, from alcohol, $2C_{25}H_{38}O_8 \cdot C_2H_5O$, m.p. 154°, from ethyl acetate. In each case the solvent of crystallisation is slowly lost in a high vacuum at 150°. On careful heating bufotalin sublimes at 225°-230°, $[\alpha]_D = +5.4^\circ$. This substance was first obtained in an impure form from the skin of the common European toad by Faust (Arch. exp. Path. Pharm. 1902, 47, 278), and was subsequently obtained pure by Wieland and Weil (Ber. 1913, 46, 3315; see particularly Wieland, Sitzber. bayer. Akad. Wiss. 1920, 329; Abstr. Chem. Soc. 1922, i. 199). Each toad skin yields about 10 mg. of bufotalin (and also 3 mg. of suberic acid). Of the six oxygen atoms, two are present as a lactone group, two as an acetyl group, and two are hydroxylic. Of the latter, one is capable of acetylation (which yields **acetyl bufotalin** $C_{28}H_{38}O_7$, m.p. 254°), the other can be oxidised to a ketone group (present in **bufatolone** $C_{25}H_{34}O_8$, m.p. 261). **Tetrahydrobufotalin** $C_{25}H_{40}O_8$, m.p. 204°-205°, and **bufotalan** $C_{24}H_{38}O_8$, m.p. 198°-199°, have also been prepared, the latter by the removal of one molecule of acetic acid and of water by the action of concentrated hydrochloric acid on bufotalin.

Bufotalin is not present as such in the skin of the toad, but is a product of the decomposition of the actual poison bufotoxin $C_{44}H_{62}O_{11}N_4$, m.p. 204°-205°, hydrolysed by dilute acids to bufotalein $C_{24}H_{38}O_8$ and suberylarginine (Wieland and Alles, Ber. 1922, 55, 1789). Bufotalein differs from bufotalan (above) by having four double bonds, and being yellow.

The carbon skeleton of bufotalin, apart from the acetyl group, consists of 24 carbon atoms, with four rings, and the same arrangement is believed to be present in the bile acids. Moreover, cholic acid has been shown by Windaus and Neukirchen (Ber. 1919, 52 [B], 1915) to differ from cholesterol by having an isopropyl group at the end of a side chain

which in cholic acid is represented by

In bufotalin this side chain is probably further oxidised to a γ -lactone

Bufotalidin is a second crystalline toxic substance from the European toad, $C_{25}H_{38}O_7$. With alcohol of crystallisation it melts at 178°.

and after heating in a high vacuum at 228°-230°; it is probably oxybufotalin.

Bufagin $C_{12}H_{22}O_4$, m.p. 217°-218°, $[\alpha]_D = +11^\circ$, occurs in the secretion of the parotid gland of the large Central-American toad *Bufo* *agua* (together with nearly 7 p.c. of adrenaline), and was isolated by Abel and Macht (J. Pharmacol. expt. Ther. 1912, 3, 319). According to Shimizu (*ibid.* 1916, 8, 347) it is also present in the Chinese drug 'senso.'

Bufo *agua* is used for the preparation of an arrow poison by South American Indians.

Wieland considers that the formula for bufagin may require alteration to $C_{27}H_{38}O_8$, which is that of the methyl ether of bufotalin. The above toad venoms are pharmacologically similar to digitalis and strophanthus (*q.v.*). Digitoxigenin is, according to Cloetta (Arch. exp. Path. Pharm. 1920, 88, 113), $C_{24}H_{38}O_8$, and strophanthidin (=cymarigenin, *see art.* STROPHANTHUS), has 23 or possibly 24 carbon atoms. All these heart poisons from animal and vegetable sources seem to be related to cholesterol and the bile acids. G. B.

TOBACCO. The botanical order of the *Solanaceae* includes many well-known plants which are extensively cultivated because certain portions of them are of great utility to the human race. The tuber of the potato and the fruit of the tomato are food substances of great value and of almost universal consumption. Other genera of the order, however, afford instances of cultivation simply for the production of foliage; the dried leaves of the thorn-apple (*Datura Stramonium* [Linn.]) are sometimes smoked as a remedy for asthma. The most important plants of this class, however, belong to the genus *Nicotiana*, and their dried leaves are known as tobacco. The etymology of the word 'tobacco' is somewhat obscure; the geographical origin assigned to it by tracing it either from Tobago, an island in the West Indies, or from Tabasco, an island in the Gulf of Mexico, is probably incorrect. When the Spaniards first visited San Domingo they found that the natives used a peculiar contrivance for inhaling the smoke of burning tobacco leaves. This instrument was called a 'tabaco,' and was shaped like a Y with the arms so close together that they could be inserted up the nostrils, and it is highly probable that the word tobacco thus originated.

Upwards of 40 species of the genus *Nicotiana* have been described, but many of them are simply modifications resulting from the influence of soil and climate on the chief species. *Nicotiana Tabacum* (Linn.), the most important member of the genus, is a fine plant, indigenous to America, where it grows from 6 to 9 ft. high. The stem is slightly viscous, and the leaves, which are oblong or lanceolate in shape, are attached alternately, and surround the stem in the form of a spiral (of which the ninth leaf overhangs the first, the tenth the second, and so on). The distance between the leaves is usually about 2 ins. Characteristic soft downy glandular hairs cover the stem and the under surface of the leaves, and these are of great service in the identification of tobacco by the microscope. The flowers have funnel-shaped corollas, about 2 ins. long, of a rose or pinkish colour, and are produced in large terminal clusters: the seed

pods have two valves, and the seeds are very small and numerous. Modifications in the type have resulted in the production of several varieties of this species, differing chiefly in the size of their leaves. The two principal groups now recognised are *Nicotiana Tabacum*, var. *macrophylla*, or 'Maryland tobacco,' comprising stalked and stalkless forms, and *Nicotiana Tabacum*, var. *angustifolia*, or 'Virginia tobacco.' The finest growths of Cuba, Manila, and Turkey (including Latakia), are now attributed to a form of the stalked Maryland tobacco. Under the name of Shiraz tobacco, *N. persica*, a very fine variety, is cultivated in Persia; but the plant is probably a form of *N. Tabacum*, obtained by cultivation of seed derived from a Brazilian variety. Of the remaining species, *Nicotiana rustica* (Linn.) is the most important. It is of hardier constitution and dwarfer habit than the preceding species, and the flowers are also of a lighter colour. It is cultivated largely in Germany, Hungary, and in the East Indies, and includes the common Hungarian and Turkish varieties.

The use of tobacco for smoking purposes is supposed to have originated among the North American Indians. When America was first discovered, and afterwards when fresh portions of the continent were explored, the practice was found to be prevalent among all the native tribes, and its introduction into Europe very soon followed. The plant was first cultivated in Spain early in the sixteenth century, and was introduced into France and Italy about the year 1560. It attained considerable fame as a medicinal herb, and was at first regarded with universal favour. Sir John Hawkins is said to have brought plants home in 1565, but Sir Walter Raleigh, who learned the uses of the plant from Mr. Ralph Lane, Governor of Virginia, probably first introduced its cultivation. The habit of smoking soon became general, but this use of the plant met with a considerable amount of opposition, not only in England, but also throughout Europe. Nearly the whole of the early literature on the subject was written in an antagonistic strain. Kings' counterblasts, Popes' anathemas, Sultans' decrees and even violent punishments failed to check the growing habit, and plantations sprang up, not only in the New England States, but also all over the United Kingdom. In the year 1604 the tax on the imported article was raised from 2d. per lb. to 6s. 10d. per lb., and English planters were forbidden to produce more than one hundredweight of the leaf. Shortly afterwards the pre-emption of tobacco was made a royal monopoly, and the King enjoined the plucking up of all tobacco found growing in England and Ireland. In the years 1652, 1660, and 1663, Acts were passed prohibiting the cultivation of tobacco in England and Ireland, and these Acts were extended to Scotland in the year 1782. The prohibition as regards Ireland was removed in the year 1779, but was subsequently reimposed in the year 1831. Notwithstanding these measures, the cultivation of tobacco in England did not really cease until the year 1782, when some planters in the vale of York were imprisoned and fined the sum of £30,000. The restrictive legislation as regards Ireland was repealed in 1907, and for Great Britain in 1910.

Culture.—The tobacco plant, though essentially tropical, can, with suitable modifications in the cultural details, be grown successfully in temperate climates. It is cultivated for commercial purposes in the United States, Cuba, Mexico, Brazil, Paraguay, the Dutch Indies and North Borneo, Australia, India, China, Burmah, the Philippines, Persia, the Transvaal, Rhodesia, Nyasaland, the Levant, Greece, Hungary, Germany, Russia, France, and Holland, and is grown on a small scale in the United Kingdom. In Spain and Egypt its cultivation is prohibited. Cigar leaf is grown in Cuba, the East Indies, North and South America, Rhodesia, and Germany; tobacco for pipe smoking in the United States, the Levant, Germany, the Transvaal, Nyasaland, Australia, China, Java, tobacco for cigarettes in the United States, the Levant, Greece, Persia, and other countries. In the United States, several types of leaf are grown, of which the principal are the Seed Leaf and Florida varieties of Cuba and Sumatra tobacco for cigars; White Burley; the Heavy Shipping or dark tobacco of Kentucky, Virginia, and Maryland; the Yellow tobacco of Carolina and Virginia; and the Perique of Louisiana. A spangled type of yellow tobacco is grown also in Ohio. Seed Leaf requires a strong, highly-manured soil, which will promote a rapid growth, so that the plants may be harvested when expansion of the leaves ceases, and the process of granulation and secretion of the gummy substances begins. White Burley flourishes in a highly fertile disintegrated limestone. Heavy Shipping tobacco thrives best on ferruginous clayey soils. Yellow tobaccos need a sandy porous, sterile soil, to which just sufficient fertilizers (superphosphate, potash, and nitrogenous) have been added to promote summer growth; in the autumn the plant's declining vitality causes the leaves to turn more and more yellow until the tint desired is reached, which is afterwards fixed in the curing process. Perique is grown on low-lying lands, black with humus, in the swampy districts of Louisiana. Climate has a great influence on the flavour, but the texture of the leaf depends largely on the nature of the soil in which the plant grows. The northern varieties, for example, planted in the Southern States gradually change in character; the plants ripen earlier and the leaves assume a lighter colour, diminish in size, and increase in thickness and sweetness. * Special attention must be paid to the fertilizers used to ensure that the proportions of ammonia, potash and phosphoric acid most suitable for the type of leaf are employed. Too much ammonia darkens the colour of the leaf and increases its nicotine-content, while too little ammonia retards the growth. Alkaline materials encourage the growth of certain fungoid diseases, especially root-rot, and lime is therefore much less used than was formerly the case.

The seed is sown in February, March, or April, in seed beds, composed of a light friable soil prepared some time beforehand, and a brush heap is burned on the ground prior to sowing to destroy harboured insects. The young plants are raised either in hot beds, or in cold frames protected by plant-matting, according to the locality. In the three months from April to June, when the plants are about 8 ins. high,

they are transplanted into well ploughed soil, thrown up in ridges; and if the weather is dry, they are watered in. A space of from 1½ to 3 ft. is allowed between each plant in the rows, which are made from 3 to 4 ft. apart. The constant removal of suckers from the plants ('suckering'), frequent harrowing of the soil, and destruction of weeds and insect pests are necessary. In Turkey and other Eastern countries, where small leaves are desired, and the buds and flowers are also used, 'topping' is not practised, but the larger growths of the United States, &c., usually require this treatment when the first bloom begins to show. Ten to a dozen leaves in the case of Heavy Shipping tobacco, and 16 to 18 leaves in the other varieties, are allowed to remain on the stem, and the increase in leaf surface may be as much as 50 p.c., when compared with leaves of normal size. Seed Leaf requires from 2 to 3 weeks after this operation to ripen, yellow leaf and Burley take a month, and Heavy Shipping tobacco 2 or 3 weeks longer. An abnormal amount of organic matter accumulates in the cells of ripe tobacco leaf, owing to the 'topping' and 'suckering' of the plant. The continuous accumulation of nicotine, oxidising enzymes and acids which takes place in the cells finally causes the chlorophyll granules to acquire a yellowish colour. The change from the normal deep green tint of the leaf is very noticeable to the experienced eye, and indicates that the time for harvesting has arrived. Another sign of ripeness is that the leaf becomes brittle, and snaps when bent between the fingers on account of the great increase in its starch contents. The constituents of the cells having fulfilled their functions are at this stage going back to the stem to be transferred thence to the upper leaves, to be used for other purposes in the economy of the plant. Compared with the young leaf, the ripe leaf has a density half as high again, and contains about 2½ times as much matter soluble in boiling water. The curing of tobacco is a skilful operation, involving much more than the simple drying of the leaf. Its object is to promote by favourable conditions the important changes in composition which are brought about by enzyme action on the surplus food material stored in the ripened leaf. Until this is accomplished, it is necessary that the life of the leaf, which may persist for several days after harvesting, should be preserved. Any actions which tend to kill the leaf prematurely are to be avoided, e.g. breaking or bruising the leaf, freezing or very rapid drying. The methods of curing are fully described in Farmer's Bulletin, No. 573 of the U.S. Department of Agriculture, 1916. White Burley and Seed Leaf are air cured in houses that can be ventilated at will: this operation requires from 6 to 8 weeks. An alternating change from the moist to the dry condition of the leaves takes place according to atmospheric conditions as the curing proceeds. Yellow leaf is cured by artificial heat, distributed by flues in air-tight barns. The temperature is maintained at 80° to 90°F. for 16 to 36 hours for the leaf to acquire the proper colour, the heat is then raised by 5° to 10° at a time, about every 2 hours, to 115° to 120°F., and maintained at this point until the leaf is properly cured. The curing of the stalks is then effected by raising the temperature hourly by 5° to 10°

to about 180° to 175° F. The whole operation takes about three days. Heavy Shipping tobacco is hung on scaffolds or in barns for some days to become yellow, and the curing is completed by open log-fires, kindled directly under the tobacco and gradually increased in size. In India, Ceylon, and other Eastern countries, sun-curing is sufficient. Where resort to artificial heat is necessary, it is essential that the increase of heat should be at first very gradual, as the object is not so much to dry the leaf as to fix as far as possible its qualities as regards colour, strength, elasticity and flavour. A high initial temperature causes the leaf to dry rapidly and retain its green colour, whereas by slow drying the tint produced will vary from shades of yellow to brown. The proper fixing of the colour of the leaf is of great financial importance to the curer. The leaves, except those of the yellow varieties which are harvested as they ripen, are not usually removed from the stems prior to curing. Perique tobacco undergoes a special process of curing. After the leaves in the drying-houses have acquired a brown tint they are twisted into rolls containing about 30 leaves; these rolls are packed into boxes holding about 50 lbs. and heavy pressure is applied; the rolls are then slightly opened out and exposed to the air to aerate the exuded juices and, when these are re-absorbed, again subjected to pressure. This operation is repeated daily for about 10 days, and at longer intervals for some 3 months, with the result that the tobacco acquires a glossy black colour, and a rich characteristic spirituous odour. In Florida, cigar leaf is now grown from Cuba and Sumatra seed, but success has been achieved only by making considerable changes in the ordinary methods of cultivation. The plants are placed closer together, about 14 ins. apart; the Cuban varieties are topped high, but the Sumatra kinds are allowed to bloom. Each plant yields from 18 to 30 suitable leaves which are primed off as they ripen. The discovery that plants shaded by trees were far superior to those grown in the open fields, led to the adoption of artificial shading, which has also been tried with success in Cuba, Porto Rico, and Connecticut.

Preparation for the market involves the grading, fermentation, and ageing of the tobacco, and is usually managed by the packers and not by the farmers. There are three methods of fermentation; the sweating in bulk, the natural sweat after packing in cases, and the forced sweat in case; but the first is generally used, as it can be more easily controlled. The natural sweat of Seed Leaf is conducted in large wooden cases, each holding about 300 lbs. of leaf; a space of about half an inch is allowed between the boards, through which the air enters and the moisture escapes. In the autumn the leaves are pressed tightly into the boxes, which are then stored in the warehouse in tiers until the sweat occurring in the following summer is finished. The temperature is maintained fairly uniform, and the loss of weight during the process amounts to from 10 to 14 p.c. White Burley and Heavy Shipping tobacco are allowed to sweat in bulk for a short time before being primed, or forced into hogheads by pressure; the hogheads are large enough to hold from 1000 to 1000 lbs. of tobacco leaf.

Yellow tobaccos are also bulked down for a month or two to fix the colour, and are afterwards packed loosely. Cuba, Sumatra, and other cigar tobaccos are carefully graded according to colour, &c., and are fermented in large bulks varying from 3000 lbs., for the light varieties to 15,000 lbs. for the dark varieties of leaf. The fermentation is allowed to proceed for from 6 to 8 days, and the heaps are then re-made, the outside portions being placed in the centre. The operations are conducted in rooms heated by steam pipes to about 165° F., but if the temperature of the heaps is allowed to rise much above 140° F. the enzymes present are liable to undergo oxidation with consequent deterioration in the quality of the tobacco.

Home-grown tobacco. In the year 1886, owing to the agricultural depression in this country, efforts were made to remove the restrictions then existing on the home cultivation of tobacco, and permission was obtained to try experimental growings in several selected localities. These experiments were repeated in the following year, and were sufficiently satisfactory to justify the opinion that tobacco could be grown successfully as a farm crop in the British Isles. Experiments under the auspices of the Department of Agriculture in Dublin were started in Ireland in the year 1900. In the year 1904, the cultivation was commenced on a commercial scale, and in the year 1907 the statutory restrictions were repealed. The Department continues to furnish all possible assistance to the tobacco growers, and annual reports on the progress of the experiments are published in its journal. A total area of about 200 statute acres was devoted to the cultivation of tobacco in the year 1914, as compared with 20 acres in the year 1904. The crop of 1914 yielded about 160,000 lbs. of marketable tobacco. During the war the area under tobacco cultivation was greatly reduced, but in 1922 about 35,000 lbs. of tobacco were raised from 50 acres planted by 46 growers. Cultivation has been tried successfully in the following counties: King's County, Louth, Meath, Kilkenny, Wexford, Tipperary, and Limerick. The experimental tests which have been carried on for several years gave promise that satisfactory roll and plug pipe-tobaccos could be produced from such hybrid varieties of leaf as 'Copper King,' 'Blue Pryor,' and 'Kentucky Black,' also 'Irish Gold' for cigarette tobacco. These varieties were found, however, to suffer from root-rot, a condition which does not obtain in the Italian hybrids 'Skiky,' and 'Turkish,' which have since been tried for pipe and cigarette use respectively. The influence of the cool, moist climate favours the production of large thin leaves which are somewhat deficient in gum, resins and aroma; but these defects have to some extent been overcome by prolonging the ripening season, during which the leaf gains in body. Irish leaf is for the most part used for blending with unfermented dark American tobacco of the Western type, and recent experiments have been directed chiefly to the raising of small crops of heavy dark varieties by working farmers. The Irish climate, however, favours the production of tobacco such as is grown in northern countries, all of which is fermented. The crop of 1922 has been treated thus with satisfactory results. The quantities

for success are deep cultivation, a fine soil, and fields protected from cold winds by high hedges or other means. As regards manures, the initial growth is found to be more rapid when farmyard manure is supplemented by artificial manures. The largest yield is obtained on uplands, when manures containing a large proportion of phosphates are used; potash is more effective for moorlands. Nitrogen and phosphates have a tendency to produce a coarse leaf; with potash a smooth leaf is obtained, and the burning qualities are improved, but the growth is somewhat retarded. In consequence of the minute size of the seed, about 300,000 to the ounce, the plant is forced to rely unusually early on external nourishment. The seeds are sown in glass-covered hot-beds some time between the middle of March and the middle of April, and the plants are transplanted at the latest by June 1st. The usual cultural details are followed: insect pests, on the whole, are not so troublesome as they are abroad, but the cool, moist climate greatly increases the tendency to produce suckers. 'Topping' of all the varieties, except Turkish, is usually practised. Ripening is hastened by the 'topping' and 'suckering' operations, but the usual indications, change of colour, curling of the edges of the leaf, &c., are less manifest under Irish climatic conditions. Harvesting lasts from about the end of July to mid-October, according to whether the leaves are primed off as they ripen, or whether the whole plant is harvested with the leaves still attached to the stem. The practice of allowing the plants to wilt in the open air on scaffolds which are capable of being protected from heavy rains, has been found very valuable. Air-curing, supplemented by suitable artificial heat at critical periods, has proved to be the best method for most classes of tobacco. The subsequent preparation of the leaf for the market involves the usual operations of grading or sorting, fermentation in bulk, and ageing, after the tobacco is packed. A statute acre of land yields on the average about 1000 lbs. of tobacco at a cost of from £20 to £60.

The enactments against the growth of tobacco in Scotland and England were repealed by the Finance Act of the year 1909-1910, and from 1911 to 1913 a rebate of one-third of the duty was allowed on home-grown tobacco. Grants have since been made by the Development Commissioners and the Board of Agriculture with the object of promoting experimental work on the culture of tobacco which has been undertaken in 27 counties in the United Kingdom under the auspices of the British Tobacco Growers Society. Thirty-three acres were planted in the year 1913, in addition to 80 acres cultivated by private growers. In the year 1915 duty was charged upon nearly 33,000 lbs. of tobacco grown in England, and upon 2000 lbs. grown in Scotland; but no tobacco has been grown in Scotland since 1916. The Ministry of Agriculture have also undertaken experiments on the growth and after-treatment of tobacco on government-owned land in Norfolk. In 1923 about 14,000 lbs. of leaf were obtained from 18 acres under cultivation in Hampshire. Since 1918, however, there has been a marked decrease in the areas under tobacco cultivation in the United Kingdom, Northern Ireland, and the

Irish Free State. Growers contended that the rebate of one-sixth from the duty allowed by law in 1919 in the case of home-grown tobacco was not sufficient to allow of tobacco being grown at a profit. A Government Committee appointed by the Treasury to inquire into this question reported in 1923, Cmd. 1983, that though a limited number of agriculturists might derive some benefit from some measure of assistance to the industry of tobacco growing in this country, they came to the conclusion that the nature and extent of that benefit were not such that the committee could recommend any further expenditure of public funds over and above the help already given by Imperial Preference. The principal grounds on which the committee's conclusions were based are as follows:—

(1) Even allowing for the improvements which might be effected in British grown tobacco as the outcome of further experience, they could not anticipate that anything more than a low-grade article would be grown generally in Great Britain.

(2) There is accordingly no prospect of tobacco being grown on a large scale so as to compete successfully with foreign tobacco, except under a preference such as the industry now enjoys; and the amount of such a preference will always be liable to alteration (apart from the automatic decrease which a reduction of duty would bring about).

(3) Competing overseas products would always have the advantage of more suitable climates and of cheaper labour, and it cannot be assumed that Great Britain will have a monopoly of improvement.

(4) The crop is not suitable for smallholders, owing to the heavy capital expenditure required, the uncertainty of the quality and amount of the yield, and the interval which must elapse before a return on the outlay can be expected.

(5) Except on a limited area of land, the crop does not offer such a prospect of effecting a general improvement in the system of agriculture nor so remunerative a substitution for existing crops, as would justify some considerable outlay in bringing about its establishment.

Provision is made for remission of duty on such home-grown tobacco as is used for the preparation of tobacco extract for insecticidal purposes. An approved denaturant must, however, be added to the extract before it is allowed to pass out of revenue control.

Composition.—The tobacco plant contains a large number of substances common to the vegetable kingdom, chief among which are cellulose, starch, albuminoids, saccharine matters, resins, chlorophyll, and many organic acids. On the character and proportion of these organic substances depend largely the uses to which the several varieties of tobacco are put. Freshly-cut green leaves contain from 80 to 90 p.c. of moisture: the normal percentage in the leaf when ready for the market is from 12 to 14 p.c., but in the finer grades of cigar and other leaf 20 p.c. is not uncommonly found. The amount of nicotine, the characteristic constituent of tobacco, varies from about 1 to 10 p.c.: thick-leaved varieties contain more than those with thin leaves, and the top leaves of a plant are richer in nicotine than those at the base of the

stem. Schlessing has shown that the amount present in the leaves increases as growth proceeds: from leaves of the same kind collected on May 25, August 27, and September 25, he obtained 0.79, 2.27, and 4.32 p.c. of nicotine respectively. Dark, heavy tobaccos contain considerably more nicotine than the light coloured varieties. The use of large quantities of nitrogenous manures favours the production of nicotine in the plant. Java leaf contains from 1 to 2 p.c., Havannah, Maryland, Manila, and Turkish from 2 to 4 p.c., Virginia and Kentucky up to 7 p.c., while some heavy French varieties contain as much as 10 p.c. of nicotine. The organic acids present in tobacco are chiefly malic, citric, oxalic, and pectic; acetic acid is sometimes found in fermented leaves. Some proportion of these acids exists in combination as acid salts and gives an acid reaction to the cell-sap. The malates, owing to their hygroscopic properties, are said by Behrens to exercise a considerable influence on the 'life' of the leaf by preserving its elasticity and softness. The changes in the colour of the leaf which occur during the curing process are concomitant with considerable changes in the chemical composition, brought about partly by the etiolation of the chlorophyll granules, and partly by the subsequent oxidation of the sap contents of the dead cells. The acidity of the leaf, and the proportions of soluble albuminoids, and of starch also markedly diminish. Further changes of a complex character occur in the sweating process. The nicotine which exists in the leaf in combination with various organic acids is partially liberated, and part of it and of the amino bodies and albuminoids also, are eliminated. The nitric acid and ammonia-content should be little affected, but excessive fermentation favours the production of ammonium salts. Experiments by Dr. Loew of the United States Department of Agriculture, supplemented by those of Oosthuizen and Shedd, have proved that various soluble ferments or enzymes exist in the tobacco plant during its growth, and their researches have thrown light on the considerable influence enzymes exercise on the changes which occur during the ripening, curing, and fermentation stages. Invertase, diastase, emulsin and reductases have been identified in the tobacco seed, and in the leaf, not only during all stages of its growth, but also after the completion of the curing process. Oxidases have been found to be present in the growing leaf, but after the 'topping' operation they gradually diminish in quantity until maturity is reached, and almost entirely vanish during the 'curing' process. Starch is converted into sugar early in the curing stage by the action of diastase, but may disappear at a later stage, probably through the action of the oxidases present. Proteolytic ferments accomplish a considerable reduction in the amount of 'fat' or protein in the leaf, and reductases exercise a reducing influence on the nitrates and nicotine content of the leaf. Considerable loss of weight occurs during the curing and fermentation periods, amounting to as much as 15 p.c. in the later stage alone, of which about a quarter is solid matter. The retardation of enzyme action by unfavourable conditions in the curing and fermentation processes adversely affects the

flavour and aroma of the tobacco. Many attempts have been made to isolate and identify the bodies which impart the aroma to tobacco, but they have so far proved unsuccessful. At one-time the source of the aroma was believed to be the so-called tobacco-camphor, or nicotianin, a crystalline volatile substance obtained by the steam distillation of fermented tobacco; but experiments have shown that it is not always associated with nicotine in tobacco leaf, as was supposed. The theory of Suchsland, that the distinctive aromas which characterise the different types of tobacco are due to the action of specific bacteria during the sweating process, has not been substantiated by other observers. The formation of the aromatic substances is believed to be due largely to the influence of enzyme action, whereby elimination or breaking down occurs, especially in the nicotine, amino-bodies and other nitrogenous constituents of the leaf, during the fermentation stage. It is well known that a high nicotine content in a cigar is often associated with a poor aroma, and that if the leaf has a high protein content the quality of the aroma is especially liable to be deteriorated by imperfect curing. The deficiency in aroma which is characteristic of bright yellow leaf is no doubt due to the destruction of the enzymes which occurs in consequence of the high temperatures required during the curing stage of this class of tobacco. The aromatic matters of tobacco are soluble in water, and more or less so in alcohol, and are readily dissipated by heat. The odour developed in smoking a cigar may be due partly to the mere volatilisation of the aromatic products of the sweating process and partly to the destruction of certain constituents. Nicotine, ammonia, carbon monoxide, pyridine, trimethylamine, butyric acid, and traces of nicotianin, hydrogen cyanide, formaldehyde, and hydrogen sulphide, in addition to water and carbon dioxide, have been found in tobacco smoke. Kissling recovered from the smoke of two different samples of burning tobacco, each containing originally 3.75 p.c. of nicotine, 27.8 and 52.0 p.c. of the nicotine, while the quantity in the unconsumed portions of the tobacco increased to 4.5 and 5.9 p.c. respectively.

Armstrong and Evans (Brit. Med. J. 1922, (1), 992) found that the amount of carbon monoxide varied with the rate of smoking. Cigarettes smoked normally yield a smoke containing 0.6 to 0.8 p.c. carbon monoxide, pipe-tobaccos from 0.7 to 1.14 p.c., and cigars from 6 to 8 p.c. As regards cigars the results are little affected by make or quality, closeness of packing and rate of smoking being the determining factors.

The table on p. 82 gives analyses of certain kinds of tobacco serves to show the wide differences in the composition of various typical varieties. It is compiled from the results of analysis of many kinds of tobacco, which were made in the Inland Revenue Laboratory under the direction of Dr. James Bell.

The amount of ash found in tobacco varies greatly, and when calculated on the dry leaf ranges from about 10 p.c. to as much as 25 p.c., or even more. The lowest amount is found in the light varieties used for making cigarettes, and the greatest amount in leaf intended for making pipe-tobacco. The ash of tobacco invariably

contains potash, lime, magnesia, iron-oxide, alumina, soda; carbonic, silicic, sulphuric and phosphoric acids, and chlorine. The potash, which exists in the tobacco mainly in combination with the organic acids, may be present to the extent of fully 30 p.c. of the total amount of the ash. The amount of lime present is generally lower than that of potash: magnesia and silica rank next, while the amounts of soda, alumina and iron oxide are relatively small. Lithia and manganous oxide are occasionally present in very small quantities. The combined chlorine varies from a mere trace to as much as 15 p.c. of the total amount of the ash (*cf.* Roberts, Analyst, 1918, 254).

The following table shows the percentage composition of the ash of the several kinds of tobacco enumerated in the preceding table.

The leaves of tobacco contain more magnesia and silicic acid, and less alkali, phosphoric acid and chlorine than the stalks. The nitrates are confined almost entirely to the stalks and stems of the young plant, and decrease in amount as the plant comes to maturity: analysis of cigar-stalks from Missouri and Connecticut showed from 0.5 to 0.75 p.c. of nitrates, as against 0.15 p.c. found in cigarette leaf. Home-grown tobacco as a rule contains a considerably higher percentage of ash than is present in similar varieties grown abroad: this circumstance is probably accounted for by the use of manures either in excessive quantities or of unsuitable character, especially when large quantities of combined chlorine are present.

Good burning qualities in tobacco are associated with a high percentage of ash, rich in

lime and potash salts: chlorides, except in the presence of much potash and lime, have a decidedly retarding effect on the combustion, but silicates, phosphates and sulphates have a beneficial effect. Albuminoids hinder, but cellulose promotes the good burning qualities of tobacco; while nicotine appears to be an unimportant factor. The comparative burning qualities, estimated by the time of glowing of the kindled leaf, vary from about four seconds in yellow varieties to as much as 175 seconds in Pennsylvania cigar-leaf.

Tobacco is analysed as regards organic and inorganic constituents by the usual methods described in text-books dealing with agricultural and quantitative chemical analysis. Special processes applicable to tobacco are described in the report on the culture and curing of tobacco in connection with the 10th United States Census of 1880. The percentage of moisture is liable to be under-estimated if the drying-oven is not maintained at a temperature of 100° . The ash should be re-carbonated by the addition of strong solution of ammonium carbonate, and subsequently dried before ascertaining the weight. A convenient method for the estimation of nicotine in tobacco is that of Kissling, which is as follows: Take 20 grms. of tobacco, finely powdered and dried at a temperature not exceeding 60° , grind it up in a mortar with 100 c.c. of alcoholic solution of soda (6 grms. of NaOH dissolved in 40 c.c. of water and then made up to 100 c.c. with absolute alcohol). Transfer the mass to a Soxhlet extraction apparatus and extract for 3 hours with sulphuric ether. Remove as much of the ether as possible by careful distillation, mix the residue with 50 c.c. of a 4 p.c. solution of soda, and distil in a current of steam. The flask containing the nicotine extract should be connected with the condensing apparatus by means of a tube having a safety bulb, and the distillation conducted rapidly and in such a manner that when 200 c.c. of the distillate have been collected not more than 15 c.c. of liquid remain in the distilling flask. Titrate the distillate with decinormal H_2SO_4 , using lacmoid or litmus paper as an indicator. By using a series of test papers and noting the burette-reading against each, the exact point of neutralisation can readily be ascertained when the papers are dry.

The method of Bertrand and Javillier, based on the precipitation of the nicotine as the silicotungstate, may advantageously be employed when the nicotine distillate also contains ammonia. A gravimetric adaptation of their process has been described by R. Spallino (*Gazz. chim. ital.* 1913, 43, 482-486). Five grms. of tobacco are placed in a Kjeldahl flask with 20 c.c. of water and 2 c.c. of 10 p.c. soda solution, and the mixture steam-distilled to a bulk of 500 c.c. Do 100 c.c. of the distillate are added 10 c.c. of dilute HCl, and 10 c.c. of a 12 p.c. solution of pure potassium silicotungstate, and the mixture well stirred and allowed to stand for 2 hours. The precipitate is filtered through a tared Gooch crucible, washed with water acidulated with HCl, and ignited at a red heat. The residue has the composition $12WO_3 \cdot SiO_2$, and its weight multiplied by the factor 0.1136 gives the quantity of nicotine in one gram of the tobacco.

The method just described for the determination

of nicotine in tobacco smoke. Popp and Contzen (*Chem. Zeit.* 1922, 46, 1001) found that the total nicotine in eight kinds of cigar and pipe tobacco varied from 0.31 p.c. to 2.21 p.c. The smoke from these tobaccos contained from 0.30 p.c. to 1.05 p.c. of nicotine. See also Analyst, 1923, 33. According to H. Rhode (*Zeitsch. Untersuch. Nahr. Genussm.* 1923, 45, 112-115), the five brands of tobacco examined contained from 0.68 to 2.37 p.c. of nicotine calculated on the dry substance. When the samples were smoked in a pipe, attached to an aspirator with an intermittent action, from 15.4 to 28.8 p.c. of the total quantity of nicotine was found in the smoke. The amount of the alkaloid present in the smoke was not proportional to that in the tobacco itself (Analyst, 1923, 48, 568, 334).

Various methods of estimating nicotine in tobacco and tobacco extracts have been critically examined by Rasmussen (*Zeitsch. anal. Chem.* 1916, 55, 81; Analyst, 1916, 208), who found that the polarimetric method of Koenig as well as the silicotungstic method of Bertrand and Javillier, and the method of Kissling above described, gave accurate results; whilst Keller's method and that of Toth were less accurate, and those of Ulex, Degrazia, and Thoms were untrustworthy. This investigation has been carried further by Shedd in the Journal of Agricultural Research (Washington D.C.) 1923, 961-970. In the recovery of nicotine by the distillation method he used solid sodium hydroxide and found that, unless the bulk in the distilling flask was maintained at from 15 to 25 c.c., extreme difficulty was experienced in distilling off all the nicotine, especially when derived from tobacco. On the other hand, when 2 grams of soda were added to liberate the nicotine, higher results were obtained from the distillate by precipitation than when less quantities of alkali were used. He attributes the difference to the presence of some other volatile substance, produced by the action of the strong alkali on the small bulk in the distilling flask, which is precipitated by silicotungstic acid. For these reasons he suggests that instead of using the distillation method, the ether extract of the nicotine obtained by the Soxhlet extraction, after careful reduction in bulk, should be extracted in a separator with cold dilute hydrochloric acid (1:4) from 4 to 6 times. The extracts are bulked and an aliquot part, representing about 0.25 gram of tobacco extract, or from 1 to 2 grams of tobacco, is taken and diluted to 400-500 c.c. with water. Sufficient dilute hydrochloric acid—at least 3 p.c. is required—is added to show an acid reaction with methyl orange before precipitation. For this purpose he uses a 12 p.c. solution of silicotungstic acid having the specific formula $SiO_2 \cdot 4H_2O \cdot 12WO_3 \cdot 22H_2O$. The factor for converting the weight of the ignited residue to nicotine is 0.114. The details of the method are as follows: Five grams of finely powdered dry tobacco, or 1 gram of tobacco extract (about 40 p.c. grade), is moistened with 25 c.c. of alcoholic sodium hydroxide solution (6 grams of sodium hydroxide in 40 c.c. of water and 80 c.c. of 90 p.c. alcohol). The extracts 5 c.c. of soda solution is used and the mixture made into a moist paste with calcium carbonate. The sample is extracted for 2 hours with ether in a Soxhlet extractor, and the

taken that the temperature of the cooling jacket does not rise above 20°C. and that the volume of solvent in the extraction flask is never less than 25 c.c. After extraction, the excess of ether is removed, but the volume remaining must be sufficient to keep the whole of the extracted matter in solution. The ether extract is transferred to a separating funnel, the flask being rinsed with ether and finally with hydrochloric acid (1 : 4), and shaken with from 4 to 6 10-c.c. portions of hydrochloric acid (1 : 4). The formation of emulsions can be avoided by adding 1 c.c. of alcohol. The washings are filtered through glass wool into a 100 c.c. graduated flask. When tested portions of the washings no longer give a turbidity with silico-tungstic acid reagent, the whole volume is made up to 100 c.c., an aliquot portion equivalent to 1 to 2 grams of tobacco is diluted to 400–500 c.c., and sufficient hydrochloric acid (1 : 4) added to ensure that at least 3 c.c. of it is present in 100 c.c. of the solution; 1 c.c. of silicotungstic acid solution is then stirred in for every 0.01 gram of nicotine supposed to be present. After stirring for 3 to 5 mins. the precipitate appears crystalline and settles readily. The solution is allowed to remain for 18 to 24 hours and filtered, preferably through a Hirsch or Buchner funnel. The precipitate is washed with hydrochloric acid (1 : 1000), dried, and transferred—with the paper to a platinum crucible. After heating until all carbon is removed the crucible is finally ignited for not more than 10 mins. over a Teclu or Meker burner. The weight of the residue $\times 0.114$ gives the weight of nicotine in the aliquot portion taken. The silicotungstic acid reagent is a 12 p.c. solution of the acid $4\text{H}_2\text{O}_3\text{SiO}_3 \cdot 12\text{WO}_3 \cdot 22\text{H}_2\text{O}$. The other silicotungstic acids do not give a suitable crystalline precipitate with nicotine (O. M. Shedd, J. Agric. Res. 1923, 24, 961–970; J. Soc. Chem. Ind. 1923, 42, 1150A).

Manufacture.—In several European countries, among which may be mentioned France, Spain, Italy, Austria-Hungary, and Turkey, the manufacture of tobacco is a State monopoly. In Canada, the United States, Germany, Holland, and other European countries the manufacture is in private hands. In the United Kingdom, tobacco is subjected to a heavy import duty, but a rebate of one-fourth is allowed on tobacco grown in the British Empire. Certain legal restrictions are imposed, which, however, chiefly affect the manufacturers of the commoner kinds of tobacco. The only substance allowed by law to be used in the manufacture of tobacco is water. The use of olive oil is permitted in spinning and making up roll tobacco, and essential oils are allowed for flavouring purposes. The finished article must not contain more than 32 p.c. of moisture, and if it is roll tobacco, not more than 4 p.c. of olive oil. The leaves of plants other than tobacco may not be employed, nor any preservative except acetic acid. Essential oils for flavouring purposes may be added to snuff, and the addition is allowed of the carbonates, chlorides and sulphates of sodium and potassium, ammonium carbonate, and of 1 p.c. of lime in the form of lime-water. The snuff, when dried, however, must not contain more than 26 p.c. of alkaline salts nor more than 13 p.c. of the oxides of lime and magnesia, inclusive of the amounts naturally

present in tobacco. More latitude is allowed in the manufacture of tobacco in bonded factories: the addition of foreign leaves is not permitted, but any suitable sweetening or flavouring matter may be used. Sugar, honey, liquorice, glycerin, gum, salt, and logwood are the ingredients most commonly used for this purpose in the manufacture of this kind of tobacco, which is known as Cake- or Cut-Cavendish, and is manufactured chiefly for exportation. If intended for home consumption, this tobacco is required to be enclosed in a specially designed Customs' wrapper to distinguish it from the ordinary article, and it is subjected to a higher rate of duty. The sale of cigarettes containing sweetening matter is not permitted.

Tobacco leaf is imported into this country either entire or with that portion of the mid-rib removed which cannot be used in manufacturing, in which case it is called 'strips', and assessed at a slightly higher rate of duty. Apart from fluctuations due to war-time conditions, the proportion of 'strip' tobacco imported is steadily declining, having fallen from 39 p.c. in the year 1907 to 30 p.c. in the year 1925. Over 85 p.c. of the raw material comes from America, and about 6 p.c. from other foreign sources, chiefly the Levant, Dutch Indies, China, and Japan. Empire-grown tobacco secured preferential tariff treatment in 1919, and in 1925 the rebate of duty allowed was increased from one-sixth to one-fourth. About 8 p.c. is now imported, chiefly from India, Nyassaland, Rhodesia, Canada, and North Borneo. The principal kinds of foreign tobacco used are Virginia, Kentucky, Western, Burley, Ohio, Perique, Havannah, Japan, Java, China, Sumatra, Borneo, Turkish, and Latakia. The more tender varieties, such as Turkish, are packed carefully in bales leaf upon leaf, but hogsheds are the usual packages employed: the leaves are packed either in layers or in bunches of ten to a dozen leaves, bound round with another leaf and known as 'hands.' Price, colour, texture, burning qualities, aroma, and body or drinking power, that is, ability to absorb and retain moisture without becoming too wet, are all factors which influence manufacturers in selecting tobacco.

Imported leaf, although apparently dry, usually contains from 10 to 20 p.c. of moisture, but 14 p.c. may be regarded as a fair average. There are two rates of duty on imported leaf tobacco depending on the amount of moisture present. The duty on leaf containing less than 10 p.c. of moisture is levied at a rate substantially higher than on leaf containing 10 p.c. or more of moisture. The manufacturer of the cheaper kinds of tobacco endeavours therefore to secure leaf containing moisture as little in excess of 10 p.c. as possible, and so to obtain a larger profit from the greater amount of water he can add in the process of manufacture. In cigarette, cigar, and other varieties of leaf requiring careful handling, a higher initial percentage of moisture is desirable, and these varieties of leaf sometimes contain as much as 20 p.c. of moisture.

The principal kinds of manufactured tobacco are cut, twist or roll, and cake tobacco; cigars, cigarettes, and snuff. Many kinds of leaf are blended for manufacturing cut tobacco, and in the commoner kinds a considerable quantity of

TOBACCO.

leaf other than American is employed. These 'substitutes' were adopted at the time of the civil war in the United States of North America, which caused a temporary shortage in the supplies of Virginia leaf tobacco. Many of these 'substitutes' have the distinct advantage of being able to retain a large quantity of moisture without appearing to be unduly moist. Other blends are made entirely from Empire-grown tobacco.

The first process in manufacturing tobacco is the 'liquoring' stage: the old crude method of employing a watering-pot has now been superseded by the use of steam appliances which ensure a more even distribution of the moisture. When 'strips' are not employed, the mid-rib of the leaf which absorbs more moisture than the lamina is then removed—this operation is called 'stripping.' A mechanically actuated knife is employed to cut the tobacco into shreds: 'shags' and such like tobaccos undergo the further process of 'panning,' which consists in thoroughly mixing up the cut tobacco on copper trays heated to a suitable temperature; the tobacco is then set aside to cool on racks. The moisture in the common kinds averages about 30 p.c., but the better kinds of smoking mixtures contain from 15 to 25 p.c. The distinctive flavours of these tobaccos are due either to the presence of Latakia, Perique, &c., in the blend of leaves used or to the addition of essential oils such as oils of cassia, geranium, cloves, bergamot, and winter-green. Acetic acid is employed as a preservative. For 'twist' tobacco the darker varieties of American leaf, such as Kentucky, Western, Clarksville, &c., are chiefly employed, but a small quantity of Empire-grown leaf is now used in this class of tobacco. 'Twist' tobacco is made either by hand or on a spinning-wheel: the damp strips or 'fillers' are formed into ropes, the thickness of which depends on the denomination of 'twist' intended to be manufactured, and these ropes are enclosed in a covering wrapper of leaf. The tobacco, at this stage, is known as 'brown twist,' for which a considerable demand exists, chiefly in the North of England. If the tobacco is intended for 'black twist' the rope of tobacco is made up into 'rolls,' consisting of several concentric layers superimposed one on the other. The rolls, after being enclosed in oiled cloths, and tightly bound up with rope, are then baked in steam-heated hydraulic presses until the tobacco assumes a rich black colour, and develops its full aroma; they are then removed to a cold press until cool and fully matured. In order to prevent the coils from sticking to one another in the rolls, olive oil is applied to the tobacco during the 'spinning' and 'rolling' or 'making up' processes, but the amount of oil used is regulated so as to ensure that the finished tobacco does not contain more than 4 p.c. of oil. Acetic acid and essential oils are also employed. Special names are given to different forms of 'twist,' e.g. the terms Ladies' twist, Aloa twist, Liverpool roll, Pigtail and Bogie, have reference to the thickness of the rope; Negrohead indicates a plaited variety; Nailrod is in the form of sticks, and Target is a thick twist coiled up in a single layer. 'Cake' tobacco is prepared either by pressing 'spun' tobacco or by flattening the damp strips under pressure

and then adding an outer covering of leaf. 'Flakes' and 'Cut Cavendish' are obtained by cutting these cakes.

The leaf employed for the manufacture of high-class cigars has to meet many requirements, and blends of different varieties are therefore employed. The component parts of a cigar are the 'filler,' the 'bunch wrapper,' and the 'outer wrapper.' The 'filler' consists of fragments or cuttings of leaf, or even cut tobacco. The 'bunch wrapper' is shaped like a balloon gore, and cut from a tobacco strip of fairly good quality. The outer wrapper is a long rectangular strip of leaf cut from a tough leaf with small veins, of a light and uniform colour and should not possess a pronounced flavour, as it comes in contact with the lips and tongue in smoking; the filler must, however, possess a good aroma, emit an agreeable odour on burning, and have good burning qualities. The finest leaf for cigars comes from Cuba, but Sumatra, North Borneo, Java, &c., supply a considerable quantity of the leaf used for cigar-making in this country. The leaves are moistened with water, opened out carefully, deprived of the midrib, smoothed out and sorted; the perfect leaves are cut in halves and are used as wrappers. The 'filler' is placed on the 'bunch wrapper,' near one end, and the bunch wrapper is then carefully wound round the filler. Over the 'bunch wrapper' the cigar-maker then winds spirally the 'outer wrapper,' commencing at the open end and finishing off at the pointed, or mouth, end. Uniformity in the commoner kinds is secured by the practice of pressing the cigars in moulds before applying the outer wrapper. The cigars are then gauged and cut to the proper length, sorted according to size and colour, dried and packed. Great dexterity is necessary in making cigars, especially in manipulating and keeping the cigars to shape, size, and weight, as well as in evenly packing. The moisture in the finished cigar is reduced to about 10 to 15 p.c. by storage in a drying-room.

The manufacture of cigarettes was introduced into this country by a Greek in the year 1860, and originally Turkish varieties of tobacco only were employed, but 'Virginian' blends are now made in very large quantities from American and other varieties of bright leaf. As the character and the aroma of a cigarette depend on the suitable blending of the various kinds of tobacco employed, this branch of the tobacco industry has become highly specialised. The tobacco used for cigarettes is comparatively dry, the moisture added is just sufficient to permit of the leaf being satisfactorily cut by the machines. The finer varieties of cigarettes are invariably made by hand, either by rolling up the tobacco in the paper, or by filling it into paper tubes closed at one end. In the latter method, charging cylinders slightly smaller in diameter are used, and the tobacco is transferred therefrom to the tubes by means of a small pipe; the closed ends of the paper tubes are subsequently cut off. A great impetus has been given to the production of cigarettes by the employment of cigarette-making machines, which can easily turn out over 60,000 cigarettes per hour. Machines for arranging and packing the cigarettes in cartons are also employed, a single machine being able to deal with at least

380,000 cigarettes per day. The moisture in cigarettes varies according to the time they are stored in the drying-room, and usually ranges from 12 to 18 p.c.; if the tobacco is made too dry it is liable to be shaken out of the wrapper; on the other hand, if the tobacco is left too damp, the cigarette will not burn well. Mouthpieces are often fitted to cigarettes made from Turkish tobacco, on account of its superior burning quality. Cigarettes vary considerably in weight; an ounce may contain from 12 to 40 cigarettes, but 20 to 30 is about the average. Sweetening matter is not allowed to be used in making cigarettes, but the paper wrappers of the 'pectoral' kinds sometimes contain a small quantity of saccharin. Alcoholic solutions of essential oils may be added by manufacturers to the tobacco used in perfumed cigarettes.

Snuff is sold in two forms, dry and moist, the former is made from the stalk or midrib of the leaf, the latter contains a proportion of the lamina. The difference in the quality is dependent on the flavour, the pungency, and the scent. The dry varieties—the Welsh, Scotch, High Toast, and Irish kinds—are, as a rule, more finely ground than the moist varieties. The moisture ranges from about 20 p.c. in Scotch snuffs, to as little as 5 p.c. in Irish snuff. 'Rappees' include such well-known varieties as Latakia, Macuba, and Prince's mixture, and contain from 30 to 50 p.c. of moisture. The tobacco stalks used for snuff-making are cut into small pieces, moistened with alkaline water or sometimes with lime-water, and allowed to ferment, the fermentation period frequently lasting for several months. The material, in the case of Scotch snuff, is then ground to the required degree of fineness, dried down, flavoured, and sifted. The stalks for Irish and Welsh snuff, before being ground, are gently roasted, by which means the characteristic odour of these varieties is produced. For moist snuffs the material is ground wet in a special kind of mortar, and is then allowed to ferment until the required depth of colour is produced. Certain kinds of alkaline salts are mixed with the snuff-flour to increase its pungency, but, as already mentioned, the quantity and the kinds which may be employed are defined by statute. Essential oils, ground orris-root and ground Tonquin beans are used for flavouring purposes. Adulteration of snuff is now rarely practised, but such substances as the oxides of iron, red lead, lead chromates, &c., have been used as colouring materials, and chalk, magnesia, borax, sand, and excessive quantities of alkaline salts have been employed to increase the weight.

Prior to the passing of the Pure Tobacco Act of the year 1842, the adulteration of tobacco with sugar, treacle, honey, gum, &c., and such foreign vegetable matters as rhubarb, coltsfoot, &c., was very general; but in consequence of the heavy penalties imposed by that Act and the vigilance of the Revenue Authorities these practices have almost ceased. The enactments relating to the amounts of moisture and oil in tobacco are also strictly enforced. Such substances as malt combining, moss-litter, &c., are occasionally offered as substitutes for tobacco, but the offenders rarely escape detection and punishment. Manufactured tobacco frequently contains considerable quantities of sand, and

manufacturers are sometimes suspected of using it as an adulterant. The sand, however, usually comes into their possession still retaining a proportion of the sand which was deposited upon it from the soil by the action of the wind and rain during growth. A portion of this sand only is detached from the leaf during the manufacturing operations, which accounts for the presence of sand in the finished article.

In the manufacture of tobacco, a considerable quantity of waste material is produced, siftings, sweepings, &c., and in addition the quantity of stalks obtained by stripping the midrib from the imported leaf is far in excess of that required for conversion into commercial snuff. Repayment of the duty, called 'drawback,' is made by the Crown Authorities on this refuse of tobacco when it is exported or deposited in an approved warehouse to be abandoned to the Crown, or in a bonded factory to be utilised in the manufacture of nicotine or the preparation of 'sheep-dip,' hop-powder, insecticides, &c. Denaturing materials are required to be added to the ground tobacco before it is allowed to be sold, in order to prevent such tobacco being used as a substitute for the duty-paid article. Anthracene oil, bone oil, ground moss-litter, and sulphur are some of the substances used for this purpose.

Statistics.—The amount of tobacco leaf imported into the United Kingdom and the consumption of manufactured tobacco have steadily increased. The imports in the year 1851 amounted to about 28,000,000 lbs. and the consumption was just over 1 lb. per head of the population; in the year 1925, the amount imported was over 152,000,000 lbs. and the consumption was slightly in excess of 3 lbs. per head of the population. The manufacture of tobacco is now one of the most important of the minor industries, and according to the returns made in connection with the Census of Production for the year 1907, the number of persons then employed in tobacco factories was 37,456. The net value of the raw material was £27,988,000 and, including 11,816,000 lbs. of manufactured tobacco exported, the output amounted to 108,292,000 lbs., representing a money value of £23,799,000. The weight of the different kinds was as follows: of cut and roll tobacco, 69,880,000 lbs.; of cigarettes, 29,904,000 lbs.; of cigars, 3,696,000 lbs.; of sweetened cavendish, 3,136,000 lbs.; and of snuff, 1,568,000 lbs. The degree of the popularity of the principal kinds of tobacco, as ascertained from these figures, is pipe tobacco 67·5 p.c., cigarettes 29·0 p.c., and cigars 3·5 p.c. respectively. Cigarettes have, however, materially gained in favour in recent years, and at the present time their proportion may be estimated at 60 p.c.

Tobacco occupies an important position as a source of revenue in the fiscal systems of most civilised countries. In the tariff of the United Kingdom the rate of duty has been more than doubled since the year 1914, and the net amount of duty paid into the Exchequer in the financial year 1924-25 was nearly fifty-two million pounds sterling.

TOBACCO-SEED OIL. Tobacco can yield on pressing, or by extraction with petroleum-ethylene, about 20 to 35 p.c. of a greenish-yellow, mild, and odourless oil, sp. gr. 0·865 at 15° solidifying at -22° which contains some when

exposed to the air. Acid value, 9.5; saponif. value, 196.4; and iodine value, 131.6.

According to Paris (Bot. tec. 1920, 17, 101), tobacco seed contains: water, 9.17 p.c.; crude protein, 21.37 p.c.; fat, 37.68 p.c.; amides and sugar, 6.05 p.c.; pentosans, 2.9 p.c.; cellulose, 7.15 p.c.; and ash, 3.84 p.c. The ash contains 80_2 , 1.97 p.c.; P_2O_5 , 22.12 p.c.; Na_2O , 3.48 p.c.; K_2O , 28.5 p.c.; CaO , 9.54 p.c.; MgO , 14.63 p.c.

A sample of oil from Kentucky seed had d_{20}^{20} 0.9408; temp. of solidification, 12°; acid number, 4; saponif. number, 196; iodine number, 132.8; ether number, 192. The oil consisted of about 52.4 p.c. of olein, 22.1 p.c. of linolein, and 23.9 p.c. of palmitin. Nicotine is not present in the seed except when germinating. The dry, fat-free seed contained 6.5 p.c. of total nitrogen; 3.76 p.c. of protein nitrogen; 2.39 p.c. of nuclein nitrogen, and 0.35 p.c. of non-protein nitrogen. Arginine is present.

TODDALIA ACULEATA (Pers.). This Indian plant, belonging to the *Rutaceae*, is a rambling shrub found in the sub-tropical Himalayas, in the Khasia mountains, and throughout the Western Peninsula and Ceylon.

The root bark is or was used in Madras as a yellow dyestuff, and it is also highly spoken of by various writers as one of the most valuable Indian medical products, possessing tonic, stimulant, and antipyretic properties. It was introduced into European medicine in 1771, and at one time enjoyed some celebrity under the name of 'Lopez Root,' but it has long since fallen into disuse.

According to Brooks (Philippine Journal of Science, 1910, v. 442), the plant is common in the Philippines, but so far as is known is not used as a dye by the natives.

The colouring matter it contains is berberine (Perkin and Hummel, Chem. Soc. Trans. 67, 413).

A. G. P.

TÔHAKU OIL. An unsaturated acid $C_{11}H_{18}O_2$, light yellow oil, was isolated from Tôhaku oil obtained from *Lindera obtusiloba*, B.L., and purified through the methyl ester, b.p. 123°-125°C., its properties being as follows: iodine value 126.33, neutral value 282.26, m.p. 1.0°-1.5°C., sp.gr. at 15°/4° 0.9246, n_D^{20} 1.44922, n_D^{15} 1.45113, molecular refraction 57.71; 100 parts of water dissolve 0.027 part of the acid at 17°C. By Hazura's oxidation method, the oil yielded a hydroxy acid, $C_{11}H_{18}O_3(OH)_2$, fine needles, m.p. 102°C., which is easily soluble in hot water, alcohol, and ether, but sparingly soluble in cold water and ether. When the original acid was ozonised and decomposed with hot water, succinic and α -caprylic acids and α -caprylaldehyde were isolated. Y. Iwamoto therefore assigns the formula

and proposes the name *linderic acid* for the fatty acid (Y. Iwamoto, Kôgyô-Kwagaku Zasshi, J. Chem. Ind. Japan, 1925, 26, 708-716; cf. J. 1923, 856.4; J. Soc. Chem. Ind. 1923, 42, 786 A).

TOLAMINE. Syn. for Chloramine T (q.v.).

TOLUENE. *Tolu*, art. BALSAMS.

TOLUENE. A method for the estimation of toluene. The sample is dissolved by heating with $N/1$ hydrochloric acid and the toluene dihydrochloride precipitated by adding 10 times the

volume of saturated sodium chloride solution. The salt is allowed to crystallise for 20-30 mins., is filtered off and washed with saturated sodium chloride solution, dissolved in warm water, and the base liberated with slight excess of ammonia solution, methyl red being used as indicator and a measured volume of standard ammonia being run in. The precipitated toluene is filtered off and washed with water and the excess of ammonia titrated with $N/10$ hydrochloric acid; 1 c.c. of $N/10$ ammonia solution equals 0.0106 gram of toluene. Test analyses carried out on purified toluene gave results varying between 99.52 p.c. and 99.96 p.c. Variations in the concentrations of sodium chloride and hydrochloric acid used are without appreciable effect on the result (S. Palkin, Ind. Eng. Chem. 1923, 15, 1045; J. Soc. Chem. Ind. 1923, 42, 1121 A).

TOLIDENE (*Orthotolidene*) v. DIPHENYL.

TOLITE. A French term for trinitrotoluene. Used as an explosive.

TOLU v. BALSAMS.

TOLOUENE, toluol or methylbenzene, C_6H_5 , or $C_6H_5CH_3$; first discovered by Pelletier and Walther (Ann. Chim. 1838 (2), 67, 278) among the by-products in the manufacture of illuminating gas from the resin of *Pinus maritima*, and named by them retinaphtha. Also obtained by distilling Tolu balsam (Deville, *ibid.* 1841 (3), 3, 168); from dragon's blood (Glenard and Boudault, Compt. rend. 1844, 19, 506); from coal tar (Mansfield, Chem. Soc. Trans. 1847, 1, 244); from wood spirit and wood tar (Cahours, Compt. rend. 1850, 30, 320); from Rangoon tar (De la Rue and Müller, *cf.* Chem. Soc. Trans. 1861, 14, 54); from American petroleum (Young, *ibid.* 1898, 73, 906); from Borneo petroleum (Jones, Chem. Soc. Trans. 1907, 81, 1146f); and from other hydrocarbons (Rittmann, Eng. Pat. 9136 of 1915; J. Ind. Eng. Chem. 1915, 7, 945, 1014, 1019); in the products of distillation of a large number of substances (Ritthausen, J. pr. Chem. 1854, 61, 74; Bunte, J. Gasbeleucht, 1892, 35, 571; and others); and in a number of naturally occurring substances (Poni, Anal. Acad. romane, 23; and others). For sources of toluene, see also Rhéad (J. Soc. Chem. Ind. 1917, 36, 764).

It may also be prepared by the action of sodium on a mixture of bromobenzene and methyl iodide in ethereal solution, thus proving its constitution as methylbenzene (Fittig and Tollens, Ann. 1864, 131, 303); by the action of methyl chloride on benzene in presence of aluminium chloride (Friedel and Crafts, Ann. Chim. 1884, (6) 1, 459; Sifton, Eng. Pat. 8886 and 9437 of 1915; Fr. Pat. 479297), and by other methods (Gardeur, Chem. Zentr. 1896, i. 438; Fromm and Achart, Ber. 1903, 36, 534; Werner and Zilkina, *ibid.* 2116; Mai, *ibid.* 1902, 35, 162; and many others). It is also obtained in a yield of 12 p.c. by treating xylene with 2-4 p.c. of aluminium chloride at the boiling-point of xylene for 2 hours (F. Fischer and Niggemann, Ber. 1916, 49, 1475; Houben, U.S. Pat. 1334033, 1337317), and by cracking solvent naphtha under a variety of conditions (Egloff, J. Ind. Eng. Chem. 1912, 10, 8; Evans, U.S. Pat. 1236087; Synthetic Hydrocarbon Co., Fr. Pat. 479211; and others).

Commercial toluene is mainly obtained from coal tar by rectification of the fraction boiling

between 100°–120° (Couper, *Dingl. poly. J.* 1866, 181, 386; Leuchart, *J. pr. Chem.* 1890, (2) 41, 301; *cf. J. Soc. Chem. Ind.* 1915, 34, 170, 416, 539, 1001; Butler and Popham, *J. Soc. Chem. Ind.* 1918, 37, 220 T).

Toluene may be purified by treatment with sulphuric acid (Friswell, *Chem. News*, 1893, 68, 27), and freed from thiotoluene by treatment with aluminium chloride (St. Denis Co., *Fr. Pat.* 240111 of 1894; D. R. P. 79505 of 1894), whilst analytically pure toluene is obtained by converting the less pure substance into the well crystalline potassium toluene *p*-sulphonate, which is subsequently hydrolysed (Miller, *Chem. Soc. Trans.* 1892, 61, 1025; *see also* Kelbe, *Ber.* 1886, 19, 93; Kraemer and Böttcher, *ibid.* 1887, 20, 601).

Properties.—Toluene is a colourless liquid, b.p. 111°/760 mm., 46·8°/92·0 mm., 38°/56·6 mm., 31·9°/42 mm., 23°/26·58 mm., 14·5°/14·56 mm. (Kahlbaum, *Siedetemp. u. Druck*, 95; *cf.* Neubeck, *Zeitsch. physikal. Chem.* 1887, 1, 656; Young, *Chem. Soc. Trans.* 1898, 73, 906; Linebarger, *Amer. Chem. J.* 1896, 18, 437; m.p. –97° to –99° (Archibald and McIntosh, *J. Amer. Chem. Soc.* 1904, 26, 305; *cf.* Ladenburg and Krügel, *Ber.* 1900, 33, 638; Altschul and Schneider, *Zeitsch. physikal. Chem.* 1895, 16, 25); D_4^{20} 0·8812, $D_4^{12\cdot6}$ 0·87403 or 0·87417 (Orton and Jones, *Chem. Soc. Trans.* 1919, 115, 1067) D 0·8723, D_{25}^{25} 0·8649 or 0·85680 (Linebarger, *l.c.*); D_{50}^{50} 0·8490, D_{100}^{100} 0·8237 (Perkin, *Chem. Soc. Trans.* 1896, 69, 1191); D_4^{100} 0·8708, D_4^{100} 0·77805 (Schiff, *Ann.* 1883, 220, 91); critical temperature 320·8° (Pawlewski, *Ber.* 1883, 16, 2634); critical pressure 41·6 atm. (Altschul, *Zeitsch. physikal. Chem.* 1893, 11, 590); magnetic rotatory power 12·16 at 13·1° (Perkin, *l.c.*; *cf.* Schönrock, *Zeitsch. physikal. Chem.* 1893, 11, 785); vapour pressure at low temperatures (Kahlbaum, *Zeitsch. physikal. Chem.* 1898, 26, 686, 616; Woring, *ibid.* 1900, 34, 257); dielectric constant (Drude, *ibid.* 1897, 23, 309; Abegg, *Ann. Physik.* 60, 56; Landolt and Jahn, *Zeitsch. physikal. Chem.* 1892, 10, 299); refractive index (Landolt and Jahn, *l.c.*); molecular refraction 50·06 (Brühl, *Ber.* 1892, 25, 3075); capillarity constant at the b.p. $\alpha^1 = 4·746$ (Schiff, *Ann.* 1884, 223, 104); molecular heat of combustion 933,762 Cal. (Stohmann, *J. pr. Chem.* 1887, [2], 35, 41; *cf.* Richards and Davis, *J. Amer. Chem. Soc.* 1917, 39, 341; 1920, 42, 1599). For the volatilisation of toluene in steam, *see* Barbaudy (*Compt. rend.* 1923, 176, 1616).

The nature of the products of oxidation of toluene is largely dependent upon the oxidising agent employed, thus, whilst chromic acid and dilute nitric acid yield mainly benzoic acid, potassium persulphate yields a mixture of dibenzyl, and benzaldehyde (Moritz and Wolfenstein, *Ber.* 1899, 32, 432), and manganese dioxide, acetic and sulphuric acids yield *o*- and *p*-tolylphenylmethane, benzaldehyde, benzyl alcohol, benzoic acid, complex hydrocarbons and carboxylic acids (Weiler, *Ber.* 1900, 33, 464).

On oxidation with manganese disulphate at 40°–50°, toluene yields benzaldehyde almost quantitatively, whilst at higher temperatures benzoic acid is formed (B. A. S. F., U.S. Pat. 799,454; D. R. P. 175,295 of 1906); for the

oxidation of toluene by means of lead peroxide, manganese peroxide, chromyl chloride, and persulphates, *see* Law and F. M. Perkin (*Chem. Soc. Trans.* 1907, 91, 260; 1908, 93, 1833), and for the preparation of benzaldehyde by oxidising toluene in presence of various catalysts, *see* Woog (*Compt. rend.* 1907, 145, 124) and Coquillion (*ibid.* 1873, 77, 444). Benzaldehyde and benzoic acid, together with other products, are also obtained by the electrolytic oxidation of toluene in presence of alcohol and dilute sulphuric acid (Renard, *Compt. rend.* 1881, 92, 965; Puls, *Chem. Zeit.* 1901, 25, 263; Merzbacher and Smith, *J. Amer. Chem. Soc.* 1900, 22, 723), the course of the reactions involved during the electrolytic oxidation is detailed by Fichter (*Zeit. elektrochem.* 1913, 19, 781).

100 grams of toluene containing 5 grams of anthraquinone yields, after exposure to sunlight and air for six weeks, 40 grams of benzoic acid, 10 grams of isohydrobenzoin and hydrobenzoin, 0·2 gram of benzaldehyde, and 0·1 gram of dibenzyl (Eckert, *Eng. Pat.* 182487, 1922).

When the vapour of toluene is passed through a red-hot tube, benzene, naphthalene, anthracene, phenanthrene, dibenzyl (Berthelot, *Bull. Soc. chim.* 1867, 7, 218; Graebe, *Ber.* 1874, 7, 48), styrene, diphenyl, &c. (Ferkö, *Ber.* 1887, 20, 662) are formed; but when a mixture of the vapours of toluene and benzene is heated in this manner, a highly complex mixture of hydrocarbons is formed (Carnelley, *Chem. Soc. Trans.* 1880, 37, 702; *cf.* Barbier, *Ann. Chim.* 1876, [5] 7, 472). When electric sparks are passed through toluene, a gas containing acetylene (23–24 p.c.) and hydrogen (76–77 p.c.) is formed (Destrem, *Bull. Soc. chim.* 1884, 42, 267; *Compt. rend.* 1884, 99, 138), whilst distillation over red-hot lead oxide (PbO) yields stilbene, diphenyl, anthracene, phenanthrene, &c. (Lorenz, *Ber.* 1874, 7, 1098; Vincent, *Bull. Soc. chim.* 1890 (3), 4, 7; *Compt. rend.* 1889, 110, 907).

When air charged with toluene vapour is passed over finely divided platinum or manganese dioxide, the temperature rises until the metals become incandescent and the toluene is completely oxidised to carbon dioxide and water. In the presence of iron, nickel, or copper oxide, at temperatures between 150°–300°, it is converted into benzaldehyde, but with carbon at 370°, benzoic acid is formed (Woog, *Compt. rend.* 1907, 145, 124; *cf.* Coquillion, *ibid.* 1873, 77, 444).

When toluene is boiled in the presence of aluminium chloride, a complex mixture of hydrocarbons, including ethyltoluene, ditolyl (Friedel and Crafts, *Compt. rend.* 1885, 100, 692), benzene, *m*- and a little *p*-xylene (Anschütz, *Ann.* 1886, 235, 178; Anschütz and Immendorff, *Ber.* 1885, 18, 657) are formed; whilst with acetylene tetrabromide, methylene chloride or chloroform in the presence of aluminium chloride, 1:6- and 2:7-dimethylantracene, m.p. 240° and 244·5° respectively, together with a little 3-methylantracene, di-*m*- and di-*p*-tolylmethane, benzene, *m*- and *p*-xylene, and other homologues are produced (Friedel and Crafts, *Ann. Chim.* 1887, [6] 11, 266; Levauz, *Compt. rend.* 1904, 139, 976; 1905, 140, 44, 141, 204, 266; 1906, 142, 687; 1908, 146, 135, 245; 1911, 153, 1400). With ethylidene chloride and aluminium chloride, on the other hand, naphthalene

(a) *p*-ditolylethane and 3-tetramethylantracene hydride, $\text{CH}_3 \cdot \text{C}_6\text{H}_4 \cdot \langle \frac{\text{CH}(\text{CH}_3)}{\text{CH}(\text{CH}_3)} \rangle \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_3$ are said to be formed (Anschütz, Ann. 1886, 235, 313; Anschütz and Romig, Ber. 1885, 18, 662). When treated with sulphur dichloride in the presence of aluminium chloride, toluene yields ditoluylene disulphide (cf. Jacobsen and Ney, Ber. 1889, 22, 904), whilst with sulphur monochloride the reaction is of a complicated nature (Böeseken and Koning, Rec. trav. chim. 1911, 30, 116). When pyrosulphuryl chloride reacts with toluene at 60° , it yields toluene *p*-sulphonic acid, toluene *p*-sulphonyl chloride, a mixture of dichlorotoluenes and 4-chloro-3 : 4'-ditolyl sulphone (m.p. 136°), which is also formed by the interaction of *o*-chlorotoluene and toluene *p*-sulphonyl chloride dissolved in light petroleum in presence of aluminium chloride at 55° . A vigorous reaction ensues when toluene is added to a mixture of pyrosulphuryl chloride and aluminium chloride at -5° to 0° with the formation of toluene *p*-sulphonic acid, *o*- and *p*-chlorotoluene, *p*:*p*-ditolylsulphone, and a substance, needles, m.p. 215° - 217° , containing chlorine but no sulphur (Steinkopf and Buchheim, Ber. 1921, 54, 2963). With isobutyl bromide and aluminium chloride, toluene yields tertiary butyltoluene, tertiary butylbenzene, ditertiary butylxylene, ditertiary butylbenzene, and ditertiary butyltoluene (Baur, Ber. 1894, 27, 1606; cf. Konowalow, J. Russ. Phys. Chem. Soc. 1898, 30, 1036; Verley, Bull. Soc. chim. 1898, (3) 19, 67). On boiling with ferric chloride a mixture of chlorotoluenes is formed, but no benzyl chloride (Thomas, Compt. rend. 1898, 126, 1213), and on heating with phosphonium iodide at 350° , a hydrocarbon, C_7H_{10} , is formed, whilst with concentrated hydriodic acid at 280° , toluene yields hexahydrotoluene, dimethylpentamethylene, and methylpentamethylene (Markownikoff and Karpowitsch, Ber. 1897, 30, 1216). On treating pure toluene with ozone, ozotoluene, $\text{C}_7\text{H}_8\text{O}_3$, an amorphous explosive compound, which is decomposed by water into benzoic acid, formic acid, and carbon dioxide, is formed. By the prolonged interaction of nitrogen peroxide and toluene, *o*-nitrotoluene, dinitro-*o*-cresol, oxalic acid, benzoic acid, and a dihydroxybenzoic acid are produced (Leeds, Ber. 1881, 14, 482).

Nitrogen tetroxide at room temperature oxidises toluene to oxalic and benzoic acids, phenols, and benzaldehyde (Schaarschmidt and Smolla, Ber. 1924, 57, 32).

Nitrosyl chloride reacts readily with toluene in sunlight to give crystals of benzaldoxime hydrochloride (Lynn and Arkley, J. Amer. Chem. Soc. 1923, 45, 1045).

Like benzene and dimethylaniline, toluene reacts with tetramethyl-diaminodiphenyl-hydroxyanthranol, forming a colourless additive compound which yields highly coloured salts and reacts with one molecule of phenylhydrazine or hydroxylamine, eliminating two molecules of water and forming the compound

where $\text{X} = \text{OH}$ or $\text{C}_6\text{H}_4\text{NH}$ (Haller and Guyot, Compt. rend. 1903, 137, 606). Toluene reacts with ethyldiazoacetate at 118° , forming ethyl 4-methylnorcaradiene carboxylate, b.p. 122° - $126^\circ/15$ mm. (Buchner and Feldmann, Ber. 1903, 36, 3509). It also condenses with benzaldehyde in presence of concentrated sulphuric acid forming di-*p*-tolylphenylmethane (Kliegl, Ber. 1905, 38, 84), and with diphenic anhydride forming fluorene derivatives (Pick, Monatsch. 1904, 25, 979).

Commercial toluene should give only a pale-brown coloration with concentrated sulphuric acid, but pure toluene should give no coloration with this reagent, and should not decolorise a N/10 solution of bromine. When shaken with nitric acid (sp.gr. 1.44), the acid should be coloured red, but should not become viscid or greenish. On distilling crude toluene at least 90 p.c. should boil below 120° ; and a 'pure toluene' of commerce should distil between 110° - 113° , and the greater part between 111° - 112° (Schultz, Chem. des. Steinkohlentheers). Unless coal-tar toluene has been purified by shaking with concentrated sulphuric acid, it always contains 2- and 3-methylthiophene (thiotoluene). For estimation of toluene in gases, see Davis, Davis and MacGregor (J. Ind. Eng. Chem. 1918, 10, 712). For the estimation of impurities in toluene, and the estimation of toluene in commercial mixtures, petroleum, &c., see Colman (J. Gas Lighting, 1915, 129, 196, 314); Wilson and erts (*ibid.* 1916, 134, 225); Harker (J. Roy. Soc. New South Wales, 1916, 50, 99); James (J. Soc. Chem. Ind. 1916, 35, 236); Edwards (*ibid.* 1916, 35, 587); Spielman and Jones (*ibid.* 1917, 36, 489); Thole (*ibid.* 1919, 38, 39 T); Colman and Yeoman (*ibid.* 1919, 38, 82 T); Lewis (*ibid.* 1920, 39, 50 T); Colman (*ibid.* 1920, 39, 50 T); Northall-Laurie (Analyst, 1915, 40, 384); Evans (*ibid.* 1920, 45, 54); Egloff (Met. and Chem. Eng. 1917, 16, 259); Orton and Jones (Chem. Soc. Trans. 1919, 115, 1055); Lumsden (*ibid.* 1366); Tausz and Stube (Zeitsch. angew. Chem. 1919, 32, 175).

Toluene is employed in the manufacture of nitrotoluene, toluidine, benzyl chloride, benzal chloride, benzotrichloride, benzaldehyde, benzoic acid, and cinnamic acid. It is also used in the manufacture of dyestuffs, explosives, synthetic drugs and perfumes. Formerly toluene formed an essential ingredient of the benzene employed as the starting-point in the manufacture of magenta, but now it is usual to start with pure benzene and pure toluene. •

HALOGEN DERIVATIVES OF TOLUENE.

In the chlorination or bromination of toluene, substitution may take place either in the nucleus or in the side chain. In contrast with the more qualitative nature of the observations relating to the process of chlorination, quantitative measurements, indicating the rôle played by the various factors in the side-chain or nuclear substitution, have been obtained in the case of the bromination of toluene. Temperature, catalysts, and the photo-chemical action of light are the conditions which play a prominent part in these reactions. A comprehensive account of the chlorination and bromination of toluene from

the point of view of 'halogen carriers' and the electrochemistry of light has been given by Bancroft (J. Phys. Chem. 1908, 12, 417). When chlorine or bromine acts upon toluene, side-chain substitution takes place in the sunlight at 0° and at higher temperatures (Schramm, Ber. 1884, 17, 2292; *ibid.* 1885, 18, 350, 606, 1272; *ibid.* 1886, 19, 212; Bull. Acad. Sci. Cracow, 1898, 61), in diffused daylight and in the dark, a mixture of *o*- and *p*-chloro- and bromo-derivatives is formed. According to Schramm, the most active rays are the yellow and green. Gaseous toluene and chlorine vapour on subjection to the action of ultra-violet rays yield benzyl chloride, benzal chloride, and benzotrichloride (Gibbs and Geiger, U.S. Pat. 1246739 of 1917).

Cannizzaro (Compt. rend. 1855, 41, 517) found that side-chain substitution also takes place in the dark at the boiling-point of toluene.

In the absence of a catalyst the chlorination of toluene at 100° yields benzyl chloride almost exclusively, but in the presence of lead chloride, however, the product is a mixture of *o*- and *p*-chlorotoluenes containing about 62 p.c. of the *o*-isomeride (Wahl, Normand and Vermeylen, Compt. rend. 1922, 174, 946; Book and Eggert, Zeitsch. Elektrochem. 1923, 29, 521).

According to Haussermann and Beck (Ber. 1892, 25, 2445) side-chain substitution is greatly facilitated in the case of nitrotoluene by the presence of sulphur, whence it appears that sulphur behaves differently from the usual 'halogen carriers.'

Selenium accelerates substitution by chlorine in the nucleus (Silberrad, Chem. Soc. Trans. 1925, 127, 2449).

On the other hand, nuclear substitution is effected in the presence of such 'carriers' as ferrio chloride, molybdenum pentachloride, antimony pentachloride, iodine chloride, pyridine, and the aluminium-mercury couple.

The work of Holleman, Polak, van der Laan and Euwe (Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 512; Rec. trav. chim. 1908, 27, 435), and of Bruner and co-workers (Zeitsch. physikal. Chem. 1902, 41, 513; Bull. Acad. Sci. Cracow, 1907, 691; 1909, 221, 285, 322; 1910, 516, 560; Zeitsch. Elektrochem. 1910, 16, 204) has shown that the relative proportion of bromine which enters the side-chain is not only increased by light, but in the dark it is increased by rise of temperature and by dilution of the reacting bromine, the influence of light being greater than that of heat in inducing substitution in the side-chain (Cohen, Dawson, Blockey and Woodmansey, Chem. Soc. Trans. 1910, 97, 1623; Cohen and Dutt, *ibid.* 1914, 105, 504; see also Cohen and Dakin, *ibid.* 1906, 89, 1455).

The influence of the nature of the medium on the distribution of bromine between the side-chain and the nucleus has also been investigated, and it has been found that the influence of such solvents as carbon disulphide, carbon tetrachloride, benzene, chloroform, acetic acid, benzonitrile, and nitrobenzene is 'not only observable in the dark, but also manifests itself in the process of photobromination. The effect of nitrobenzene, and, to a lesser extent, of acetic acid and benzonitrile, is greatly to diminish the

proportion of side-chain substitution, whilst in the case of dilution with carbon tetrachloride the distribution is the same as in the case of pure toluene. The most noteworthy contribution is the work of Cohen, Dawson, Blockey and Woodmansey (*l.c.*), who showed that at the boiling-point of toluene moist chlorine in the dark produces nuclear substitution to the extent of nearly 90 p.c., whereas, in the light, dry chlorine increases side-chain substitution, yielding on the average about 94 p.c. of benzyl chloride. It thus appears to be established that side-chain substitution is favoured by light, rise of temperature and the absence of moisture, and that the effect of moisture is opposed to that of light.

Various hypotheses have been proposed to account for these phenomena. Bruner supposes that side-chain substitution is due to molecular halogen, whilst nuclear substitution is effected by atomic or ionic bromine, resulting from the dissociation of the bromine molecules. According to this hypothesis, the action of 'carriers,' such as iodine, consists in forming compounds with bromine, which undergo dissociation with the production of bromine atoms or ions in much greater concentration than that which is obtained in the case of pure solutions of bromine; hydrogen perbromide is supposed to be a dissociating compound of this nature.

Bruner's theory that nuclear substitution is due to ionic bromine is shared by Bancroft (*l.c.*), who further assumes that nuclear substitution only occurs when negative bromine ions are present in excess of the corresponding positive ions, a condition which would be attained by the combination of molecular bromine with the positive bromine ions, thus: $\text{Br}_2 = \text{Br}^+ + \text{Br}^-$;

$\text{Br}_2 + \text{Br}^+ \rightarrow \text{Br}_3^+$. On the other hand, Bancroft maintains that side-chain substitution is effected under conditions which tend to produce a preponderance of positive bromine ions.

Holleman (*l.c.*), however, assumes that side-chain substitution is due to molecular bromine and that nuclear substitution is induced by a perbromide, HBr_3 .

According to Cohen (*l.c.*), the view that nuclear substitution is due to halogen in the form of polyhalogen compounds appears, on the whole, to be the more acceptable, for the facts are difficult to reconcile with the ionic theory of nuclear substitution, and it must be confessed that nothing definite is known about the mechanism of the process. An explanation of these and similar phenomena on the basis of the electronic theory of valency has been put forward by Fry (The Electronic Conception of Valency, and the Theory of Benzene, by H. S. Fry, Longmans, Green and Co., 1921).

Fichter and Glantzstein (Ber. 1918, 49, 2473) have observed that at least three atoms of chlorine are introduced into the benzene nucleus before the methyl group is attacked when toluene is electrochemically chlorinated in the dark. This is taken as evidence in support of Bruner's hypothesis that atomic chlorine attacks the ring and molecular chlorine the aliphatic side-chain, and the fact that the electrochemical chlorination is an almost impossible process in the aliphatic series confirms this.

FLUORO DERIVATIVES OF TOLUENE.

ω-Difluoro-toluene $C_6H_5CHF_2$. By treating *ω*-difluoro-*ω*-chlorotoluene with sodium amalgam in alcoholic solution. Liquid, b.p. 133°5'. Decomposed by warm concentrated sulphuric acid or water at 200°, yielding hydrogen fluoride and benzaldehyde (Swarts, Bull. Acad. roy. Belg. 1900, 414).

ω-Trifluoro-toluene.—Together with *ω*-difluorochlorotoluene and *ω*-dichlorofluorotoluene by treating benzotrichloride with antimony fluoride. Colourless liquid, b.p. 103°5', D_{14}^{20} 1.19632, n_D^{20} 1.41707. Very resistant to the action of water, alkalis, arylamines, phenol and copper (Swarts, Bull. Acad. roy. Belg. 1920, 389, 399).

p-Fluoro-toluene.—By heating *p*-fluorotoluene sulphonic acid (prepared from *p*-toluidine *m*-sulphonic acid) with concentrated hydrochloric acid (Paterno and Oliveri, Gazz. chim. ital. 1883, 13, 535); by treating *p*-toluenediazopiperidine (obtained by treating a cold aqueous solution of *p*-toluenediazonium chloride with piperidine) with concentrated hydrofluoric acid (Wallach, Ann. 1886, 235, 261; cf. Holleman, Rec. trav. chim. 1906 (2), 25, 330); by warming an aqueous solution of *p*-toluenediazonium chloride with hydrofluoric acid (Valentiner and Schwarz, Eng. Pat. 9827 of 1897; U.S. Pat. 656229; Fr. Pat. 266155; D. R. P. 96153 of 1896).

Liquid, with odour of bitter almonds, b.p. 116°–117°, sp.gr. 0.992 at 25° (Wallach). Oxidised by chromic acid mixture at 160° to *p*-fluorobenzoic acid. On nitration it yields a very small proportion of two fluoronitrotoluenes, m.p. 27°, b.p. 138°–139°/83 mm., and b.p. 134°–135°/83 mm., respectively, the chief product being 3-nitro-*p*-cresol (Slothouwer, Chem. Weekblad, 1914, 11, 956).

CHLORO DERIVATIVES.

As previously mentioned chlorotoluenes are usually prepared by means of chlorine in the presence of a carrier, but there are other methods of producing these compounds, thus the electrolytic chlorination of toluene has been studied by Cohen, Dawson and Crossland (Chem. Soc. Trans. 1905, 87, 1034); Brunner and co-workers, Bull. Acad. Sci. Cracow, 1907, 691; 1909, 221, 265, 322; Fichter and Glantzstein (Ber. 1916, 49, 2473). Datta and Fernandes (J. Amer. Chem. Soc. 1914, 36, 1007) found that toluene could be chlorinated by means of a mixture of nitric and hydrochloric acids, whilst advantage is often taken of the ease with which derivatives of toluene, such as the sulphonic acids, are chlorinated and subsequently hydrolysed (B. A. S. F., D. R. P. 294635 of 1914; Ges. für Chem. Ind. in Basel, D. R. P. 133000 of 1901; Green and Herbert, Eng. Pat. 170056 of 1920). Amino-derivatives of toluene are readily chlorinated in the nucleus by means of sodium chlorate and acetic and hydrochloric acids (Reverdin and Répéaux, Ber. 1900, 33, 2503), and this reaction together with the Sandmeyer reaction readily leads to the production of higher chlorinated toluenes. The use of bleaching powder as a chlorinating agent in the case of amino-derivatives—a reaction employed by Claus and Beilstein (Ann. 1892, 374, 296), and studied in detail by Gattermann and Orton (Chem. Soc.

Trans. 1900, 77, 790, &c.)—is often of advantage for the preparation of chloro-derivatives of toluene, for by this method better yields are sometimes obtained than by the ordinary methods.

Toluene on chlorination in the presence of the aluminium-mercury couple yields 65 p.c. *o*-chloro-toluene and 35 p.c. *p*-chloro-toluene (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1111). For the rapid analysis of chlorinated toluenes, see Lubs and Clark (J. Amer. Chem. Soc. 1918, 40, 1449).

Prior to the exhaustive examination of the products of the nuclear chlorination of toluene by Cohen and his collaborators, the work carried out by various observers on the formation of dichloro-toluenes was both conflicting and unsatisfactory. Beilstein and Geitner (Ann. 1866, 139, 331), Beilstein and Kuhlberg (*ibid.* 1869, 150, 313; 152, 234) in their first papers described only one monochlorotoluene. Hübner and Majert (Ber. 1873, 6, 790) found two chloro-derivatives, and identified them as *o*- and *p*-compounds. Aronheim and Dietrich (Ber. 1875, 8, 1401), using molybdenum pentachloride, gave proof of the existence of two dichloro-derivatives, by conversion into the barium salts of the dichlorobenzoic acids, thus agreeing substantially with Beilstein and Kuhlberg. R. Schultz (Ann. 1877, 187, 260) repeated the work of the previous investigators, and by the fractional crystallisation of the barium salts of the chlorobenzoic acids, obtained on oxidation of the crude product of chlorination, gave evidence of the existence of three dichloro-toluenes. A more thorough investigation by Seelig (Ann. 1887, 237, 129) of the action of chlorine on toluene in the presence of ferric chloride or molybdenum chloride, showed the presence of a 2:4- and 2:3-dichloro-derivative, with no mention of either the 3:4- or 2:6-isomerides. According to Seelig the 2:3- and 2:4-dichlorotoluenes may be separated by means of their calcium sulphonates, and the 2:3-dichlorotoluene gives a dinitro-compound, m.p. 121°, and the 2:4-dichloro-toluene a dinitro-derivative, m.p. 101°–102°. Wynne (Chem. Soc. Trans. 1892, 61, 1051) regards the evidence in support of the 2:3-formula as inconclusive, and considers the 2:5-formula more probable. Armstrong (*ibid.* 1892, 61, 1035), after a study of the bromination of toluene carried out by Miller (*ibid.* 1892, 61, 1023), also favours the 2:5-formula. Miller (*loc.*) states that by brominating *o*-bromotoluene, 2:5-dibromotoluene is formed as the chief product and 2:4-dibromotoluene as the subsidiary product, whilst from *p*-bromotoluene he obtained 3:4-dibromotoluene as the chief, and the 2:4-isomeride as the subsidiary product. Contrary evidence, however, is afforded by the work of Willgerodt and Sahnmann (J. pr. Chem. 1889, (3) 39, 465), who showed that by brominating *o*-chlorotoluene the 2:4- and 2:6-compounds are formed, whilst by chlorinating *p*-bromotoluene, the 2:4- and 3:4-derivatives are produced, no 2:5-derivative being observed. Claus and Stavenhagen (Ann. 1892, 269, 236) have found that by chlorinating *o*-chlorotoluene two dichlorotoluenes are formed, which, on oxidation, give 2:4- and 2:6-dichlorobenzoic acids, from which it would appear that 2:5-dichlorotoluene is one of the direct products.

of chlorination. The combined results of all these observers afford evidence of the existence of four dichlorotoluenes formed by chlorinating toluene in the presence of molybdenum or ferric chloride, viz. 2:3-, 2:4-, 3:4-, 2:6-, with the possibility of a fifth, 2:5-dichlorotoluene. The cause of these conflicting results is the impossibility of separating the liquid dichloro-derivatives into the constituents by fractional distillation as their boiling-points lie too close together, and the isolation of solid derivatives is a matter of difficulty. Cohen and Dakin (Chem. Soc. Trans. 1901, 79, 1111), by using the aluminium-mercury couple as the 'carrier,' established the presence of 2:3-, 2:4-, 2:6-, 3:4-, and the probable existence of 2:5-dichlorotoluene, but could find no trace of the 3:5-isomeride. *o*-Chlorotoluene on chlorination yields 2:3-, 2:6-, 2:4-, and probably the 2:5-dichlorotoluene, whilst *m*-chlorotoluene yields 3:4- and 2:5-dichlorotoluene, and *p*-chlorotoluene yields the 2:4- and 3:4-isomerides. With regard to the trichlorotoluenes, though some of the various isomerides have been obtained by the direct chlorination of toluene in the presence of various 'carriers,' it is preferable to obtain them by chlorinating the dichlorotoluenes. Thus, 2:4:5- and 2:3:4-trichlorotoluene have been obtained by Limpricht (Ann. 1866, 139, 326), Aronheim and Dietrich (Ber. 1875, 8, 1401), and Seelig (Ann. 1887, 237, 231), by chlorinating toluene and *o*- or *p*-chlorotoluene in presence of iodine, molybdenum pentachloride, or ferric chloride, whilst the former is also obtained, together with 2:3:4-trichlorotoluene and probably a small amount of the 2:4:6-isomeride, by chlorinating 2:4-dichlorotoluene in presence of the aluminium-mercury couple, and, together with 2:3:6-trichlorotoluene, by chlorinating 2:5-dichlorotoluene in a similar manner (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1340, 1342). 2:3:4-Trichlorotoluene is accompanied by a tetrachlorotoluene when 2:3-dichlorotoluene is chlorinated in presence of the couple (Cohen and Dakin, *ibid.* 1339). 3:4-Dichlorotoluene, on the other hand, yields 2:4:5-trichlorotoluene almost exclusively in a similar manner, whilst 2:3:5-trichlorotoluene and 2:3:6-trichlorotoluene are obtained almost exclusively from 3:5- and 2:6-dichlorotoluene, respectively.

By chlorinating toluene Limpricht (Ann. 1886, 139, 327) obtained a tetrachlorotoluene, m.p. 96°, b.p. 276.5°, whilst Beilstein and Kuhlberg (Ann. 1869, 150, 286), repeating Limpricht's work which they carried out in the first stage with iodine and subsequently with antimony pentachloride, obtained a product, fine needles, m.p. 91°-92°, b.p. 271°. Pieper (Ann. 1867, 142, 305) prepared a liquid tetrachlorotoluene (b.p. 280°-290°) by heating the additive compound, $C_7H_4Cl_4$, with alcoholic potash at 110°. This product is impure or more probably a totally different compound, and the substance prepared by Beilstein and Kuhlberg would be either 2:3:4:6- or 2:3:5:6-tetrachlorotoluene, m.p. 91°-92° and 93°-94° respectively, or a mixture of the two, since both compounds are formed on chlorination (Cohen and Dakin, Chem. Soc. Trans. 1904, 85, 1279). 2:3:4:6-Tetrachlorotoluene is also produced by the further chlorination of 2:4:6-trichlorotoluene in presence of the aluminium-mercury

couple, whilst 2:3:5:6-tetrachlorotoluene is produced by the chlorination of 2:3:6- and 2:3:5-trichlorotoluene under similar conditions. On the other hand, there is no evidence of the production of 2:3:4:5-tetrachlorotoluene by the further chlorination of 2:4:5-trichlorotoluene (Cohen and Dakin, Chem. Soc. Trans. 1904, 85, 1279; 1906, 89, 1453). Beilstein and Kuhlberg (Ann. 1869, 150, 298) by chlorinating toluene initially in the presence of iodine and finally with phosphorus pentachloride obtained pentachlorotoluene.

Benzyl chloride, ω -chlorotoluene, $C_6H_5CH_2Cl$; by passing hydrogen chloride into benzyl alcohol (Cannizzaro, Ann. 1853, 88, 130; 1855, 96, 246; Deville, Ann. Chim. 1841, [3] 3, 178); by the action of chlorine on boiling toluene (Cannizzaro, Ann. Chim. 1855, [3] 45, 468; Beilstein and Geitner, Ann. 1866, 139, 337; Wahl, Normand and Vermeylen, Compt. rend. 1922, 174, 946); by the action of chlorine on toluene in sunlight (Schramm, Ber. 1885, 18, 608); from equimolecular proportions of methylene chloride and benzene in carbon disulphide solution in presence of zinc dust or zinc chloride and hydrochloric acid (Grasse-Cristaldi and Maselli, Gazz. chim. ital. 1898, 28, 498); from benzylamine and nitrosyl chloride in ethereal solution at -15° to -20° (Solonina, J. Russ. Phys. Chem. Soc. 1898, 30, 431); in small quantities together with other products by the action of *aqua regia* on benzylamine (Solonina, *l.c.* 822).

Benzyl chloride is manufactured by passing chlorine into toluene contained in acid-proof earthenware vessels and heated to boiling by means of a lead steam-spiral. The operation is interrupted when the toluene shows the theoretical increase in weight (37.5 p.c.). The vapours are condensed in a reflux worm, and the escaping hydrogen chloride passed into water. The product is shaken with dilute alkali and then rectified, by which means it is freed from unchanged toluene and higher chlorinated products. The addition of a small quantity of phosphorus trichloride and the action of sunlight increases the velocity of chlorination. Very good yields are also said to be obtained by allowing sulphuryl chloride to act on an excess of toluene in the dark at a temperature a little below 130° (Wohl, D. R. P. 139552 of 1901). Further, a mixture of toluene and bleaching powder is treated with sulphur dioxide, and the resulting benzyl chloride separated by distillation (Conant, U.S. Pat. 1233986 of 1917; J. Soc. Chem. Ind. 1917, 36, 1002).

M.p. -48° (Haase, Ber. 1893, 26, 1063), or -43.2° (Schneider, Zeitsch. physikal. Chem. 1897, 22, 233); b.p. 175°-176.2°/760.3 mm. (Schiff, Ann. 1883, 220, 99; cf. Ber. 1889, 19, 543); b.p. 63°/8-16 mm.; 73.9°/17 mm.; 78.2°/22-14 mm.; 81.8°/26-74 mm.; 89.9°/40 mm.; 98.8°/62 mm.; 106.2°/92 mm.; 179°/760 mm. (Kahlbaum, Siedetemp. u. Druck, 84); 64°-64.2°/12 mm. (Anschütz and Burns, Ber. 1887, 20, 1390); D_4^{20} 1.1135; D_{16}^{15} 1.1040; D_{25}^{25} 1.0967 (Perkin, Chem. Soc. Trans. 1896, 89, 1243); D_4^{175} 0.94535 (Schiff, *l.c.*); absorption spectrum (Spring, Rec. trav. chim. 1897, 16, 1); magnetic rotatory power 14.01 at 15.3° (Perkin, *l.c.*); dielectric

constant (Jahn and *Zeitsch. physikal. Chem.* 1894, 13, 387).

Insoluble in water, but by heating with water to 100°–110°, or by boiling with water under a reflux for 24 hours, it is converted into benzyl alcohol (Vandeveldt, *Bull. Acad. roy. Belg.* 1897, [3] 34, 894; Niederist, *Ann.* 1879, 196, 353); the same transformation is still more readily effected by boiling benzyl chloride with the calculated quantity of potassium carbonate dissolved in about 8 to 10 parts of water (Meunier, *Bull. Soc. chim.* 1882, [2] 38, 159; Busch and Weiss, *Ber.* 1900, 33, 2702). When boiled with hydrazine hydrate in aqueous alcoholic solution, it yields *α*-dibenzyl-hydrazine (Busch and Weiss, *l.c.*), dibenzyl and stilbene (Rothenburg, *Ber.* 1893, 26, 867). On oxidation it yields first benzaldehyde and then benzoic acid, and on heating with water at 200° and distilling the product, anthracene and benzyl-toluene, amongst other substances, are formed (Dorp, *Ber.* 1872, 5, 1070; Zincke, *Ber.* 1874, 7, 276; Limpricht, *Ann.* 1866, 139, 308). When treated with aluminium chloride in carbon disulphide solution, an insoluble hydrocarbon ($C_{11}H_{10}$) is obtained (Friedel and Crafts, *Bull. Soc. chim.* 1885, 43, 53). Aluminium chloride or zinc dust acts upon a mixture of benzyl chloride and benzene yielding diphenylmethane and a product which on distillation yields anthracene and toluene (Zincke, *Ann.* 1871, 159, 374; Friedel and Crafts, *Ann. Chim.* 1884, (6) 1, 478; *cf.* Perkin and Hodgkinson, *Chem. Soc. Trans.* 1880, 37, 726; Hirst and Cohen, *ibid.* 1895, 67, 827; Radziewanowski, *Ber.* 1894, 27, 3236; 1895, 28, 1136). With a large amount of benzene in presence of aluminium chloride, anthracene is the main product (Schramm, *Ber.* 1893, 26, 1706). On boiling with zinc dust a vigorous reaction occurs with evolution of hydrogen chloride, and the product, on distillation, yields toluene, anthracene, phenyl-tolyl-methane and a substance $C_{11}H_{10}$ (?) (Prost, *Bull. Soc. chim.* 1886, [2] 46, 248). Phenyl acetate and benzyl chloride in the presence of aluminium chloride yield acetic anhydride, toluene, anthracene and an oil, b.p. 310°–320° (Perkin and Hodgkinson, *l.c.*). By heating benzyl chloride with aromatic hydrocarbons and zinc dust, the benzyl group enters the hydrocarbon nucleus, thus with benzene, benzylbenzene is formed, and with toluene, *p*-benzyltoluene, a little *o*-benzyltoluene, anthracene, and a hydrocarbon $C_{11}H_{10}$ are formed (Zincke, *Ann.* 1872, 161, 93; *Ber.* 1873, 6, 137). When heated with sodium or copper, benzyl chloride is converted into dibenzyl (Cannizzaro and Rossi, *Ann.* 1862, 121, 250; Fittig and Stelling, *Ann.* 1866, 137, 258; Comey, *Ber.* 1890, 23, 1115; Onufrowicz, *Ber.* 1884, 17, 838). When benzyl chloride is boiled with an aqueous solution of lead nitrate benzaldehyde is obtained. The latter is also formed, together with benzoic acid and anthracene, by heating benzyl chloride with potassium nitrite and a little water at 150° (Brunner, *Ber.* 1876, 9, 1745). Fuming nitric acid yields nitrobenzyl chloride, whilst alcoholic ammonia yields a mixture of benzylamine, dibenzylamine and tribenzylamine (Cannizzaro, *Ann.* 1865, 134, 128; *ibid.* Suppl. 4, 24, 80; Dhonmès, *Compt. rend.* 1901, 123, 636). When treated with chromyl chloride in carbon disulphide solution benzyl chloride yields a brown pre-

cipitate, $C_6H_5CH_2Cl \cdot CrO_2Cl_2$, which is converted slowly by moist air into benzaldehyde. The compound when heated to 170° loses hydrogen chloride, forming a compound, $C_6H_5CHCl \cdot CrO_2Cl_2$, which also yields benzaldehyde with moist air (Etard, *Ann. Chim.* 1881, [5] 22, 235). With aniline, benzyl chloride forms benzylaniline, and with methylaniline it gives the hydrochloride of benzylmethylaniline, from which the free base, b.p. 305°–306°, may be obtained by treatment with sodium hydroxide. The corresponding ethyl compound, b.p. 286°/710 mm., $D_{18}^{20} 1.034$, is obtained in a similar manner. Both these substances and their sulphonic acids are used as intermediates in the preparation of dyes. When treated with a metallic salicylate at 130°–140° benzyl chloride yields *benzyl salicylate*, an odourless, colourless liquid, b.p. 208°/26 mm., which is said to be useful for external application in medicine (Eng. Pat. 25735 of 1899). When subjected to an electric current, hydrochloric acid is evolved and stilbene is formed (Loeb, *Zeitsch. Elektrochem.* 1903, 9, 903).

Benzyl chloride is used in the preparation of benzaldehyde and benzoic acid, and also for introducing the benzyl group into basic colouring matters, prior to sulphonation, in the preparation of acid colouring matters.

Commercial benzyl chloride generally contains moisture, benzal chloride and benzo-trichloride, chlorotoluenes, and even unchanged toluene. It should show the correct boiling-point and specific gravity. In order to determine the chlorine present in the side-chain, a weighed quantity of the substance is boiled for some minutes with a hot saturated alcoholic solution of silver nitrate under a reflux; the silver chloride, which will represent only the chlorine from the side-chain, is then collected and weighed (Schulze, *Ber.* 1884, 17, 1675). Benzo-trichloride may be detected by the green colouring matter (Malachite Green) which is formed when the substance is heated with dimethylaniline and zinc chloride (Döbner).

m-Chlorobenzyl chloride; by chlorinating *m*-chlorotoluene at its boiling-point until the increase in weight amounts to about one-half of that required by theory. B.p. 213°–214°/740 mm. (Kenner and Witham, *Chem. Soc. Trans.* 1921, 119, 1460).

p-Chlorobenzyl chloride; by chlorinating benzyl chloride in presence of iodine, or more conveniently, by chlorinating *p*-chlorotoluene at its boiling-point (Beilstein, Kuhlberg and Neuhof, *Ann.* 1868, 146, 320; Jackson and Field, *Amer. Chem. J.* 1880–1, 2, 85; *P. Amer. A.* 14, 54; *Ber.* 1878, 11, 904); by chlorinating toluene first in the cold and finally at the boiling-point (Walther and Wetzlich, *J. pr. Chem.* 1900, [2] 61, 187; *cf.* van Raalte, *Rec. trav. chim.* 1899, 18, 387). Needles or prisms, m.p. 29°, b.p. 213°–214° (Jackson and Field; *cf.* Beilstein, Geitner and Kuhlberg, *Zeit. f. Chem.* 1868, 2, 66, 307, 653; Beilstein, Kuhlberg and Neuhof, *Ann.* 1868, 147, 339). On boiling with water it yields *p*-chlorobenzyl alcohol (Jackson and Field), whilst with lead nitrate it yields *p*-chlorobenzaldehyde (Beilstein and Kuhlberg, *Ann.* 1868, 146, 320; 1868, 147, 352), and with oxidising agents *p*-chlorobenzoic acid. By the action of potassium cyanide on a boiling alcoholic solution at 120°–130°, it yields *p*-chlorobenzyl acetonitrile (Neuhof, *l.c.*), and on treatment

potassium iodide, *p*-chlorobenzyl iodide, needles, m.p. 64°.

Dichlorobenzyl chloride, b.p. 241°; by chlorinating benzyl chloride in presence of iodine (Beilstein and Kuhlberg).

Trichlorobenzyl chloride; by chlorinating hot trichlorotoluene. Oil, b.p. 273°, D_{20}^{25} 1.547 (Beilstein and Kuhlberg, Ann. 1869, 150, 286).

Tetrachlorobenzyl chloride; by chlorinating tetrachlorotoluene at high temperatures. Oil, p.b. 290°, D_{20}^{25} 1.634 (Beilstein and Kuhlberg, Ann. 1869, 15 0, 298). Further chlorination gives hexachlorobenzene and carbon tetrachloride.

Pentachlorobenzyl chloride; by chlorinating benzyl chloride in presence of antimony pentachloride; also by chlorinating boiling pentachlorotoluene (Beilstein and Kuhlberg; cf. Deville, Ann. 1841, 44, 304).

Benzylidene chloride, *benzal chloride*, *o*-dichlorotoluene, $C_6H_4CHCl_2$; by the action of phosphorus pentachloride (Cahours, Ann. Chim. 1848, (3) 23, 329; Ann. 1849, 70, 39; Suppl. 2, 253, 306), succinyl chloride (Rembold, Ann. 1866, 138, 189), or phosgene (Kempf, Zeit. f. Chem. 1871, 7, 79), on benzaldehyde; by chlorinating toluene at the boiling-point (Beilstein, Ann. 1860, 116, 336; Beilstein and Kuhlberg, Ann. 1868, 146, 322; Lauth and Grimaux, Bull. Soc. chim. 1860, 2, 347; cf. Limpricht, Ann. 1866, 139, 318); in nearly theoretical yield from toluene with 2 mols. of phosphorus pentachloride at 170°–200° (Colson and Gautier, Ann. Chim. 1887, (6) 11, 21). It is manufactured by chlorinating boiling toluene in direct sunlight.

Colourless, powerfully refractive liquid, b.p. 212°–214° (Hübner and Bente, Ber. 1873, 6, 804), or 203.5°/756.2 mm. (Schiff, Ber. 1886, 19, 563), m.p. –16.1° (Zeitsch. physikal. Chem. 1897, 22, 234; cf. Altschul, *ibid.* 1895, 16, 24); D_{20}^{25} 1.2699; D_{20}^{25} 1.2122; D_{20}^{25} 1.1877; D_{20}^{25} 1.0407 (Schiff, *l.c.*), D_{14}^{25} 1.2557.

Water at 140°–160°, or sulphuric acid at 50° (Oppenheim, Ber. 1869, 2, 213), alkalis and silver oxalate (Golowsinsky, Ann. 1859, 111, 252), convert benzylidene chloride into benzaldehyde. When treated with sodium it yields stilbene, and with copper powder at 100° stilbene dichloride, $C_6H_4CHCl_2CHCl_2C_6H_5$, and the corresponding tetrachloride are produced (Onufrowicz, Ber. 1884, 17, 833). Ammonia yields hydrobenzamide ($C_6H_5NH_2$, cf. Böttger, Ber. 1878, 11, 840). The reaction with triethylphosphine in presence of alcohol at 120°–130° proceeds thus:

whilst phosphonium iodide yields tribenzylphosphine (Hofmann, Ann. Suppl. 1, 323).

When treated with anhydrous alkali acetates for 10–20 hours at 180°–200° cinnamic acid is formed (B. A. S. F., Eng. Pat. 3330 of 1880; Fr. Pat. 138275; D. R. PP. 17467 of 1890, and 18232 of 1881). For the behaviour of benzylidene chloride with acid esters or alcohols in presence of metals or metallic salts, see E. Jacobsen, Eng. Pat. 2878 of 1880; Fr. Pat. 137419; D. R. PP. 11494 of 1879, and 13127 of 1880.

It forms *p*-nitrobenzylidene chloride

(Hübner and Bente, Ber. 1873, 6, 803; cf. Beilstein, Ann. 1868, 146, 333); red-hot soda lime forms benzene (Limpricht, Bull. Soc. chim. 1866, (2) 6, 467); and zinc ethyl diluted with benzene forms $C_{11}H_{10}$, diethylphenylmethane, and $C_{12}H_{10}$ (Dafert, Monatsch. 1884, 4, 618).

Benzylidene chloride is employed in the manufacture of benzaldehyde, benzoic acid and cinnamic acid. The commercial product is always impure. It may be tested by its boiling-point, and by determining the percentage of chlorine.

o-Chlorobenzylidene chloride; from salicylaldehyde and phosphorus pentachloride (Henry, Ber. 1869, 2, 135); by passing a current of chlorine through a mixture of dry *o*-chlorotoluene and phosphorus pentachloride at 150°–180° in bright daylight (Erdmann, Ann. 1893, 272, 151; Vanino, Präparative Chemie, 1923, vol. ii. p. 410); by passing chlorine over *o*-toluenesulphonyl chloride at 150°–200° (Gilliard, Monnet and Cartier, Eng. Pat. 29717 of 1896; U.S. Pat. 606470; Fr. Pat. 268607; D. R. P. 98433 of 1896); by chlorinating benzylidene chloride in presence of iodine (Beilstein and Kuhlberg, *l.c.*). Oil, b.p. 227°–230° [H], or 228.5° (Gill, Ber. 1893, 26, 650); D_{20}^{25} 1.4 [H], D_{14}^{25} 1.399 [G]. It is decomposed by water at 170°, yielding *o*-chlorobenzaldehyde and hydrogen chloride, and with chromic acid yielding *o*-chlorobenzoic acid, whilst with silver in methyl alcoholic solution it yields *o*:*o*-dichloro-stilbene dichloride, and on distillation with dry oxalic acid *o*-chloro-benzaldehyde is formed (Anschütz, Ann. 1884, 226, 19).

p-Chlorobenzylidene chloride; by chlorinating benzylidene chloride in presence of iodine (Beilstein and Kuhlberg, *l.c.*); together with *p*-chlorobenzotrichloride by passing chlorine over toluene *o*-sulphonyl chloride (Gilliard, Monnet and Cartier, *l.c.*). Hübner and Bente (Ber. 1873, 6, 804) obtained a chlorobenzylidene chloride, b.p. 255°–260°, which on oxidation yielded impure *p*-chlorobenzoic acid. *p*-Chlorobenzylidene chloride is a liquid, b.p. 234°.

(β) 2:4-Dichlorobenzylidene chloride; by passing chlorine into 2:4-dichlorotoluene heated at 230°. Liquid, b.p. about 260°. On treatment with sulphuric acid it yields the corresponding dichlorobenzaldehyde (Seelig, Ann. 1887, 237, 167).

2:5-Dichlorobenzylidene chloride; by careful addition of chlorosulphonic acid to a chloroform solution of 2:5-dichlorobenzaldehyde. Cubic crystals, m.p. 42° (Gnehm and Schuele, Ann. 1898, 299, 358).

3:4-Dichlorobenzylidene chloride; by chlorinating boiling 3:4-dichlorotoluene. Oil, b.p. 257°, D_{20}^{25} 1.518 (Beilstein and Kuhlberg). When heated with water at 220°, 3:4-dichlorobenzaldehyde is formed.

2:3:4-Trichlorobenzylidene chloride; by chlorinating 2:3:4-trichlorotoluene near the boiling-point. It melts at 84°, boils at 275°–285°, and yields 2:3:4-trichlorobenzaldehyde with fuming sulphuric acid (Seelig).

2:4:5-Trichlorobenzylidene chloride; by chlorinating 2:4:5-trichlorotoluene at the boiling-point. Liquid, solidifying to crystalline needles at 0°. It boils at 280°–281°, and has D_{20}^{25} 1.607. Decomposed by water at 250°, or by sulphuric acid, yielding hydrochloric acid and

2:4:5-trichlorobenzaldehyde (Beilstein and Kuhlberg, Ann. 1869, 150, 298).

Tetrachlorobenzylidene chloride; by chlorinating boiling tetrachlorotoluene. Liquid, b.p. 305°–306°, D_{20}^{25} 1.704. With water at 280° it yields tetrachlorobenzaldehyde (Beilstein and Kuhlberg; cf. Cassella & Co., Eng. Pat. 16317 of 1914).

Pentachlorobenzylidene chloride; by chlorinating benzylidene chloride in presence of iodine and subsequently in presence of antimony pentachloride. Long flat plates, m.p. 109°, b.p. 334° (Beilstein and Kuhlberg), m.p. 119.5° (Zincke, Ber. 1893, 26, 318). It is not affected by water at 300°.

Benzotrichloride, phenyl-chloroform; from benzoyl chloride and phosphorus pentachloride (Schischkoff and Rösing, Compt. rend. 1858, 46, 367; Limpricht, Ann. 1865, 134, 55; 1865, 135, 80; Bull. Soc. chim. 1866, (2) 6, 468; Wöhler and Liebig, Ann. 1832, 3, 265); by exhaustive chlorination of heated toluene (Limpricht, Ann. 1865, 135, 80; 1866, 139, 323); by chlorinating toluene (Naquet, Compt. rend. 1862, 55, 407; 1863, 56, 482), or benzylidene chloride (Cahours, *ibid.* 1863, 56, 703); manufactured by chlorinating boiling toluene in direct sunlight until the weight of the product no longer increases. Colourless, powerfully refractive liquid, m.p. –22.5° (Haase, Ber. 1893, 26, 1053) or –21.2° (Schneider, Zeitsch. physikal. Chem. 1897, 22, 234); setting-point –17° (Altschul, *ibid.* 1895, 16, 24); b.p. 213°–214° (Beilstein and Kuhlberg); D_{15}^{20} 1.380 [L]. With water at 150° or with water in presence of iron or iron salts at 90°–95° (Schultze, D. R. P. 82927 of 1894) it yields benzoic and hydrochloric acids; with alcohol, ethyl benzoate and hydrochloric acid; with sodium benzoate, ethyl orthobenzoate $C_6H_5C(OC_2H_5)_2$; with ammonia, benzoic acid, benzamide and benzonitrile; with aniline, benzenyldiphenylamide; with dimethylaniline and zinc chloride, Malachite Green; with methyldiphenylamine or diamylaniline, similar green colouring matters; with aniline hydrochloride, nitrobenzene and iron filings at 180° for 3–4 hours, diamino-triphenylcarbinol $(NH_2C_6H_4)_3C \cdot OH(C_6H_5)$ (Doebner, Ber. 1882, 15, 232); with phenol, dihydroxy-triphenylcarbinol (Doebner, Ann. 1883, 217, 226); with copper powder, toluene tetrachloride $C_{11}H_9Cl_4$, α - and β -tolane di-chloride $C_{11}H_7Cl_2$ (Hanhart, Ber. 1882, 15, 899; cf. Onufrowicz, Ber. 1884, 17, 825); with zinc ethyl in presence of benzene, diethylphenylmethane $C_6H_5CH(C_2H_5)_2$ (Lippmann and Loughaine, Zeitsch. f. Chem. 1867, (2) 3, 674); with fuming nitric acid, *m*-nitro-benzoic acid (Beilstein and Kuhlberg, Ann. 1868, 146, 333). By treating benzotrichloride with chlorine in sunlight, the compound $C_{11}Cl_{11}$, m.p. 152°–153°, is obtained, which on treatment with zinc and sulphuric acid yields the compound $C_{11}HCl_{11}$, m.p. 102° (Smith, Jahresbericht, 1877, 420; Ber. 1880, 13, 33). For the behaviour of benzotrichloride with metals, metallic chlorides and other salts, see E. Jacobsen (Eng. Pat. 2878 of 1890; Tr. Pat. 137419; D. R. P. 11494 of 1879, and 13127 of 1890); and for its use in the preparation of rhodamine dyes, see B. A. S. F. (D. R. P. 36018 of 1889).

Commercial benzotrichloride is tested by

examining its boiling-point. It generally contains compounds chlorinated in the nucleus.

o-Chlorobenzotrichloride; from salicylaldehyde and phosphorus pentachloride (Kolbe and Lautemann, Ann. 1860, 116, 195), m.p. 30°, b.p. 260°, D_{15}^{20} 1.51 (in liquid state). With water at 150° it yields hydrochloric acid and *o*-chlorobenzoic acid, and with copper powder in presence of benzene it yields α - and β -*o*-dichlorotoluene dichloride (Fox, Ber. 1893, 26, 653).

m-Chlorobenzotrichloride; from *m*-sulphobenzoic acid and phosphorus pentachloride (Carius and Kämmerer, Ann. 1864, 131, 158); from *m*-hydroxy-benzoic acid and 3 mols. of phosphorus pentachloride at 180° (Anschütz and Moore, Ann. 1887, 239, 342). Liquid, b.p. 247°–250° (A. and M.).

p-Chlorobenzotrichloride; by chlorinating benzotrichloride in presence of iodine (Beilstein and Kuhlberg, l.c.); by heating *p*-oxybenzide

$C_6H_5 \begin{matrix} \diagup O \\ | \\ \diagdown CO \end{matrix}$ with phosphorus pentachloride at

290°–300° (Klepl, J. pr. Chem. 1883, (2) 28, 204); in small quantities by heating 1 mol. of *p*-hydroxybenzoic acid with 3 mols. of phosphorus pentachloride at 180° (Anschütz and Moore, l.c. 347); in small quantities, together with benzotrichloride, from benzoyl chloride and phosphorus pentachloride in a similar manner (Limpricht, Ann. 1865, 134, 57; 1866, 139, 326); from toluene *p*-sulphonyl chloride by the action of chlorine at 150°–200° (Gilliard, Monnet and Cartier, D. R. P. 98433 of 1896). Liquid, b.p. 245° or 255°, D_{15}^{20} 1.495 (Limpricht). With water at 200° or warm concentrated sulphuric acid it is decomposed, yielding *p*-chlorobenzoic acid.

Dichlorobenzotrichloride; by chlorinating boiling dichlorotoluene. Liquid, b.p. 273°, D_{15}^{20} 1.587 (Beilstein and Kuhlberg, Ann. 1869, 150, 298). From the work of Aronheim and Dietrich (Ber. 1875, 8, 1401), as well as that of Schultz (Ann. 1877, 187, 260), it appears that by the chlorination of dichlorotoluene three isomerides are formed, since crude dichlorotoluene is itself a mixture of 3 isomerides.

2:4:5-Trichlorobenzotrichloride; by passing chlorine into boiling trichlorotoluene. Very fine needles, m.p. 82°, b.p. 307°–308°. Decomposed by water at 250°, yielding 2:4:5-trichlorobenzoic acid (Beilstein and Kuhlberg, Ann. 1869, 156, 305).

Tetrachlorobenzotrichloride; by chlorinating boiling tetrachlorotoluene. Needles, m.p. 104°, b.p. 316°. Decomposed by prolonged action of water at 270° into tetrachlorobenzoic acid (Beilstein and Kuhlberg, l.c., 306).

Dichlorotoluene hexachloride $Cl_6 \cdot C_6H_2Cl_2 \cdot CH_3$; by treating toluene with an excess of chlorine and allowing the mixture to stand (Pieper, Ann. 1867, 142, 304). Large prisms, m.p. 150°, partially decomposed by water at 200°. When treated with alcoholic potash at 100° it is said to yield a *tetrachlorotoluene*, b.p. 280°–290° (but this is either impure or possibly a totally different substance), and dichlorobenzoic acid.

ω-Difluoro-*ω*-chlorotoluene $C_6H_4 \cdot CF_2 \cdot CH_2$; together with trifluorotoluene from benzotrichloride and antimony fluoride. Colourless liquid of strongly irritant odour, b.p. 142°–170 mm., D_{15}^{20} 1.2645. With water it yields

acid; and with sodium amalgam, *o*-difluoro toluene; with fuming nitric acid and phosphoric oxide below 0° it yields a *nitro-derivative*, colourless liquid, b.p. 230°, D_{15}^{20} 1.4638, and some *m*-nitrobenzoic acid (Swarts, Bull. Acad. roy. Belg. 1900, 414).

o-Dichloro-*o*-fluorotoluene; by the action of antimony fluoride on benzotrichloride at low temperatures. Colourless liquid of piercing odour, b.p. 178°–180°, D_{15}^{20} 1.3138, n_D^{20} 1.5180; *nitro-derivative*, colourless liquid, b.p. 280° (Swarts, *l.c.*). Fluorine derivatives of toluene have been described by Holleman (Rec. trav. chim. 1906, (2) 25, 330).

o-Chlorotoluene; by chlorinating toluene in presence of iodine (Hübner and Majert, Ber. 1873, 6, 790), or better, in presence of ferric chloride or molybdenum pentachloride (Seelig, Ann. 1887, 237, 152); in a yield of 65 p.c. by chlorination in presence of the aluminium-mercury couple (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1119); from *o*-toluidine by the diazo-reaction (Beilstein and Kuhlberg, Ann. 1870, 156, 79; Erdmann, *ibid.* 1893, 272, 145; Sandmeyer, Ber. 1884, 17, 2651; Gasiorowski and Wajss, Ber. 1885, 18, 1939; Vanino, Präparative Chemie, 1923, vol. ii. p. 406; Wynne, Chem. Soc. Trans. 1892, 61, 1072); by chlorination of toluene *p*-sulphonic acid, or its chloride or amide in sulphuric acid solution, followed by the removal of the sulphonic group by heating in a current of steam (B. A. S. F., D. R. P. 294638 of 1914); by hydrolysis of *o*-chlorotoluene *p*-sulphonic acid by boiling with 80 p.c. sulphuric acid (Ges. für Chem. Ind. in Basel, D. R. P. 133000 of 1901); readily by hydrolysis of 6-chlorotoluene *o*-sulphonic acid (B. D. C., Green and Herbert, Eng. Pat. 170056 of 1920). M.p. –34° (Haase, Ber. 1893, 26, 1053); b.p. 159.5°/759.5 mm., n_D^{20} 1.4977 (Wibaut, Rec. trav. chim. 1913, (2) 32, 244); D_{15}^{20} 1.0973, D_{15}^{25} 1.0877, D_{25}^{20} 1.0801 (Perkin, Chem. Soc. Trans. 1896, 69, 1243), D_{25}^{20} 1.08073 (Seubert, Ber. 1889, 22, 2520). For specific gravity and boiling-point under diminished pressure, see Feitler (Zeitsch. physikal. Chem. 1889, 4, 73); molecular refractive power and dispersion coefficient (Seubert, *l.c.*); magnetic rotatory power at 15.4°, 13.72° (Perkin, *l.c.*).

On treatment with chromyl chloride and subsequent treatment of the product with water, *o*-chlorotoluene yields *o*-chlorobenzaldehyde (Stuart and Elliot, Chem. Soc. Trans. 1888, 53, 804); the latter product is also obtained in a yield of 66 p.c. by the gradual addition of cerium oxide to a suspension of *o*-chlorotoluene in 60–65 p.c. sulphuric acid at 50°, the temperature being raised gradually to 90° (M. L. B., D. R. P. 174238 of 1903). It is reduced by hydriodic acid and phosphorus to toluene (Klages and Liecke, J. pr. Chem. 1900, (2) 41, 322), whilst on oxidation with potassium permanganate it yields *o*-chlorobenzoic acid, m.p. 134°–135° (Wroblewski, Zeit. f. Chem. 1869, (2) 5, 460; Cohen and Dakin, *l.c.* 1120). *o*-Chlorotoluene exists in two modifications (von Ostrowskij, Zeitach. physikal. Chem. 1906, 57, 341).

m-Chlorotoluene; from *m*-toluidine or 3-chloro-*p*-toluidine (Wroblewski, Ann. 1873, 168, 199; Vanino, Präparative Chemie, 1923, vol. ii. p. 406); by the diazo-reaction; from 5-chloro-*o*-

toluidine and 3-chloro-*p*-toluidine by treating the corresponding hydrazines with copper sulphate solution (Wynne, Chem. Soc. Trans. 1892, 61, 1047, 1059); from the dibromide of dihydro-*m*-chlorotoluene by boiling with quinoline (Klages and Knoevenagel, Ber. 1894, 27, 3022). M.p. –47.8°; b.p. 162.2°/756.52 mm.; $D_{162.2}^{20}$ 0.92723 (Haase, Ber. 1893, 26, 1053); D_{162}^{20} 1.07218 (Seubert, Ber. 1889, 22, 2520); molecular refractive power and dispersion coefficient (Seubert, *l.c.*); specific gravity and boiling point under diminished pressure (Feitler, Zeitsch. physikal. Chem. 1889, 4, 76). On nitration it yields a mixture of *o*- and *p*-nitro-chlorotoluenes (Reverdin and Crépiaux, Ber. 1900, 33, 2505). On heating with dilute nitric acid in a sealed tube at 130°–140° it yields 3-chlorobenzoic acid, needles, m.p. 152° (Wynne, *l.c.*).

p-Chlorotoluene; by chlorinating toluene in presence of iodine (Beilstein and Geitner, Ann. 1866, 139, 334; Bull. Soc. chim. 1869, (2) 1, 251), or molybdenum pentachloride (Aronheim and Dietrich, Ber. 1875, 8, 1402), in a yield of 35 p.c. by using the aluminium-mercury couple (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1119); from *p*-toluidine by the diazo-reaction (Gasiorowski and Wajss, Ber. 1885, 18, 1939; Hübner and Majert, Ber. 1873, 6, 794; Sandmeyer, Ber. 1884, 17, 2651; Vanino, *l.c.*); by hydrolysis of *p*-chlorotoluene *o*-sulphonic acid (B. D. C., Green and Herbert, Eng. Pat. 170056 of 1920). M.p. 7.4° (Seubert); b.p. 162.3°/756.4 mm.; $D_{162.3}^{20}$ 1.0847, D_{15}^{20} 1.0749, D_{25}^{20} 1.0672 (Perkin, Chem. Soc. Trans. 1896, 69, 1243), $D_{162.3}^{20}$ 1.06974 (Seubert, Ber. 1889, 22, 2519), $D_{162.3}^{20}$ 0.92360 (cf. Feitler, Zeitsch. physikal. Chem. 1889, 4, 78); magnetic rotatory power at 15.2°, 13.25° (Perkin, *l.c.*). It is oxidised by chromic acid mixture or by potassium permanganate (Cohen and Dakin, *l.c.* 1120) to *p*-chlorobenzoic acid, m.p. 236°; and when treated with hydriodic acid and phosphorus it is converted into toluene (Klages and Liecke, J. pr. Chem. 1900, (2) 61, 322).

(a) 2:3-Dichlorotoluene; by chlorination of *o*-chlorotoluene in presence of the aluminium-mercury couple; from 2-chloro-3-toluidine by the diazo-reaction (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1128); *o*-chlorotoluene sulphonic acid (Wynne and Greeves, Chem. Soc. Proc. 1895, 11, 151); by chlorination of toluene or *o*-chlorotoluene in presence of ferric chloride or molybdenum pentachloride (Seelig, Ann. 1887, 237, 157, 168); from crude dichlorotoluene by treatment with fuming sulphuric acid at high temperatures, then neutralising the product with lime, the calcium sulphate of 2:3-dichlorotoluene being less soluble than that of the accompanying 2:4-dichlorotoluene. The calcium salt is then converted into the sodium salt, and the sulphonic group removed by steam distillation at 180° in presence of sulphuric acid (Seelig). Doubt has been cast upon the orientation of Seelig's product by Wynne (Chem. Soc. Trans. 1892, 61, 1051) and by Armstrong (*ibid.* 1892, 61, 1035).

Liquid, b.p. 204°–206°/755 mm. (Cohen and Dakin, *l.c.* 1128) or 207°–208°/760 mm. (Wynne and Greeves, *l.c.*). On oxidation with nitric acid in a sealed tube at 140° for some hours it yields

2:3-dichlorobenzoic acid, m.p. 163° (Cohen and Dakin, *l.c.*), or 164° (Wynne and Greeves, *l.c.*), or 166° (Seelig, *l.c.*). It yields a *nitro-derivative*, m.p. 50.5°–51.5°; a *dinitro-derivative*, m.p. 71°–72°; a *sulphonamide*, m.p. 221°–222° (Cohen and Dakin, *l.c.*); a *sulphonyl chloride*, needles, m.p. 45° (Wynne and Greeves, *l.c.*). Wynne and Greeves state that 2:3-dichlorotoluene on sulphonation yields two isomeric sulphonic acids, the one whose amide and chloride are described above being accompanied by 2:3-dichlorotoluene 5-sulphonic acid (*chloride*, prisms, m.p. 85°, *amide*, m.p. 183°), but this was not confirmed by Cohen and Dakin.

(β) 2:4-Dichlorotoluene; by chlorination of toluene or *p*-chlorotoluene (Seelig, Ann. 1887, 237, 182), in presence of the aluminium-mercury couple (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1116); from 2:4-toluylenediamine (Erdmann, Ber. 1891, 24, 2769; Vanino, *l.c.*) or *o*-chloro-*p*-toluidine (Lellmann and Klotz, Ann. 1885, 231, 314); by treating 2:4-dibromo-*o*-toluenediazonium chloride with hydrogen chloride in alcoholic solution (Hantzsch, Ber. 1897, 30, 2334); from 2:4-dinitro-*o*-toluidine; from *o*-chlorotoluenesulphonic acid (Wynne and Greeves, Chem. Soc. Proc. 1895, 11, 151). M.p. 26.5° (Hantzsch, *l.c.*), b.p. 194°/735 mm. (Lellmann and Klotz); b.p. 199°–200°/760 mm. (Wynne and Greeves, *l.c.*), D₂₀²⁰ 1.24597 (L. and K.). - It yields a *mononitro-compound*, m.p. 54°–55°, and a *dinitro-compound*, prisms, m.p. 103°–104° (Cohen and Dakin, *l.c.* 1129) on nitration; 2:4-dichlorotoluene 5-sulphonic acid (*chloride*, m.p. 71°, *amide* m.p. 177°) on sulphonation (Wynne and Greeves, *l.c.*); and 2:4-dichlorobenzoic acid, m.p. 159°–160°, b.p. 198°–200°, on oxidation (Cohen and Dakin, *l.c.*).

2:5-Dichlorotoluene; from 5-chloro-*o*-toluidine by the diazo-reaction (Lellmann and Klotz, Ann. 1885, 231, 318; Wynne, Chem. Soc. Trans. 1892, 61, 1049); by chlorination of *o*- and *m*-chlorotoluene in presence of the aluminium-mercury couple (Cohen and Dakin, *l.c.*); by chlorination of aceto-*o*-toluidide followed by hydrolysis and replacement of the amino-group by chlorine (Lellmann and Klotz, *l.c.*); by the action of sodium hypochlorite on aceto-*o*-toluidide followed by conversion of the nitrogen chloride into 5-chloroaceto-*o*-toluidide, hydrolysis and replacement of the amino-group by chlorine (Chattaway and Orton, Chem. Soc. Trans. 1900, 77, 790; Cohen and Dakin, *l.c.* 1130); by hydrolysis of 2:5-dichlorotoluene *p*-sulphonic acid which is prepared by chlorinating toluene *p*-sulphonic acid or its soluble salts (B. D. C. Green and Clibbens, Eng. Pat. 169025 of 1920; cf. Wynne, *l.c.*). Liquid, b.p. 200°/770 mm. (Wynne, *l.c.*), 194°/745 mm. (Lellmann and Klotz), 198°–199°/760 mm., which lies in a freezing mixture to crystals, m.p. 5° (Cohen and Dakin, *l.c.*).

On nitration it yields a *mononitro-derivative*, m.p. 50°–51°, and a *dinitro-derivative*, m.p. 100°–11°, and on oxidation with dilute nitric acid at 10°–140° for 10 hours it yields 2:5-dichlorobenzoic acid, m.p. 152° (Wynne, *l.c.*; Cohen and Dakin, *l.c.*).

2:6-Dichlorotoluene; by chlorination of *o*-toluene in presence of the aluminium-mercury couple (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1117); from 6-nitro-*o*-toluidine

or 6-nitro-*p*-toluidine (Cohen and Dakin, *ibid.* 1131); readily by distilling an aqueous solution of the sodium salt of 2:6-dichlorotoluene *p*-sulphonic acid with superheated steam at 250° (Davies, Chem. Soc. Trans. 1920, 119, 873). Liquid, b.p. 197°–199°/757 mm. (Davies), yielding on nitration a *mononitro-derivative*, m.p. 53°, and a *dinitro-derivative*, m.p. 121°–122° (Cohen and Dakin, *ibid.* 1132; Davies, *l.c.*); and, on oxidation with dilute nitric acid in a sealed tube, 2:6-dichlorobenzoic acid, colourless needles, m.p. 139°–140° (Cohen and Dakin, *l.c.*; Wynne and Greeves, *l.c.*; cf. Claus and Stavenhagen, Ann. 1892, 269, 224.)

3:4-Dichlorotoluene; from 3-chloro-*p*-cresol and phosphorus pentachloride (Schall and Dralle, Ber. 1884, 17, 2535); by chlorination of toluene, *o*- and *m*-chlorotoluene (Beilstein and Geitner, Ann. 1866, 139, 341; Beilstein and Kuhlberg, Ann. 1869, 150, 313; Aronheim and Dietrich, Ber. 1875, 8, 1401; Neuhof, Zeit. f. Chem. 1886 (2), 2, 653; Schultz, Ann. 1877, 187, 263; Cohen and Dakin, *l.c.*); from 3-nitro-*p*-toluidine (Cohen and Dakin); from 3-chloro-*p*-toluidine (Lellmann and Klotz, Ann. 1885, 231, 312; Wynne, Chem. Soc. Trans. 1892, 61, 1060; Vanino, *l.c.*); by hydrolysis of 3:4-dichlorotoluene sulphonic acid (Wynne, *ibid.* 1069). Liquid, b.p. 205.5°–206.5°/763.5 mm. (Wynne), 200.5°/741 mm. (L. and K.); D₂₀²⁰ 1.2512 (L. and K.). On nitration it yields 3:4-dichloro-6-nitrotoluene, m.p. 63°–64°, and 3:4-dichloro-2:6-dinitrotoluene, m.p. 91.5°–92.5° (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1133; 1902, 81, 1349); and, on oxidation with dilute nitric acid in a sealed tube, 3:4-dichlorobenzoic acid, m.p. 202° (Wynne; Cohen and Dakin).

3:5-Dichlorotoluene (cf. Hantzsch, Ber. 1897, 30, 2334); from 3:5-dichloro-*p*-toluidine (Lellmann and Klotz, Ann. 1885, 231, 323); from 3:5-dichloro-*o*-toluidine (Wynne and Greeves, Chem. Soc. Trans. 1892, 61, 1060); from 3:5-dichloroaceto-*o*-toluidide (prepared according to the method of Chattaway and Orton, *ibid.* 1896, 69, 850) by hydrolysis with hydrochloric acid in a sealed tube for 8 hours at 160°, followed by elimination of the amino-group (Cohen and Dakin, *ibid.* 1133). M.p. 26°, b.p. 195°/729 mm. (L. and K.), or 201°–202°/atm. (Wynne and Greeves), sublimes at the ordinary temperature. Yields a *nitro-derivative*, needles, m.p. 61°–62°, and a *dinitro-derivative*, needles, m.p. 99°–100°, and on oxidation with dilute nitric acid at 150° it yields 3:5-dichlorobenzoic acid, long needles, m.p. 182°–183° (Cohen and Dakin).

(β) 2:3:4-Trichlorotoluene, together with 2:4:5-trichlorotoluene, by chlorinating either *o*- or *p*-chlorotoluene in presence of ferric chloride or molybdenum pentachloride (Seelig, Ann. 1887, 237, 36, 133; cf. Prentiss, Ann. 1897, 296, 180); together with a tetrachlorotoluene, by chlorinating 2:3-dichlorotoluene in presence of the aluminium-mercury couple; together with 2:4:5-trichlorotoluene and probably a small amount of 2:4:6-trichlorotoluene by 2:4-dichlorotoluene in a similar manner; from 4-nitro-2:3-dichlorotoluene by reduction and diazotisation (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1323, 1329).

Forms a *mononitro-derivative*, white needles, m.p. 60°–61°, a 5:6-*dinitro-derivative*, m.p. 140°–141°, and a *sulphonic acid* which is decomposed by superheated steam at 210°, whilst on oxidation with dilute nitric acid in a sealed tube at 150° it yields 2:3:4-trichlorobenzoic acid, m.p. 186°–187° (Cohen and Dakin; Seelig, *l.c.*, gives m.p. 129°).

2:3:5-*Trichlorotoluene*; almost exclusively by chlorination of 3:5-dichlorotoluene in presence of the aluminium-mercury couple; from 3:5-dichloro-*o*-toluidine (prepared by hydrolysis of the acetyl-derivative obtained by the action of bleaching powder on aceto-*o*-toluidide according to the method of Chattaway and Orton, Chem. Soc. Trans. 1900, 77, 791) by the diazo-reaction, and from 2:5-dichloro-*m*-toluidine. Long needles, m.p. 45°–46°, b.p. 229°–231°/757 mm. Yields a *nitro-derivative*, felted needles, m.p. 58°–59°, a *dinitro-derivative*, flat needles, m.p. 149°–150°, and with 20 p.c. nitric acid in a sealed tube at 140°, it yields 2:3:5-trichlorobenzoic acid, m.p. 162° (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1330).

2:3:6-*Trichlorotoluene*; almost exclusively by chlorination of 2:6-dichlorotoluene; together with 2:4:5-trichlorotoluene by chlorination of 2:5-dichlorotoluene in presence of the aluminium-mercury couple; from 2:6-dichloro-*m*-toluidine by the diazo-reaction. On nitration it yields a *mononitro-derivative*, long needles, m.p. 57°–58°, and 2:3:6-trichloro-4:5-*dinitro-toluene*, prisms, m.p. 140°–142°, and on oxidation, 2:3:6-trichlorobenzoic acid, flaky crystals, m.p. 163°–164° (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1331, 1343). The chlorination of toluene *p*-sulphonic acid or its soluble salts results in the formation of 2:5-dichloro- and 2:3:6-trichlorotoluene *p*-sulphonic acid. The latter is readily separated on account of the much greater insolubility of its sodium salt, and on hydrolysis a good yield of 2:3:6-trichlorotoluene is claimed (B. D. C., Green and Clibbens, Eng. Pat. 169025 of 1920).

(a) 2:4:5-*Trichlorotoluene*, together with 2:3:4-trichlorotoluene by chlorinating toluene in presence of iodine (Limpricht, Ann. 1866, 139, 326), $\frac{1}{4}$ –1 p.c. of molybdenum pentachloride (Aronheim and Dietrich, Ber. 1875, 8, 1401) or ferric chloride (Seelig, Ann. 1887, 237, 131), the crude product being shaken with two parts of fuming sulphuric acid for a minute at 60° (whereby only the 2:3:4-isomeride is sulphonated) and precipitated with water and steam distilled; together with 2:3:4-trichlorotoluene and probably a small amount of 2:4:6-trichlorotoluene by chlorinating 2:4-dichlorotoluene in presence of the aluminium-mercury couple; together with 2:3:6-trichlorotoluene by chlorinating 2:5-dichlorotoluene in a similar manner, and as sole product by chlorinating 3:4-dichlorotoluene in a similar manner; from 4:6-dichloro-*m*-toluidine and 4:5-dichloro-*o*-toluidine (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1332, 1343); from 2:5-dichloro-*p*-toluidine and 5-chloro-2:4-toluylenediamine by the diazo-reaction (Morgan and Drew, *ibid.* 1920, 117, 789; 1900, 77, 1209). Long white needles volatile with steam, m.p. 81°–82° (Cohen and Dakin), b.p. 229°–230°/716 mm. On nitration it yields a *mononitro-derivative*, m.p. 91°–92°, 2:4:5-trichloro-3:6-*dinitrotoluene*,

m.p. 226°–227°, and on oxidation 2:4:5-trichlorobenzoic acid, white silky needles, m.p. 162°–164° (Cohen and Dakin; Seelig; Jannasch, Ann. 1887, 142, 301).

2:4:6-*Trichlorotoluene*; see 2:3:4- and 2:4:5-trichlorotoluenes; by chlorinating aceto-*m*-toluidide in glacial acetic acid—hydrochloric acid solution by means of sodium chlorate at 15°–25°, followed by hydrolysis and elimination of the amino-group (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1335); from 6-chloro-2:4-toluylenediamine by the Sandmeyer reaction (Morgan and Drew, *ibid.* 1920, 117, 786). Long white needles, m.p. 33°–34°, yielding on nitration the 3-*nitro-derivative*, m.p. 54° (indefinite), the 3:5-*dinitro-derivative*, m.p. 178°–180°, and on oxidation 2:4:6-trichlorobenzoic acid, m.p. 160°–161° (Cohen and Dakin, *l.c.*).

3:4:5-*Trichlorotoluene*; by hydrolysis of potassium 3:4:5-trichlorotoluene sulphonate (Wynne, Chem. Soc. Trans. 1892, 61, 1070); from 3:5-dichloro-*p*-toluidine or 4:5-dichloro-*m*-toluidine (Cohen and Dakin, *ibid.* 1902, 81, 1336); as a derivative of the products of the action of sulphuryl chloride on aceto-*p*-toluidide (Wynne, *ibid.* 1892, 62, 1042). M.p. 41.5°–45.5°, volatile with steam (Cohen and Dakin). On oxidation with dilute nitric acid it yields the corresponding trichlorobenzoic acid (Wynne; Cohen and Dakin).

2:3:4:5-*Tetrachlorotoluene*; from 2:4:5- or 3:4:5-trichlorotoluene by nitration, reduction and replacement of the amino-group by chlorine. There is no evidence of the formation of this substance by the further chlorination of 2:4:5-trichlorotoluene (Cohen and Dakin, Chem. Soc. Trans. 1906, 89, 1453); the product, m.p. 86°–88°, previously stated (*ibid.* 1904, 85, 1280) to be 2:3:4:5-tetrachlorotoluene is probably a mixture of tetrachlorotoluene and trichloronitrotoluene (m.p. 81°). 2:3:4:5-Tetrachlorotoluene melts at 97°–98° and forms a *nitro-derivative*, m.p. 159° (Cohen and Dakin, *ibid.* 1906, 89, 1483).

2:3:4:6-*Tetrachlorotoluene*; from 2:4:6-trichloro-aceto-*m*-toluidide by hydrolysis and replacement of the amino-group by chlorine; by further chlorination of 2:4:6-trichlorotoluene in presence of the aluminium-mercury couple. Shining needles, m.p. 91.5°–92°. 5-*Nitro-derivative*, m.p. 131°–134° (not pure), and on further nitration a compound, highly refractive plates, m.p. 153°, is formed (Cohen and Dakin, Chem. Soc. Trans. 1904, 85, 1280, 1284).

2:3:5:6-*Tetrachlorotoluene*; from 2:3:6-trichlorotoluene by nitration, reduction and replacement of the amino-group by chlorine; by chlorination of 2:3:5- and 2:3:6-trichlorotoluene in presence of the aluminium-mercury couple. White opaque felted needles, m.p. 93°–94°; 4-*nitro-derivative*, small hexagonal plates, m.p. 150°–152° (Cohen and Dakin, Chem. Soc. Trans. 1904, 85, 1281). The tetrachloro-derivatives obtained by Limpricht (Ann. 1866, 189, 327), Beilstein and Kuhlberg (Ann. 1869, 150, 286), and Pieper (Ann. 1867, 145, 305) are impure. A tetrachlorotoluene has been obtained in 90 p.c. yield, together with less highly halogenated derivatives and traces of pentachlorotoluene, |

| mixture of dry toluene and chloride with stirring; the maximum

were being 50°, whilst, if the temperature be kept at 12°–15°, trichlorotoluene is formed (Casella & Co., Eng. Pat. 16317 of 1914).

Pentachlorotoluene; by chlorinating toluene initially in presence of iodine and finally in presence of phosphorus pentachloride. Long hair-like needles, m.p. 218°, b.p. 301° (Beilstein and Kuhlberg, Ann. 1869, 150, 298).

Bromo derivatives.—A quantitative examination of the influence of light, temperature and bromine 'carriers' on the action of bromine on an excess of toluene has been carried out by Holleman and van der Laan (Proc. K. Akad. Wetensch. Amsterdam, 1906, 8, 512), van der Laan (Chem. Weekblad, 1906, 3, 15), Holleman, Polack, van der Laan and Euwe (Rec. trav. chim. 1908, (2) 27, 435); cf. Andrich and le Blanc (Zeitsch. Wiss. Photochem. 1916, 15, 148) and Swenson (*ibid.* 1921, 20, 206). The investigations of van der Laan have left the question undecided whether *m*-bromotoluene is formed by the bromination of toluene in addition to *o*- and *p*-bromotoluene and benzyl bromide. Holleman (Rec. trav. chim. 1914 (2), 33, 183) concludes, on the evidence of the index of refraction and of the first and second points of solidification of the products of bromination, that *m*-bromotoluene is not produced when bromine acts on a large excess of toluene. Cohen and Dutt (Chem. Soc. Trans. 1914, 105, 504), however, arrive at a contrary conclusion when using the aluminium-mercury couple, although Holleman regards the experimental proof of the presence of *m*-bromotoluene as not sufficiently definite. A further proof of the contention of Cohen and Dutt is given in Chem. Soc. Proc. 1914, 30, 271.

In addition to the ordinary methods for brominating toluene, a mixture of nitric and hydrobromic acids may be used, but it is preferable to use a mixture of bromine and nitric acid (Datta and Chatterjee, J. Amer. Chem. Soc. 1916, 38, 2545).

***o*-Bromotoluene** on further bromination in of the aluminium-mercury couple mainly 2:5-dibromotoluene with smaller quantities of 2:4-dibromotoluene; *m*-bromotoluene similarly yields 2:5-dibromotoluene with 3:4-dibromotoluene, a little 4:5-tribromotoluene and a trace of 3:4-dibromotoluene; whilst *p*-bromotoluene yields 4-dibromotoluene as the main product ether with 3:4-dibromotoluene (Cohen and L., *l.c.*) and 2:4:5-tribromotoluene (Miller, 1892, 61, 1023).

2:3-Dibromotoluene on similar treatment 2:3:6-tribromotoluene as the main act, together with a little of the 2:3:5- whilst the presence of 2:3:4-olene is doubtful; 2:4-dibromotoluene yields a mixture of 2:4:5- and 2:4:6-oluenes; 2:5-dibromotoluene yields 2:4:5-tribromotoluene together with 2:3:5-isomeride; whilst 3:4-dibromotoluene yields mainly 2:4:5-tribromotoluene, with a very small amount of 3:4:5-oluenes, and 3:5-dibromotoluene yields 1:5-tribromotoluene (Cohen and Dutt, Chem. 1914, 105, 501). The bromination in presence of the aluminium-yields mainly 2-chloro-5-bromo- with smaller quantities of

2-chloro-4-bromotoluene; of *m*-chlorotoluene, 3-chloro-6-bromotoluene and smaller quantities of 3-chloro-4-bromotoluene; of *p*-chlorotoluene, mainly 4-chloro-2-bromotoluene together with 4-chloro-3-bromotoluene. The chlorination of *o*-bromotoluene under similar conditions yields mainly 4-chloro-2-bromotoluene together with 6-chloro-2-bromotoluene; of *m*-bromotoluene, mainly 6-chloro-3-bromotoluene together with 4-chloro-3-bromotoluene; and of *p*-bromotoluene, 2-chloro-4-bromotoluene as main product together with 3-chloro-4-bromotoluene (Cohen and Smithells, *ibid.* 1914, 105, 1910).

Benzyl bromide; by saturating benzyl alcohol with hydrogen bromide (Kekulé, Ann. 1866, 137, 190); by the action of bromine on toluene at the boiling-point (Beilstein, Ann. 1867, 143, 369; Jackson and Field, Amer. Chem. J. 1880–1, 2, 11), in sunlight (Schramm, Ber. 1885, 18, 608; cf. Grimaux and Lauth, Bull. Soc. chim. 1867 (2), 7, 108). From benzyl chloride and arsenic tribromide (Brix, Ann. 1884, 225, 163). Liquid, b.p. 198°–199° D_{20}^{22} 1.4380. The vapour has lachrymatory properties.

The zinc-copper couple reacts energetically with benzyl bromide yielding two isomeric benzylenes (C_7H_8)₂ with evolution of hydrogen bromide, whilst if the reaction be carried out in ethereal solution no hydrogen bromide is evolved, and toluene and dibenzyl are formed when the reaction product is treated with water. Similar products are obtained in presence of ethyl alcohol or water (Gladstone and Tribe, Chem. Soc. Trans. 1885, 47, 448).

***o*-Bromobenzyl bromide**; together with the *p*-compound by brominating crude toluene, most of the *p*-compound being removed by pressing the cooled product, the remainder being distilled with steam when the *o*-compound distils first; in a pure condition by brominating *o*-bromotoluene. Crystallises at 0° in very pungent rhombic plates, volatile with steam, m.p. 30°, and on treatment with sodium in ethereal solution it yields phenanthrene, anthracene, dibenzyl and other products (Jackson and others, Amer. Chem. J. 1879, 1, 93; 1880–1, 2, 315; Ber. 1876, 9, 932; 1879, 12, 1965; 1880, 13, 1218).

***m*-Bromobenzyl bromide**; by brominating heated *m*-bromotoluene. Pungent plates or needles, m.p. 41°, slightly volatile with steam, but very volatile with ether vapour; like *o*-bromobenzyl bromide, it is unattacked by chromic acid (Jackson, Ber. 1876, 9, 931; Amer. Chem. J. 1879, 1, 93).

***p*-Bromobenzyl bromide**; by passing bromine vapour into boiling *p*-bromotoluene; by brominating benzyl bromide (Jackson, *l.c.*); by brominating *p*-bromotoluene in the cold and in presence of sunlight (Schramm, Ber. 1884, 17, 2922; 1885, 18, 350). Very pungent needles or large rhombic prisms, m.p. 61°, volatile with steam. When boiled with alcoholic potash it yields *p*-bromobenzyl alcohol and ethyl *p*-bromobenzoate (Elbe, J. pr. Chem. 1886, (2) 24, 241), and with zinc dust *p*-*p*-dibromodibenzyl (Errera, Gazz. chim. ital. 1886, 16, 227; cf. Fittig and Stelling, Ann. 1866, 137, 266).

Benzylidene bromide; from benzyl alcohol and phosphorus pentabromide (Michaelson and Lammann, Bull. Soc. chim. 1865, (2) 2, 251; Curran

and Quedenfeldt, J. pr. Chem. 1898, (2) 58, 389) Liquid, b.p. 156°/23 mm., D_{15}^{20} 1.51, n_D^{20} = 1.541 It is decomposed by cold water forming hydrogen bromide and benzaldehyde, whilst with alcohol it yields ethyl bromide and a liquid, b.p. 50°/11 mm. ($C_6H_5 \cdot CHBrOC_2H_5$), which on treatment with water yields hydrogen bromide and benzaldehyde (Curtius and Quedenfeldt). With sodium at 180° it yields toluene and dibenzyl (Michaelson and Lippmann).

p-Bromobenzyl chloride; by heating *p*-bromobenzyl alcohol with fuming hydrochloric acid at 150° for 3-4 hours. Glistening needles, m.p. 38°-39° (Errera, Gazz. chim. ital. 1888, 18, 239)

o-Bromotoluene; together with *p*-bromotoluene by brominating cold toluene in the dark in daylight or in presence of iodine (Longuinine, Ber. 1871, 4, 514; Dmochowsky, Ber. 1872, 5, 333; Schramm, Ber. 1885, 18, 607; Glinzer and Fittig, Ann. 1865, 133, 47; 1865, 136, 301; Kekulé, Ann. 1866, 137, 192; Cannizzaro Ann. 1867, 141, 198; Beilstein, Ann. 1867, 143, 369; Fittig, Ann. 1868, 147, 39; Hübner and Post, Ann. 1873, 169, 1; Hübner and Jannasch Ann. 1873, 170, 117; Hübner and Wallach Ann. 1870, 154, 293; Zeit. f. Chem. 1869, (2) 5, 22, 138, 499; Rosenstiel and Nikiforoff, *ibid.* 1869, (2) 5, 635; Hübner and Retschy, *ibid.* 1871, (2) 7, 618; Lauth and Grimaux, Bull. Soc. chim. 1866, (2) 5, 347; 1867, (2) 7, 108; Miller, Chem. Soc. Trans. 1892, 61, 1025).

The product is shaken with dilute sodium hydroxide to remove bromine, steam distilled and fractionated. The crude mixture of *o*- and *p*-bromotoluenes is then subjected to the alternate action of a good freezing mixture and weakly fuming sulphuric acid, when an approximate separation is effected (Miller); another method of separation is given by Reymann (Bull. Soc. chim. 1876, (2) 26, 533). A better method of preparing *o*-bromotoluene is to add bromine to a concentrated solution of pure potassium toluene *p*-sulphonate and to heat at 60°-70°. The mixture is then steam distilled, when the *o*-bromosulphonate crystallises from the residual solution on cooling. On hydrolysing the latter, pure *o*-bromotoluene is obtained (Miller). It may also be prepared from *o*-toluidine by the Sandmeyer reaction (Wroblewsky, Ann. 1873, 168, 171) and together with naphthalene by the action of α -bromonaphthalene on toluene in the presence of aluminium chloride (Roux, Bull. Soc. chim. 1886, (2) 45, 520). M.p. -25.9°; b.p. 180.33°/753.91 mm. (Haase, Ber. 1893, 26, 1053; cf. Feitler, Zeitsch. physikal. Chem. 1889, 4, 73); D_{15}^{20} 1.4437, D_{15}^{20} 1.4309 or 1.431, D_{25}^{20} 1.4222 (Perkin, Chem. Soc. Trans. 1896, 69, 1243; Miller, *ibid.* 1892, 61, 1029; Kelbe, Ber. 1886, 19, 93), D_{20}^{20} 1.4222 (Seubert, Ber. 1889, 22, 2520), D_{15}^{20} 1.21861 (Haase, *l.c.*); molecular refractive power and dispersion coefficient (Seubert, *l.c.*); magnetic rotatory power at 16.7° 15.67 (Perkin, *l.c.*).

On treatment with dilute nitric acid (Zincke, Ber. 1874, 7, 1502) or by prolonged heating with potassium ferrocyanide (Noyes, Amer. Chem. J. 1885, 7, 145) it is oxidised to *o*-bromobenzoic acid; and with chromyl chloride in carbon disulphide solution, followed by decomposition of the product with water, it yields *o*-bromobenzaldehyde and *o*-bromobenzylidene chloride

(Stuart and Elliot, Chem. Soc. Trans. 1888, 53, 804). When brominated in presence of iodine (Miller, *ibid.* 1892, 61, 1032) or the aluminium-mercury couple (Cohen and Dutt, *ibid.* 1914, 105, 501) it yields 2:5-dibromotoluene and a small quantity of 2:4-dibromotoluene, and on reduction with hydriodic acid and phosphorus at 250° it yields toluene (Klages and Liecke, J. pr. Chem. 1900, (2) 61, 322). The zinc-copper couple has no action (Gladstone and Tribe, Chem. Soc. Trans. 1885, 47, 448). For its conversion into *o*-ditolyl, see Fittig (Ann. 1866, 139, 178) and Carnelley (Jahresbericht, 1877, 384), and for the two modifications of *o*-bromotoluene, see Ostromisslensky (Zeitsch. physikal. Chem. 1906, 57, 341).

For its conversion into *o*-cresol, see Bodroux (Compt. rend. 1903, 136, 158; Bull. Soc. chim. 1904, (3) 31, 34).

m-Bromotoluene; from *m*-toluidine by the diazo-reaction and from *m*-bromo-*p*-toluidine by the elimination of the amino-group (Wroblewsky, Zeit. f. Chem. 1871, (2) 7, 609; Ann. 1873, 168, 155; cf. Grete, *ibid.* 1875, 177, 231; Morgan and Clayton, Chem. Soc. Trans. 1905, 87, 950); from *m*-bromo-*p*-toluidine by nitration, elimination of the amino-group, reduction and replacement of the amino-group by bromine (Wroblewsky, Ann. 1878, 192, 206). M.p. -39.8°; b.p. 183.67°/759.46 mm.; D_{15}^{20} 1.20082 (Haase, Ber. 1893, 26, 1053; Feitler, Zeitsch. physikal. Chem. 1889, 4, 73); D_{15}^{20} 1.40988, D_{25}^{20} 1.4009 (Wroblewsky) (Seubert, Ber. 1889, 22, 2520). Optical behaviour (Seubert) Oxidised by chromic acid to *m*-bromobenzoic acid. When sodium acts on a mixture of *m*-bromotoluene and bromobenzene in ethereal solution at 40°-50° for 5 hours, a mixture of diphenyl, *m*-ditolyl and *m*-phenyltoluene is formed (Perrier, Compt. rend. 1891, 114, 484; Bull. Soc. chim. 1892, (3) 182).

On bromination in presence of the aluminium-mercury couple, *m*-bromotoluene yields 2:5-dibromotoluene, 3:4-dibromotoluene, a little 2:4:5-tribromotoluene and a trace of 3:5-dibromotoluene (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 506), whilst on chlorination under similar conditions yields mainly 4-chloro-2-bromotoluene together with 6-chloro-2-bromotoluene (Cohen and Smithells, *ibid.* 1914, 105, 1910).

p-Bromotoluene; together with *o*-bromotoluene by brominating cold toluene (see under *o*-bromotoluene and Hübner and Post, Ann. 1873, 169, 1; Miller, Chem. Soc. Trans. 1892, 61, 1025; Michaelis and Geuzen, Ann. 1887, 242, 165); together with *o*-bromotoluene-sulphonic acid by brominating potassium toluene *p*-sulphonate (Miller). The products of the latter reaction are steam distilled, and the oily, volatile product, consisting of *p*-bromotoluene, a dibromotoluene and *p*-bromobenzyl bromide, is fractionally distilled. The fraction boiling at about 185° solidifies on cooling and consists of *p*-bromotoluene, which is readily obtained pure by redistillation and crystallisation (Miller).

Rhombic crystals (Hübner and Post) or colourless plates (Miller); m.p. 28.5°; b.p. 85.2° (Hübner and Post) or 183.67°/759.46 mm. (Feitler); D_{15}^{20} 1.3959, D_{25}^{20} 1.3856, D_{15}^{20} 1.3637 (Perkin, Chem. Soc. Trans. 1896, 69,

1243), D_{40}^{20} 1.19306 (Hübner and Post; cf. Feitler, D_{40}^{20} 1.38977 (Seubert, Ber. 1889, 22, 2519; cf. Kekulé, Ann. 1866, 137, 192); magnetic rotatory power at 39° 15.06 (Perkin); optical behaviour (Seubert).

On bromination in presence of the aluminium-mercury couple (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 509) or iodine (Miller, *ibid.* 1892, 61, 1304), it yields 2:4- and a little 3:4-dibromotoluene, and on treatment with chromyl chloride in carbon disulphide, followed by decomposition of the product with water, it yields *p*-bromobenzaldehyde (Etard, Ann. Chim. 1881, (5) 22, 241), whilst on reduction with hydriodic acid at 250° it is converted into toluene (Klages and Liecke, J. pr. Chem. 1900, (2) 61, 322). Sodium reacts with a mixture of *p*-bromotoluene and bromobenzene to form *p*-phenyltoluene (Carnelley, Chem. Soc. Trans. 1876, 29, 16; 1880, 37, 706). With sodium it yields 4:4-ditolyl, dibenzyl, 3:4-ditolyl and 4-tolylphenylmethane, etc. (Zincke, Ber. 1871, 4, 396; Longuinine, Ber. 1871, 4, 514; Weiler, Ber. 1899, 32, 1056). The zinc-copper couple has no reaction (Gladstone and Tribe), whilst chromic acid yields *p*-bromobenzoic acid. When chlorinated hot *p*-bromotoluene yields *p*-bromobenzyl chloride (Baeseken, Rec. trav. chim. 1904, 23, 98). It condenses with benzophenone in the presence of sodium to yield *p*-tolylidiphenylmethane (Acree, Amer. Chem. J. 1903, 29, 588).

The magnesium derivative of *p*-bromotoluene on treatment with oxygen yields *p*-cresol (Bodroux, Compt. rend. 1903, 136, 158; Bull. Soc. chim. 1904, (3) 31, 34), whilst it condenses with ethyl-*o*-formate to yield *p*-tolualdehyde (Bodroux, Bull. Soc. chim. 1904, (3) 31, 586; Compt. rend. 1904, 138, 92, 700), with dimethyl sulphate to form *p*-xylene (Werner and Zilkens, Ber. 1903, 36, 2116; Houben, *ibid.* 3083), and with carbonyl sulphide to form *p*-thiotoluic acid and a little tritolyl-carbinol. A similar reaction takes place with the magnesium derivative of *o*-bromotoluene (Weigert, *ibid.* 1007).

2:3-Dibromotoluene; from 5:6-dibromo-*m*-toluidine by elimination of the amino-group (Nevile and Winther, Ber. 1880, 13, 962; 1881, 14, 417; Chem. Soc. Trans. 1880, 37, 429). According to Fittig (Ann., 1868, 147, 39) a *p*-bromotoluene, long needles, m.p. 107° – 108° , obtained by brominating cold toluene without the addition of iodine. The constitution of product is questioned by Nevile and Finther, and Miller (Chem. Soc. Trans. 1892, 61, 1031) regards it as being probably impure 1:4:5-tribromotoluene.

2:3-Dibromotoluene melts at 27.4° – 27.8° and W.) or 30° – 31° (Wynne, Chem. Soc. ns. 1892, 61, 1040). On oxidation with fute nitric acid at 130° , 2:3-dibromobenzoic m.p. 146° – 148° , is formed, whilst on action in carbon tetrachloride solution presence of the aluminium-mercury couple yields mainly 2:3:6-tribromotoluene together with a little of the 2:3:5-tribromotoluene, whilst the presence of the 2:3:4-*iso*-isomeride is doubtful (Cohen and Chem. Soc. Trans. 1914, 105, 616).

2:4-Dibromotoluene; from *p*-bromo-*o*-toluene and 4:5-dibromo-*o*-toluidine by the

dialzo-reaction (Nevile and Winther, *l.c.*); together with a greater proportion of 2:5-dibromotoluene by bromination of *o*-bromotoluene, or together with 3:4-dibromotoluene and 2:4:5-tribromotoluene by brominating *p*-bromotoluene (Miller, Chem. Soc. Trans. 1892, 61, 1023).

Liquid, which does not solidify at -20° , b.p. 152° – $158^\circ/80$ mm. (Cohen and Zortman, Chem. Soc. Trans. 1906, 89, 50). On oxidation with dilute nitric acid it yields 2:4-dibromobenzoic acid, tables, m.p. 168° – 170° (N. and W.), whilst on bromination a mixture of 2:4:5- and 2:4:6-tribromotoluene is formed (Cohen and Dutt, *l.c.*).

2:5-Dibromotoluene; by brominating toluene (Wroblewsky, Zeit. f. Chem. 1870, (2) 6, 239) or *m*-bromotoluene (Wroblewsky, Ann. 1873, 168, 681); from 6-bromo-*m*-toluidine or 5-bromo-*o*-toluidine by the dialzo-reaction (Nevile and Winther, *l.c.*); as the main product, together with 2:4-dibromotoluene, by brominating *o*-bromotoluene (Miller, Chem. Soc. Trans. 1892, 61, 1031; cf. Cohen and Dutt, *ibid.* 1914, 105, 506).

Liquid, which does not solidify at -20° , b.p. 236° , D_{40}^{20} 1.8127 (Wroblewsky). On prolonged boiling with dilute nitric acid it yields 2:5-dibromobenzoic acid, and on bromination in carbon tetrachloride solution in presence of the aluminium-mercury couple, it yields mainly 2:4:5-tribromotoluene together with the 2:3:6-isomeride (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 518).

2:6-Dibromotoluene; from 2:6-dibromo-*m*-toluidine, 2:6-dibromo-*p*-toluidine (Nevile and Winther, *l.c.*; Wroblewsky, *l.c.*), and 6-bromo-*o*-toluidine (Blankama, Chem. Weekblad. 1912, 9, 968) by the dialzo-reaction.

Colourless crystals, m.p. 2° (Blankama), b.p. 246° , D_{40}^{20} 1.812 (Wroblewsky; cf. Cohen and Zortman, Chem. Soc. Trans. 1906, 89, 51). On bromination it yields 2:3:6-tribromotoluene (Cohen and Dutt, *l.c.*).

3:4-Dibromotoluene; from 3-bromo-*p*-toluidine (Nevile and Winther, *l.c.*; Wroblewsky); the product obtained by Jannasch (Ann. 1876, 176, 286) by brominating toluene is stated to be a mixture of isomerides by Miller (Chem. Soc. Trans. 1892, 61, 1605); together with other products by brominating *p*-bromotoluene (Miller, *l.c.*). Liquid, b.p. 160° – $165^\circ/65$ mm. (Cohen and Zortman, Chem. Soc. Trans. 1906, 89, 52), b.p. 238° – 239° , D_{40}^{20} 1.812 (Wroblewsky). On oxidation with dilute nitric acid or chromic acid, 3:4-dibromobenzoic acid, m.p. 232° – 233° (cf. Burghardt, Ber. 1875, 8, 559), is obtained. On further bromination 2:4:5-tribromotoluene, together with a very small quantity of 3:4:5-tribromotoluene, is formed (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 519).

3:5-Dibromotoluene; from 3:5-dibromo-*p*-toluidine or 3:5-dibromo-*o*-toluidine (Wroblewsky, *l.c.*; Nevile and Winther). Long needles, m.p. 39° , b.p. 246° (Nevile and Winther). On oxidation with chromic acid it yields 3:5-dibromobenzoic acid, m.p. 208° – 209° , whilst on further bromination 2:3:5-tribromotoluene is formed (Cohen and Dutt, *l.c.*).

Dibromotoluene, m.p. 106° . The existence of this substance, said to be formed by the bromination of toluene (Fittig, Ann. 1868, 147, 39) is questioned by Nevile and Winther.

2:3:4-Tribromotoluene; from 4:5:6-tribromo-

bromo-*m*-toluidine (Nevile and Winther, *l.c.*); by bromination of 4:5-dibromoaceto-*m*-toluidine, followed by hydrolysis with dilute sulphuric acid and elimination of the amino-group. It melts at 45°–46° and when heated for 6 hours in a sealed tube at 150°–160° with dilute nitric acid it yields 2:3:4-tribromobenzoic acid (Cohen and Dutt, *Chem. Soc. Trans.* 1914, 105, 511).

2:3:5-*Tribromotoluene*; from 3:5-dibromo-*o*-toluidine (N. and W.) or 5:6-dibromo-*m*-toluidine (Cohen and Dutt, *l.c.*) by the diazo-reaction. Long flat needles, m.p. 52°–53°. On oxidation with dilute nitric acid at 135°–140° for 6 hours it yields 2:3:5-tribromobenzoic acid, m.p. 193°–194°.

2:3:6-*Tribromotoluene*; from 2:5:6-tribromo-*m*-toluidine (N. and W.), 2:5:6-tribromo-*p*-toluidine, and 5:6-dibromo-*o*-toluidine (Cohen and Dutt, *Chem. Soc. Trans.* 1914, 105, 514). Flat needles, m.p. 58°–59° (N. and W.). The corresponding tribromobenzoic acid could not be obtained by direct oxidation with dilute nitric acid in a sealed tube (Cohen and Dutt, *l.c.*).

2:4:5-*Tribromotoluene*; from 4:6-dibromo-*m*-toluidine and 4:5-dibromo-*o*-toluidine (Nevile and Winther, *l.c.*; Cohen and Dutt, *l.c.*); from 5-bromo-2:4-toluylenediamine (Morgan and Clayton, *Chem. Soc. Trans.* 1905, 87, 951); by nitration of 3:4-dibromotoluene followed by reduction (Nevile and Winther, *Ber.* 1881, 14, 417); by brominating *p*-bromotoluene (Miller, *Chem. Soc. Trans.* 1892, 61, 1033).

Colourless needles, m.p. 112°–113°. On oxidation with dilute nitric acid in a sealed tube it yields 2:4:5-tribromobenzoic acid, m.p. 195°–196° (Cohen and Dutt, *l.c.*). According to Pfankuch (*J. pr. Chem.* 1873, (2) 6, 108) a *tribromotoluene*, small needles, m.p. 150°, is obtained by heating the potassium salt of tribromophenol with potassium acetate.

2:4:6-*Tribromotoluene*; from 2:4:6-tribromo-*m*-toluidine by the diazo-reaction (Nevile and Winther, *Ber.* 1880, 13, 975; 1881, 14, 417; *Chem. Soc. Trans.* 1880, 37, 446); by brominating *m*-toluidine followed by the elimination of the amino-group (Cohen and Dutt, *l.c.*). M.p. 66° (N. and W.), b.p. 290° (Wroblewsky, *Ann.* 1873, 168, 194). On oxidation it yields 2:4:6-tribromobenzoic acid, m.p. 186°–187° (Cohen and Dutt).

3:4:5-*Tribromotoluene*; from 3:5-dibromo-*p*-toluidine by the diazo-reaction. M.p. 88°–89° (Nevile and Winther, *l.c.*; Cohen and Dutt, *l.c.*). On oxidation it yields 3:4:5-tribromobenzoic acid, m.p. 235° (Cohen and Dutt).

(v)-2:3:4:5-*Tetrabromotoluene*; from 4:5:6-tribromo-*m*-toluidine by the diazo-reaction. Needles, m.p. 111°–111.5° (Nevile and Winther).

(a)-2:3:4:6-*Tetrabromotoluene*; from 2:4:6-tribromo-*m*-toluidine and tetrabromo-*m*-toluidine (m.p. 224°) by the diazo-reaction. M.p. 106.8°–108° (Nevile and Winther).

(s)-2:3:5:6-*Tetrabromotoluene*; from 2:5:6-tribromo-*m*-toluidine by the diazo-reaction. Fine needles, m.p. 116°–117° (Nevile and Winther).

Pentabromotoluene; by careful addition of toluene to pure bromine at 0° in presence of

aluminium bromide (Gustavson, *J. Russ. Phys. Chem. Soc.* 1877, 9, 236; *Bull. Soc. chim.* 1877, (2) 28, 347; *Ber.* 1877, 10, 971); from tetrabromo-*m*-toluidine (m.p. 223°–224°) (Nevile and Winther, *Ber.* 1880, 13, 976; *Chem. Soc. Trans.* 1880, 37, 450); from cycloheptane (Markownikoff, *J. Russ. Chem. Phys. Soc.* 1893, 25, 544) or methylcyclohexane (Kursanoff, *Ber.* 1899, 32, 2973) by the action of bromine in presence of aluminium bromide; from ethyl- and propyl-cymene by means of bromine in presence of aluminium (Klages and Sommer, *Ber.* 1906, 39, 2306; Klages, *Ber.* 1907, 40, 2360).

Long needles which sublime, m.p. 282°–283° (Kursanoff) or 279°–280° (Zelinsky and Generosow, *Ber.* 1896, 29, 732; cf. Jäger, *Z. Kristall*, 1903, 38, 89). It is reduced to toluene by phosphorus and hydriodic acid at 302° (Klages and Liecke, *J. pr. Chem.* 1900, (2) 61, 322).

2-*Chloro-3-bromotoluene*, m.p. 18°, on oxidation yields 2-chloro-3-bromobenzoic acid, m.p. 165°, and on nitration yields a *mononitro-derivative*, m.p. 44°–45°, and a *dinitro-derivative*, m.p. 89°–93° (Cohen and Smithells, *Chem. Soc. Trans.* 1914, 105, 1908).

2-*Chloro-4-bromotoluene*; from 2-nitro-*p*-toluidine (Cohen and Raper, *Chem. Soc. Trans.* 1904, 85, 1266); together with 3-chloro-4-bromotoluene by chlorinating *p*-bromotoluene (Cohen and Smithells, *l.c.* 1910; cf. Willgerodt and Salzmann, *J. pr. Chem.* 1889, (2) 39, 465.) Liquid, b.p. 100°–110°/10 mm., which on oxidation yields 2-chloro-4-bromobenzoic acid, m.p. 166°–167° (Cohen and Raper). Its *nitro-derivative* melts at 65°–66° and its *dinitro-derivative* at 110°–111° (Cohen and Smithells).

2-*Chloro-5-bromotoluene*; from 5-nitro-*o*-toluidine. Liquid, b.p. 127°–129°/45 mm. It yields 2-chloro-5-bromobenzoic acid on oxidation (Cohen and Raper), and on nitration a *mononitro-derivative*, m.p. 68°–69°, and a *dinitro-derivative*, m.p. 109°–110° (Cohen and Smithells).

2-*Chloro-6-bromotoluene*; from 2:6-dinitrotoluene. Liquid, b.p. 118°–120°/40 mm. which yields 2-chloro-6-bromobenzoic acid, m.p. 143°–144°, on oxidation (Cohen and Raper, *l.c.*; Willgerodt and Salzmann) and a *mononitro-derivative*, m.p. 50°–52°, and a *dinitro-derivative*, m.p. 143°–144°, on nitration (Cohen and Smithells).

3-*Chloro-2-bromotoluene*; from 3-nitro-*o*-toluidine (Cohen and Raper, *Chem. Soc. Trans.* 1904, 85, 1266). It melts at 4°–5° (Cohen and Smithells, *ibid.* 1914, 105, 1908) and boils at 103°–105°/25 mm. On oxidation it yields 3-chloro 2-bromobenzoic acid, m.p. 143°–144° (Cohen and Raper), and on nitration a *mono-* and a *dinitro-derivative*, m.p. 58°–59.5° and 81° respectively (Cohen and Smithells).

3-*Chloro-4-bromotoluene*; from *m*-chloro-*p*-toluidine by the diazo-reaction (Cohen and Raper, *l.c.*); by chlorinating *p*-bromotoluene (Willgerodt and Salzmann, *l.c.*). Liquid, b.p. 125°–130°, which on oxidation yields 3-chloro-4-bromobenzoic acid, m.p. 218° (Cohen and Raper), and on nitration yields a *mono-* and a *dinitro-derivative*, melting at 72° and 101°–102° respectively (Cohen and Smithells, *l.c.*).

3-*Chloro-5-bromotoluene*; from aceto-*p*-toluidide by successive bromination and chlorination with hydrochloric acid and sodium chlorate in acetic acid, followed by hydrolysis to 3-chloro-

5-bromo-*p*-toluidine and elimination of the amino-group; by chlorination of aceto-*p*-toluidine and hydrolysis to 3-chloro-*p*-toluidine followed by bromination and elimination of the amino-group. Crystals, m.p. 26°–27°. Its 6-nitro-derivative, colourless needles, melts at 71° and its 2:6(1)-dinitro-derivative at 144°. On oxidation it yields 3-chloro-5-bromobenzoic acid, m.p. 189°–190° (Cohen and Raper; Cohen and Smithells; Cohen and Murray, Chem. Soc. Trans. 1915, 107, 847).

4-Chloro-2-bromotoluene; by chlorinating o-bromotoluene or by brominating *p*-chlorotoluene; from 2-nitro-*p*-toluidine. Liquid, b.p. 112°–114°/12 mm. On oxidation it yields 4-chloro-2-bromobenzoic acid, m.p. 154°–155° (Cohen and Raper, Chem. Soc. Trans. 1904, 85, 1267; cf. Willgerodt and Salzmann, J. pr. Chem. 1889, (2) 39, 465, and Cohen and Dakin, Chem. Soc. Trans. 1899, 75, 895), and on nitration a mononitro- and a dinitro-derivative, melting at 64°–65° and 124°–5° respectively, are formed (Cohen and Smithells, Chem. Soc. Trans. 1914, 105, 1908).

4-Chloro-3-bromotoluene; from *m*-nitro-*p*-toluidine. Liquid, b.p. 120°–125°/28 mm. It yields 4-chloro-3-bromobenzoic acid, m.p. 214°, on oxidation (Cohen and Raper, l.c.), and a mononitro-derivative, m.p. 67°–5°, and a dinitro-derivative, m.p. 127°, on nitration (Cohen and Smithells).

4-Chloro-dibromotoluene; by brominating bromo-*p*-chlorotoluene in presence of the aluminium mercury couple. M.p. 94° (Cohen and Dakin, Chem. Soc. Trans. 1899, 75, 893).

5-Chloro-2-bromotoluene; from 5-chloro-*o*-toluidine. Liquid, b.p. 98°–100°/25 mm. The nitro-derivative melts at 66°–67°, the dinitro-derivative at 117°, and oxidation yields 5-chloro-2-bromobenzoic acid, m.p. 153° (Cohen and Raper; Cohen and Smithells).

The following compounds have been obtained by Willgerodt and Salzmann (J. pr. Chem. 1889, (2) 39, 482): *o*-chloro-dibromotoluene, needles, m.p. 100°, b.p. 275°–280°, by brominating *o*-chlorotoluene; dichloro-*p*-bromotoluene, glistening needles, m.p. 87°, b.p. 240°–245°; trichloro-*p*-bromotoluene, needles, m.p. 55°–60°, b.p. 265°–275°; and tetrachloro-*p*-bromotoluene, needles, m.p. 213°, by chlorinating *p*-bromotoluene.

3:4:6(1)-Trichloro-5-bromotoluene, m.p. 98°–100°, is obtained from 3:4-dichloro-5-bromotoluene by nitration, reduction and replacement of the amino-group by chlorine. Its nitro-derivative melts at 171°–173° (Cohen and Dakin, Chem. Soc. Trans. 1906, 89, 1453).

2(1):3:4-Trichloro-5-bromotoluene, m.p. 92°–94°, is formed by chlorinating 3:4-dichloro-5-bromotoluene. Its nitro-derivative melts at 175°–176° (Cohen and Dakin, l.c.).

2-Chloro-3:4:5:6-tetrabromotoluene melts at 256°–259° (Mouneyrat and Pourcet, Compt. rend. 1899, 129, 607).

o-Iodotoluene; from *o*-toluidine by the diazo-reaction (Beilstein and Kuhlberg, Ann. 1871, 158, 347; Kekulé, Ber. 1874, 7, 1007; Mabery and Robinson, Amer. Chem. J. 1882, 4, 101); together with *p*-iodotoluene by heating a solution of toluene in light petroleum with powdered sulphur iodide and an excess of dilute nitric acid (D 1.34) for several hours at 100°

(Edinger and Goldberg, Ber. 1900, 33, 2875). Oil, b.p. 204° (B. and K.) or 211° (Kekulé), D₂₀ 1.697 (B. and K.).

When oxidised with dilute nitric acid it yields *o*-iodobenzoic acid, m.p. 157°. With chromyl chloride and treatment of the product with water, it yields *o*-iodo-*o*-dichlorotoluene and a little *o*-iodobenzaldehyde (Stuart and Elliot, Chem. Soc. Trans. 1888, 53, 805). When heated with sulphuric acid it yields di- and tri-iodotoluene, together with iodotoluene sulphonic acid (Neumann, Ann. 1887, 241, 62; Ber. 1887, 20, 581), whilst on nitration mainly 5-nitro-2-iodotoluene is formed (Reverdin, Ber. 1897, 30, 3000). On treatment with chlorine in chloroform solution *o*-iodotoluene yields a dichloride, crystals, decomposing about 91° (Willgerodt, Ber. 1893, 26, 360).

m-Iodotoluene; from *m*-toluidine by the diazo-reaction (Beilstein and Kuhlberg, l.c.). Liquid, b.p. 204°, D₂₀ 1.698.

p-Iodotoluene; from *p*-toluidine by the diazo-reaction (Körner, Zeitsch. f. Chem. 1868, (2) 4, 327; Bull. Acad. roy. Belg. 1867, 157); together with *o*-iodotoluene by the iodination of toluene according to the method of Edinger and Goldberg (above). Plates which sublime, m.p. 35°, b.p. 211°–5°. *p*-Iodotoluene is stated to be formed also by the action of iodine on mercury ditolyl, the melting-point being given as 20° (Dreher and Otto, Ann. 1870, 154, 171).

When chlorinated, two forms of the iodo-dichloride are obtained, the α -form separates from chloroform in needles, decomposing at 85°, and the β -form in irregular rhombic crystals, exploding at 110°–118° (Willgerodt, Ber. 1893, 26, 357). With nitric acid (D 1.51) at the ordinary temperature it yields *p*-nitrotoluene, *p*-iodo-*o*-nitrotoluene, and a di-iodo-nitrotoluene (Reverdin, Ber. 1897, 30, 3001), and on heating with sulphuric acid di- and tri-iodotoluene and iodotoluene sulphonic acid are formed (Neumann, Ann. 1887, 241, 58; Ber. 1887, 20, 581). On oxidation it yields *p*-iodobenzoic acid.

2:3-Di-iodotoluene; from 2-iodo-*m*-toluidine by the diazo-reaction. Colourless plates, m.p. 31°–32° (Wheeler and Liddle, Amer. Chem. J. 1909, 42, 441).

2:4-Di-iodotoluene; by heating 1 part of *o*- or *p*-iodotoluene with 1 part of sulphuric acid (D 1.85) at 170°. Oil, b.p. 295°–296°. With dilute nitric acid at 200° it yields 2:4-di-iodobenzoic acid (Neumann, Ann. 1887, 241, 51; Ber. 1887, 20, 581).

2:5-Di-iodotoluene; from 5-iodo-*o*-toluidine by the diazo-reaction. Long colourless plates, m.p. 30°–31° (Wheeler and Liddle, Amer. Chem. J. 1909, 42, 498).

2:6-Di-iodotoluene; from 2-iodo-6-amino-toluene by the diazo-reaction. Almost colourless needles, m.p. 40°–42° (Cohen and Miller, Chem. Soc. Trans. 1904, 85, 1827).

3:5-Di-iodotoluene; from 3:5-di-iodo-*p*-toluidine by the diazo-reaction. Yellow needles, m.p. 44°–45° (Wheeler and Liddle, Amer. Chem. J. 1909, 42, 441).

2:3:4-Tri-iodo-toluene; from 4:5:6-tri-iodo-*m*-toluidine by the diazo-reaction. It melts at 92° (Wheeler, Brautlecht, Hoffman and Scholes, Amer. Chem. J. 1910, 44, 126, 493).

2:3:5-*Tri-iodotoluene*; from 2:5^o or 5:6-di-iodo-*m*-toluidine by the diazo-reaction. Pale orange plates, m.p. 72°-73° (Wheeler, etc.).

2:3:6-*Tri-iodotoluene*; m.p. 80°-5°, is obtained from 2:6-di-iodo-*m*-toluidine or 3:6-di-iodo-*o*-toluidine by the diazo-reaction (Wheeler, etc.).

2:4:5-*Tri-iodotoluene*; from 4:5-di-iodo-*o*-toluidine, 2:5-di-iodo-*p*-toluidine, and 4:6-di-iodo-*m*-toluidine (Wheeler, etc.); or by heating equal parts of *o*- or *p*-iodotoluene with sulphuric acid (D 1·85) at 170° (Neumann, Ann. 1887, 241, 55). Long brown needles, m.p. 119°-120°, b.p. above 300°.

2:4:6-*Tri-iodotoluene*; from 2:4:6-tri-iodo-*m*-toluidine by the diazo-reaction. Colourless needles, m.p. 105° (Wheeler, etc.).

3:4:5-*Tri-iodotoluene*; from 3:5-di-iodo-*p*-toluidine by the diazo-reaction. Long silky needles, m.p. 122°-123° (Wheeler and Liddle, Amer. Chem. J. 1909, 42, 441).

2:3:4:5-*Tetraiodotoluene*; from 4:5:6-tri-iodo-*m*-toluidine by the diazo-reaction. Straw-coloured needles, m.p. 284°-285° (Wheeler, etc.).

2:3:4:6-*Tetraiodotoluene*; from 2:4:6-tri-iodo-*m*-toluidine by the diazo-reaction. Long needles, m.p. 170° (Wheeler, etc.).

2:3:5:6-*Tetraiodotoluene*; from 2:5:6-tri-iodo-*m*-toluidine by the diazo-reaction. Colourless needles, m.p. 125° (Wheeler, etc.).

Penta-iodotoluene; from 2:4:5:6-tetraiodo-*m*-toluidine by the diazo-reaction. Small dull yellow needles, m.p. 340° (decomp.) (Wheeler, etc.).

Chloro-o-iodotoluene; from chlorinated *o*-toluidine. B.p. 240°, D₄²⁰ 1·702 (Beilstein and Kuhlberg, Ann. 1870, 156, 82).

α-Chlorotoluene does not solidify at -14°, b.p. 242°, D₄²⁰ 1·716 (Wroblewsky, Ann. 1873, 168, 210).

β-Chlorotoluene solidifies at 10°, b.p. 240°, D₄²⁰ 1·770 (Wroblewsky).

2-*Chloro-6-iodotoluene*; from 2-chloro-6-aminotoluene by the diazo-reaction. Colourless liquid, b.p. 132°-133°/25 mm., D₂₀²⁰ 1·844 (Cohen and Miller, Chem. Soc. Trans. 1904, 85, 1627).

5-*Chloro-4-iodo-3-nitrotoluene*; from 5-chloro-3-nitro-*p*-toluidine. Colourless plates, m.p. 92° (Kenner and Judd, *ibid.* 1920, 117, 776).

m-Bromo-o-iodotoluene; by treating *m*-bromo-*o*-diazo-toluene with hydriodic acid (Wroblewsky). Colourless liquid, b.p. 260°, D₁₅²⁰ 2·139.

2-*Bromo-6-iodotoluene*; from 2-bromo-6-aminotoluene by the diazo-reaction. Colourless liquid, b.p. 135°-140°/15 mm., D₂₀²⁰ 2·044 (Cohen and Miller).

3-*Bromo-4-iodotoluene*; from *m*-bromo-*p*-toluidine by the diazo-reaction. Oil, b.p. 265°, D₂₀²⁰ 2·044. It yields a *mononitro-derivative*, m.p. 118° (Wroblewsky).

3-*Bromo-2-iodotoluene*; from 6-iodo-*m*-toluidine by the diazo-reaction. B.p. 262°-265°, n_D^{20} 1·684 (Holleman, Rec. trav. chim. 1912, 31, 267).

The constitution of the product obtained by Hirtz (Ber. 1896, 29, 1406) by brominating *o*-iodotoluene as 4-(1)-*bromo-2-iodotoluene* is doubtful, as the reaction-product is of a very complicated nature (Holleman, *l.c.*).

3:5-*Dibromo-2-iodotoluene*; from 3:5-di-bromo-*o*-toluidine by the diazo-reaction. Needles, m.p. 68°, b.p. 314° (with slight decomp.).

On chlorinating in chloroform solution it yields a *dichloride*, yellow cubic crystals, m.p. 95° (decomp.) (McCrae, Chem. Soc. Trans. 1898, 73, 691).

3:5-*Dibromo-4-iodotoluene*; from 3:5-di-bromo-*p*-toluidine by replacement of the amino-group by iodine (Wroblewsky, Ann. 1873, 168, 190); from 3-bromo-5-nitro-*p*-toluidine by replacement of the amino-group by iodine and of the nitro-group by bromine (Wroblewsky, Ann. 1878, 192, 209). Long needles, m.p. 86°, b.p. 270°. Its *mononitro-derivative* melts at 69°.

3:5-*Dibromo-2:4-di-iodotoluene*; from nitrated bromiodotoluene by replacing the nitro-group by iodine. Prisms, volatile with steam, m.p. 68°. Its *mononitro-derivative* melts at 129° (Wroblewsky, Ann. 1878, 192, 212).

o-Iodosotoluene; from *o*-iodotoluene dichloride and dilute sodium hydroxide solution (Willgerodt, Ber. 1893, 26, 361) or water and pyridine (Ortoleva, Gazz. chim. ital. 1900, 30, ii. 5). Almost colourless crystals, m.p. 178° (decomp.), acetate m.p. 130°-132° (Ortoleva). 3:5-*Dibromo-2-iodosotoluene*, is obtained from the corresponding dichloride by treatment with soda solution. Yellow amorphous mass decomposing at about 87°. Its acetate forms needles, m.p. 66°-5° (McCrae, *l.c.*).

m-Iodosotoluene; from *m*-iodotoluene dichloride (yellow needles, decomposing at 104°) by the action of water on a solution in pyridine (Ortoleva), or by the action of sodium hydroxide (Willgerodt and Umbach, Ann. 1903, 327, 269). Yellowish-white amorphous powder exploding at 206°-207° (Willgerodt and Umbach) or decomposing at 180°-185° (Ortoleva). The acetate, colourless needles, melts at 148°-149° (Ortoleva; Willgerodt and Umbach), the *difluoride*, small colourless needles, melts at 180°, decomposing at 188°, on rapid heating (Weinland and Stille, Ann. 1903, 328, 132).

p-Iodosotoluene; by treating *p*-iodotoluene dichloride with dilute sodium hydroxide solution, followed by purification of the crude product with chloroform (Willgerodt, Ber. 1893, 26, 359); or in a manner analogous to that of the *o*-isomeride (Ortoleva, *l.c.*). It decomposes at 175°-178°, and on boiling with water yields a mixture of *p*-iodotoluene and *p*-iodoxytoluene (Willgerodt). On adding hydrofluoric acid slowly to a solution of *p*-iodosotoluene in acetic acid, *p*-toluene-iodo-fluoride, small yellow needles, m.p. 112°, decomposing at 115°, is formed (Weinland and Stille, *l.c.*).

o-Iodoxytoluene; by boiling *o*-iodosotoluene with water in presence of air (Willgerodt, Ber. 1893, 26, 361); by oxidising *o*-iodotoluene with Caro's acid (Bamberger and Hill, Ber. 1900, 33, 535). Crystalline mass, exploding at 210°, which when treated with hydrofluoric acid yields *o*-toluene-iodosulphuride, leafy aggregates of granules, commencing to melt at 120° and decomposing at 170°-190° (Weinland and Stille, Ber. 1901, 34, 2631).

m-Iodoxytoluene; by treating an intimate mixture of *m*-tolyl iododichloride and a concentrated solution of bleaching powder with a little hydrochloric acid (Willgerodt and Umbach); by oxidising a pyridine solution of *m*-iodotoluene

with chlorine (Ortoleva, Gazz. chim. ital. 1900, 30, ii. 1). White needles, exploding at 220° (Ortoleva, l.c.; cf. Bamberger and Hill). On warming with aqueous hydrogen peroxide it yields *m*-iodotoluene.

p-Iodoxytoluene; in a similar manner to the *o*- and *m*-isomerides. Silky leaflets, exploding at 228° (Willgerodt, Ber. 1896, 29, 1573; Bamberger and Hill, Ber. 1900, 33, 525; Ortoleva, Gazz. chim. ital. 1900, 30, ii. 8). It forms an iodosulfuride, lustrous needles, decomposing at 206° (Weinland and Stille, l.c.).

NITROSO- AND NITRO-DERIVATIVES.

2-Nitrosotoluene; by oxidation of *o*-tolylhydroxylamine (Bamberger, Ber. 1895, 28, 249); by the action of nitrogen trioxide or peroxide on a cold chloroform solution of mercury-*o*-ditolyl (Kunz, Ber. 1898, 31, 1530). White needles, melting at 72°–72.5° to a green liquid, extremely volatile with steam. On treatment with cold concentrated sulphuric acid it yields 4-nitroso-2:3-ditolylhydroxylamine, glistening yellow needles (+H₂O), decomposing about 130°; the anhydrous product melts at 110°–115° (Bamberger, Büsdorf and Sand, Ber. 1898, 31, 1517). 3-Nitro-2-nitrosotoluene, pale yellow leaflets, m.p. 126°–127° (decomp.), is obtained by oxidising 3-nitro-*o*-toluidine with Caro's acid, and is transformed by nitric acid into 2:3-dinitrotoluene (Meisenheimer and Hesse, Ber. 1919, 52, 1161). Its 5-nitro-derivative, almost colourless crystals, m.p. 143°–144°, is formed by the action of Caro's acid on the corresponding amine, and together with dinitroazoxytoluene by treating 2:5-dinitrotoluene with hydroxylamine followed by acidification. It is readily oxidised to 2:5-dinitrotoluene. When the reduction of 2:5-dinitrotoluene by means of hydroxylamine is effected in highly concentrated solution potassium nitrotoluene-iso-diazotate is precipitated in yellow needles, decomposing at 202° (Meisenheimer and Hesse, l.c.). Its 6-nitro-derivative, obtained by oxidising an aqueous alcoholic solution of 6-nitro-*o*-tolylhydroxylamine with ferric chloride in presence of sodium acetate, forms colourless needles, melting at 117° to a green liquid (Brand and Zöller, Ber. 1907, 40, 3324).

3-Nitrosotoluene is prepared in a similar manner to the *o*-derivative. Small needles, readily volatile with steam, m.p. 53°–53.5° (Bamberger, l.c.). Its 2-nitro-derivative forms yellow leaflets, m.p. 92°–93°, and its 4-nitro-derivative, yellow leaflets, m.p. 141° (Meisenheimer and Hesse, l.c.); its 6-nitro-derivative, m.p. 113°, is obtained by oxidising 6-nitro-*m*-toluidine by means of Caro's acid (Kenner and Parkin, Chem. Soc. Trans. 1920, 117, 859).

4-Nitrosotoluene; by oxidation of *p*-tolylhydroxylamine (Bamberger, l.c.; Bamberger and Brady, Ber. 1900, 33, 274); by oxidation of *p*-toluidine by means of potassium permanganate in sulphuric acid solution in presence of form- (Bamberger and Tschirner, Ber. 1898, 31, 1524); together with other products by the action of nitrogen trioxide or peroxide on a cold chloroform solution of mercury-*p*-ditolyl (Kunz, Ber. 1898, 31, 1528). White needles, extremely volatile with steam, m.p. 48.5°. For the action of hydrogen chloride and hydrogen bromide, see Bamberger, Büsdorf and Szalaydi (Ber. 1899,

32, 216). Its 2-nitro-derivative, colourless needles, m.p. 87°, is formed by oxidising 2-nitro-*p*-tolylhydroxylamine (Brand and Zöller); its 3-nitro-derivative is obtained by oxidising *m*-nitro-*p*-toluidine by means of Caro's acid (Bamberger and Hübner, Ber. 1903, 36, 3803), or together with 4-nitro-3-nitroso-toluene and other products by the action of hydroxylamine on 3:4-dinitrotoluene, followed by acidification (Meisenheimer and Hesse), and forms greenish-yellow needles, m.p. 145°–145.5°.

As a result of the work of Green and Rowe (Chem. Soc. Trans. 1912, 101, 2452; 1913, 103, 897), Forster and Fierz (*ibid.* 1907, 91, 1942), and Forster and Barker (*ibid.* 1913, 103, 1918), the compounds originally regarded as '*o*-dinitroso' compounds are shown to be actually iso-oxadiazole oxides, furoxans or furazan oxides, and whereas the above constitution has been proved to be correct for the '*o*-dinitroso' compounds, it appears probable that only the '*p*-dinitroso' compounds have the constitution of 'quinone-dioxime peroxides,' ascribed by Forster and Fierz to the whole class.

Tolu-2: 3-iso-oxadiazole oxide, tolu-furoxan,

tolufurazon oxide, CH₃C₆H₄, from 3-

nitro-2-diazo-toluene-imide by the action of heat. Leaflets, m.p. 60° (Zincke, J. pr. Chem. 1896, [2] 53, 340; Zincke and Schwarz, Ann. 1899, 307, 28). The corresponding dioxime melts at 140° (decomp.) and the iso-oxadiazole or

furazan, CH₃C₆H₄, at 44° (Zincke, and

Schwarz). The 4(?)*-nitro-derivative* forms brown crystals, m.p. 162°; the 5-nitro-derivative, yellow plates, m.p. 70°; the 4:6(?)*-dinitro-derivative*, yellow needles, m.p. 122°–123° (Zincke and Drost, Ann. 1900, 313, 299).

Tolu-2: 5-quinonedioximeperoxide

by oxidation of 2:5-toluquinonedioxime with alkaline potassium ferriyanide (Nietzki and Guitermann, Ber. 1888, 21, 432; Mehne, *ibid.* 21, 734). Yellow crystals, volatile with steam, m.p. 133° (N. and G.) or 144° with slight detonation (M.). Oxidation with nitric acid yields 2:5-dinitrotoluene, whilst treatment with hydroxylamine regenerates the dioxime. Its 4-chloro-derivative is a lemon-yellow powder, m.p. 163°–165° (Kehrmann, Silva and Keleti, Ber. 1915, 48, 2029).

Tolu-3: 4-iso-oxadiazole oxide, m.p. 96°–97°, is formed by heating the corresponding nitro-diazoimide (Zincke, J. pr. Chem. 1896, [2] 53, 340), or by the oxidation of *m*-nitro-*p*-toluidine or *p*-nitro-*m*-toluidine with alkaline sodium hypochlorite (Green and Rowe). The corresponding dioxime, yellowish-brown needles, melts at 127°–128°, and the iso-oxadiazole or furazan, long white needles, melts at 37° (Zincke and Schwarz, Ann. 1899, 307, 28); the latter compound is also formed by the oxidation of *m*-nitrosoaceto-*p*-toluidide with alkaline sodium hypochlorite (Green and Rowe, Chem. Soc.

Trans. 1917, 111, 612). The 2 (or 6)-*nitro-derivative*, obtained by nitrating the furoxan or the imide of *o*-nitro-*p*-toluidine and heating the product of the latter reaction in a brine-bath, forms pale yellow needles, m.p. 164° (decomp.). This nitro-compound, on nitration in presence of sulphuric acid, yields the 2 : 6-*dinitro-derivative*, silky yellow needles, m.p. 133° (decomp.). Its 5(?)*-nitro-derivative* forms yellowish-leaflets, m.p. 145° (Zincke and Drost, Ann. 1900, 313, 299).

NITRO DERIVATIVES.

When toluene is nitrated with nitric acid (D 1.475), the quantity of *o*-, *m*-, or *p*-mononitro-derivative obtained depends on the temperature, solvent, and other factors (Holleman, Proc. K. Akad. Wetensch. Amsterdam, 1908, 11, 248; Holleman, Vermeulen and de Mooy, Rec. trav. chim. 1914, 33, 1; Bruner and Vorbrodt, Anzeiger Akad. Wiss. Cracow, 1909, 221; cf. Kohn, Monatsh. 1910, 31, 745; Fischer, Zeitsch. Elektrochem. 1910, 16, 161; Bell and Spry, J. Ind. Eng. Chem. 1921, 13, 60; Friswell, J. Soc. Chem. Ind. 1908, 27, 258; van der Arend, Verslagen. K. Akad. Wetensch. Amsterdam, 1908, 208; Gibson, Duckham and Fairbairn, Chem. Soc. Trans. 1922, 121, 275; Holdermann, Ber. 1906, 39, 1256). When the nitration is carried out at -30°, 0°, 30°, and 60° with nitric acid (D 1.475) the product contains 41.7 p.c., 40.9 p.c., 39.9 p.c., and 38.5 p.c. respectively, of *p*-nitrotoluene, 55.6 p.c., 56 p.c., 56.9 p.c., and 57.5 p.c. respectively, of *o*-nitrotoluene, and 2.7 p.c., 3.1 p.c., 3.2 p.c., and 4.0 p.c. respectively, of *m*-nitrotoluene (Holleman), thus showing that the percentage of *p*-nitrotoluene decreases with rise of temperature, whilst that of the *o*- and *m*-nitrotoluenes increases, the last being always present only in small quantity. When a mixture of pure nitric acid and acetic anhydride is added to toluene at 30° a violent reaction sets in and the product contains 57.7 p.c. *o*-, 4.4 p.c. *m*-, and 37.3 p.c. *p*-nitrotoluene (Holleman, Vermeulen and De Mooy).

Toluene is readily nitrated in the cold with nitric acid of specific gravity not less than 1.5. In the manufacture of nitrotoluene 1 part of toluene is poured into 1½ parts of nitric acid (D 1.5), the temperature not exceeding 15°. By this means the *o*-derivative is readily formed and is isolated by fractionating the oil which is formed when the nitration mixture, after standing for 10 hours, is poured into water. Commercial nitrotoluene usually contains about 60 p.c. *ortho*-, 2 p.c. *meta*-, and 38 p.c. *para*-nitrotoluene; this mixture has a specific gravity of 1.167, and distils between 220°-240°.

o- and *p*-Nitrotoluene may be separated by treating the crude nitrotoluene with sulphonating agents, whereby the *o*-derivative is sulphonated, and the *p*-isomeride remains unchanged (Lange, Eng. Pat. 1407 of 1890), or by fractional reduction by means of sulphides or hydrosulphides, particularly with Le Blanc soda residues (Clayton Aniline Co., Fr. Pat. 255957; D. R. P. 92991 of 1896). *o*-Nitrotoluene may also be separated from its isomerides by heating with salts of arsenious acid, and the *o*-nitrotoluene, which is unaltered by this treatment, is isolated by treatment with acid, steam distillation, &c. (Loeser, D. R. P. 78002 of 1894; J. pr. Chem.

1894, [2] 50, 567). *o*- and *p*-Nitrotoluenes may also be separated by fractional distillation at a pressure of 20 mm. (Molinari, Atti Congr. Nar. Chim. Ind., 1924, 402; Chem. Soc. Abstr. 1925, 128, i. 380).

For the estimation of nitrotoluenes by means of stannous chloride and titanous chloride, see Colver and Prideaux (J. Soc. Chem. Ind. 1917, 36, 480, 856) and Knecht (*ibid.* 1917, 36, 694).

o-Nitrotoluene; by nitration of toluene (Glenard and Boudault, Compt. rend. 1844, 19, 505; Hofmann and Muspratt, Ann. 1845, 53, 221; Kekulé, Zeit. f. Chem. 1867 [2] 3, 225; Rosenstiehl, Ann. Chim. 1872, [4] 27, 433); by elimination of the amino-group from 2-nitro-*p*-toluidine and nitrated *m*-toluidine (Beilstein and Kuhlberg, Ann. 1870, 155, 1; 1871, 188, 348). When freshly distilled *o*-nitrotoluene is cooled rapidly to -20°, it solidifies sometimes to the labile α -modification, m.p. -10.56°, and sometimes to the stable β -form, m.p. -4.14°. The latter may also be prepared by cooling the liquid to -50° or -60°, when the α -form separates first, but changes rapidly into the β -form. Superheating of the vapours during distillation also favours the formation of the latter modification (Ostromisslensky, Zeitsch. physikal. Chem. 1907, 57, 341; cf. Walker and Spencer, Chem. Soc. Trans. 1904, 85, 1109). According to Knoevenagel (Ber. 1907, 40, 508) the α -form melts at -9.4° and the β -form at -3.6° (cf. Streng, Ber. 1891, 24, 1987, and Schneider, Zeitsch. physikal. Chem. 1896, 19, 157). It is possible to purify *o*-nitrotoluene by cooling the crude product to temperatures between -4° and -10°, and removing the liquid portion by means of the centrifuge when about half has crystallised (M. L. B., D. R. P. 158219 of 1903; Fr. Pat. 350200 of 1904).

Pure *o*-nitrotoluene is a clear liquid, solidifying at -10.56° (see above), b.p. 218° (Spreng, Ber. 1891, 24, 1987) or 225.7° (corr.) (Perkin, Chem. Soc. Trans. 1896, 69, 1250) or 220.4°/760 mm. (Kahlbaum, Zeitsch. physikal. Chem. 1898, 26, 624); D_4^{15} 1.1742, D_{15}^{15} 1.1643, D_{25}^{25} 1.1572 (Perkin), D_{15}^{15} 1.168 (Spreng). Refractive index, see Brühl (Zeitsch. physikal. Chem. 1895, 16, 218); absorption spectrum, Spreng (Rec. trav. chim. 1897, 16, 1); magnetic rotatory power, Perkin (*loc.*); dielectric constant, Turner (Zeitsch. physikal. Chem. 1901, 35, 421); n_D^{21} 1.5462, $n_D^{21.5}$ 1.5271 (Holleman, Vermeulen and de Mooy, Rec. trav. chim. 1914, 33, 1).

When oxidised with nitric acid or chromic acid in the cold it yields *o*-nitro-benzaldehyde (Lauth, Bull. Soc. chim. 1904, (3) 31, 133), whilst treatment with potassium permanganate or long boiling with alkaline potassium ferricyanide yields *o*-nitrobenzoic acid. The extent to which manganese dioxide and sulphuric acid oxidise *o*-nitrotoluene depends upon the concentration of the acid. When heated in an autoclave with 2 parts of finely powdered manganese dioxide and 10 parts of sulphuric acid (D 1.36-1.38) at 140°-105° for 2-3 hours at a pressure not exceeding 10 atmospheres, the product is chiefly *o*-nitrobenzaldehyde, whilst with sulphuric acid (D 1.68-1.71) at 135°-145° *o*-nitrobenzoic acid is the main product (B. A. S. F., D. R. P. 179559 of 1899).

The former product is also formed when the oxidation is effected by means of cerium dioxide

and sulphuric acid (60-65 p.c.) at 80°-85° (M. L. B., D. R. P. 174238 of 1903). When oxidised electrolytically *o*-nitrotoluene yields chiefly *o*-nitrobenzyl alcohol (Pierron, Bull. Soc. chim. 1901, [3] 25, 852; Fichter and Bonhöte, Helv. Chim. Acta. 1920, 3, 395). When treated with bromine at 170° *o*-nitrotoluene is converted into 3 : 4-dibromo-2-(or 6)-aminobenzoic acid (Wachendorff, Ann. 1877, 185, 281; Greiff, Ber. 1880, 13, 288), but with bromine in the presence of iron 4-bromo-2-nitrotoluene is formed (Gluud, Ber. 1915, 48, 432). It forms a compound with chromyl chloride which on treatment with water regenerates *o*-nitrotoluene and yields a little *o*-nitrobenzaldehyde (Richter, Ber. 1886, 19, 1062). On chlorination it yields *o*-nitrobenzyl chloride, *o*-chlorotoluene, and *o*-chlorobenzyl chloride and other products (Kalle & Co., Eng. Pat. 11260 of 1897; D. R. P. 110010 of 1898).

On long keeping in contact with alcoholic or aqueous potassium hydroxide, anthranilic acid, together with the corresponding azo- and azoxybenzoic acids are formed (Preuss and Binz, Zeit. für angew. Chem. 1900, 14, 385; B. A. S. F., Eng. Pat. 18319 of 1899; Fr. Pat. 292468; D. R. P. 114839 of 1899). With nitrous esters and sodium ethoxide it yields *o*-nitrobenzaldehyde (M. L. B., D. R. P. 107095 of 1898; Fr., Pat. 290643 of 1899). When reduced by heating with iron or zinc and sodium hydroxide at 100°, it yields *o*-azoxytoluene, but when acid is added to the product, toluene-*o*-azobenzoic acid is produced. The sulphonation product of *o*-nitrotoluene differs from that of *p*-nitrotoluene in giving no red colour when boiled with alkalis (Reverdin and de la Harpe, Bull. Soc. chim. 1888, [2] 50, 44).

m-Nitrotoluene; in small quantity by nitration of toluene (cf. Holleman and co-workers under *o*-nitrotoluene; Monnet, Reverdin and Nölting, Ber. 1879, 12, 443; Nölting and Witt, Ber. 1885, 18, 1337); from nitrated *o*- or *p*-toluidine (Beilstein and Kuhlberg, Ann. 1878, 158, 335; Vanino, Präparative Chemie, 1923, vol. ii. p. 451); or from 3-nitro-*p*-toluidine (Buchka, Ber. 1889, 22, 829) by the diazo-reaction. M.p. 16°, b.p. 230°-231° (cf. Neuback, Zeitsch. physikal. Chem. 1887, 1, 658), D_{20}^{20} 1.168, n_D^{20} 1.5470, n_D^{25} 1.5275 (Holleman, Vermeulen and de Mooy, Rec. trav. chim. 1914, 33, 1). It is oxidised readily to *m*-nitrobenzoic acid by chromic acid mixture and slowly by alkaline potassium ferricyanide. When oxidised electrolytically it yields chiefly *m*-nitrobenzaldehyde (Pierron, Bull. Soc. chim. 1901, [3] 25, 852) and, in sulphuric acid solution, 5-amino-*o*-cresol (Gattermann, Ber. 1894, 27, 1930). With bromine at 140° it yields *m*-nitrobenzyl bromide and *m*-nitrobenzylidene bromide (Wachendorff, Ann. 1877, 185, 266; Ber. 1876, 9, 1345). Stannous chloride and aqueous hydrochloric acid reduce it to pure *m*-toluidine, while zinc dust and aqueous hydrochloric acid yield chloro-*m*-toluidine also. *m*-Nitrotoluene is readily reduced by the method of Elbs and Kopp (Zeitsch. Elektrochem. 1898, 5, 108), forming

a yield of 91 p.c.; further it gives *m*-hydrazotoluene (Rohde, *ibid.* 1899, 5, 332). When *m*-nitrotoluene is nitrated with nitric and sulphuric acids at 80°, 3 : 4-dinitrotoluene, together with smaller amounts of 2 : 3- and 2 : 6-dinitrotoluenes, are formed, the separation of the three isomerides being effected

by fractionation *in vacuo* and freezing the distillate (Holleman and Sirks, Proc. K. Akad. Wetensch. Amsterdam, 1906, 9, 280; Sirks, Rec. trav. chim. 1907, 27, 208; cf. Gibson, Duckham and Fairbairn, Chem. Soc. Trans. 1922, 121, 276).

p-Nitrotoluene (see also under *o*-nitrotoluene); by nitration of toluene (Rosenstiehl, Zeitsch. f. Chem. 1869, (2) 5, 190; cf. Jaworsky, *ibid.* 1865, 223); 1 part of toluene is poured into 3-4 parts of nitric acid (D 1.5) and heated to 30°. The yellow oil produced consists chiefly of *p*-nitrotoluene, which crystallises on cooling the fraction boiling above 225°.

Large thick rhombic crystals, m.p. 51.6°-51.9° (Rintoul, J. Soc. Chem. Ind. 1915, 34, 60), 51.4° (Holleman, Vermeulen and de Mooy, Rec. trav. chim. 1914, 33, 1; cf. van der Arend, *ibid.* 1909, 28, 408), or 54° (Schiff, Ann. 1884, 223, 261; Gazz. chim. ital. 1884, 14, 181). The increase in melting-point with increase of pressure has been studied by Puschin (Chem. Soc. Trans. 1924, 125, 2628). B.p. 237.7°/760 mm. (Kahlbaum, Zeitsch. physikal. Chem. 1898, 26, 624); D_{20}^{20} 1.1392, D_{25}^{25} 1.1358 (Perkin, Chem. Soc. Trans. 1896, 69, 1239); magnetic rotatory power at 54.3° 10.17 (Perkin); n_D^{20} 1.5554, n_D^{25} 1.5346 (Holleman, Vermeulen and de Mooy). It is much less volatile with steam than the *o*-nitro-derivative. Chlorine in presence of aluminium chloride or iodine yields *p*-nitrobenzyl chloride and *p*-nitrobenzoic acid (Zimmermann and Müller, Ber. 1885, 18, 996). By the electrolysis of *p*-nitrotoluene in 5-10 parts of sulphuric acid, amino-nitro-*o*-benzyltoluene is obtained (Gattermann, Ber. 1893, 26, 1852; cf. Gattermann and Koppert, *ibid.* 2811). When heated with bromine at 140°, it yields *p*-nitrobenzyl bromide and *p*-nitrobenzylidene bromide (Wachendorff, Ann. 1877, 185, 266). It is oxidised by alkaline potassium ferricyanide to *p*-nitrobenzoic acid (Noyes, Ber. 1883, 16, 52), whilst electrolytic oxidation in acetic-sulphuric acid yields *p*-nitrobenzyl alcohol (Elbs, Zeitsch. Elektrochem. 1896, 2, 522), *p*-nitrobenzaldehyde and *p*-nitrobenzoic acid (Fichter and Bonhöte, Helv. Chim. Acta. 1920, 3, 395). It is reduced by iron and dilute hydrochloric acid to *p*-toluidine, whilst zinc dust and dilute hydrochloric acid yield a chlorinated toluidine. Reduction in alkaline solution yields *p*-azotoluene, and in presence of formaldehyde and hydrochloric acid *p*-dimethyl-toluidine and dimethylene-di-toluidine are produced (Löb, Zeitsch. Elektrochem. 1898, 4, 428). It condenses with ethyl oxalate in presence of sodium ethoxide yielding *p*-nitrophenylpyruvic acid (Reissert, Ber. 1897, 30, 1047).

Zinc dust and sodium hydroxide yield azotoluene, m.p. 144°, two azoxy-compounds, m.p. 75° and 70° respectively, and a hydrazo-compound, m.p. 126° (Janowski and Reimann, Ber. 1889, 22, 40). For the action of sodium and caustic alkalis on *p*-nitrotoluene, see Bender and Schultz (Ber. 1886, 19, 3234), Schmidt (*ibid.* 1899, 32, 2911), Klinger (*ibid.* 1883, 16, 941), Fischer and Hepp (*ibid.* 1893, 26, 2233), Green and collaborators (*ibid.* 1897, 30, 3097; 31, 1078; Chem. Soc. Trans. 1904, 85, 1424, 1429; 1907, 91, 2076; *ibid.* 1908, 93, 1771). By heating with a solution of sulphuric acid in

in sulphuric acid it is converted into *p*-amino-benzaldehyde (Geigy & Co., D. R. P. 86874 of 1895). When treated with amyl nitrite in presence of sodium ethoxide the oxime of *p*-nitrobenzaldehyde is formed (Angeli and Angelico, Atti R. Accad. Lincei. 1900, [5] 8, ii. 32; Gazz. chim. ital. 1900, 31, i, 27; cf. M. L. B., Fr. Pat. 290643 of 1899; D. R. P. 107095 of 1898). For estimation of *p*-nitrotoluene, see Reverdin and de la Harpe (Zeit. f. analyt. Chem. 1890, 29, 215), and for volumetric estimation of *p*-nitrotoluene in crude nitrotoluene, see Glas-mann (Ber. 1903, 36, 4260; J. Russ. Phys. Chem. Soc. 1904, 36, 312).

Normal- ω -nitrotoluene, phenylnitromethane, $C_6H_5CH_2(NO_2)$; together with phthalic anhydride by decomposing a dilute aqueous solution of the disodium derivative of nitrobenzylidene-phthalide with 12 mols. of very dilute acetic acid; by boiling hydroxynitrobenzylidiphenyl-maleide with water (Cohn, Ber. 1891, 24, 3867); from toluene and nitric acid (D. 1.12) by heating for 48 hours at 100° in a sealed tube (Konowalow, Ber. 1895, 28, 1861; J. Russ. Phys. Chem. Soc. 1899, 31, 254); from benzyl chloride (Holleman, Rec. trav. chim. 1894, 13, 405) or benzyl iodide (Hantzsch and Schultze, Ber. 1896, 29, 700) and silver nitrite, or preferably mercurous nitrite (Neogi and Adhichary, Zeitsch. anorg. Chem. 1911, 40, 270); together with other products by the interaction of *iso*-nitromethane and diazo-benzene in alkaline solution (Bamberger, Schmidt and Levinstein, Ber. 1900, 33, 2053); together with phthalic anhydride by dissolving nitroxylyl-idene-phthalide in sodium hydroxide and saturating the solution with oxalic acid (Goldberg, Ber. 1900, 33, 2818), and by other methods (van Raalte, Rec. trav. chim. 1899, 18, 383).

Liquid, which does not solidify in a freezing mixture, b.p. 225°–227°, decomposing into water, nitric oxide and benzaldehyde, or b.p. 158°–160°/35 mm. with slight decomposition (Holleman); D_4^{20} 1.1756, D_4^{30} 1.1598; molecular refractive power 36.61, n_D^{20} 1.53230.

On treatment with zinc dust and dilute sulphuric acid it yields phenylamine. With fuming hydrochloric acid at 150° it is decomposed into hydroxylamine and benzoic acid (Gabriel and Koppe, Ber. 1886, 19, 1145). With alkalis it is converted into the salt of *iso*-phenylnitromethane, from which phenylnitromethane is obtained by treatment with carbon dioxide, or *iso*-phenylnitromethane by treatment with cold dilute hydrochloric acid. It is unaffected by phenyl *iso*-cyanate (Hantzsch and Schultze, Ber. 1896, 29, 2254). Its *o*-, *m*-, and *p*-nitro-derivatives melt at 72°, 94°, and 90° respectively (Holleman, Rec. trav. chim. 1896, 15, 356, 365; *ibid.* 1895, 14, 123; Hantzsch and Veit, Ber. 1899, 32, 621).

Phenyl-iso-nitromethane, $C_6H_5CH(OH)NO$; by the action of dilute hydrochloric acid on the potassium salt of phenylnitromethane (Hantzsch and Schultze, Ber. 1896, 29, 700); together with other products by oxidising benzaldoxime with Caro's acid (Bamberger, Ber. 1900, 33, 1781). It crystallises from a mixture of absolute ether and ligroin and melts at 84° when heated quickly (Hantzsch, Ber. 1896, 29, 2251). It is readily soluble in soda solution, and in contrast

to the indifferent phenylnitromethane, when treated with ammonia in presence of water-free solvents it yields the ammonium salt. It also readily reacts with phenyl *iso*-cyanate and phosphorus pentachloride (Hantzsch and Veit, Ber. 1899, 32, 620). On warming with ether or alcohol, or on keeping with hydrochloric acid, it is converted into the normal phenylnitromethane. On reduction with sodium amalgam or zinc dust in alkaline solution it yields benzaldoxime. When the sodium salt is treated with acetyl chloride acetylbenzhydroxamic acid is formed (van Raalte, *ibid.* 1899, 18, 383). When treated with benzoyl chloride, dibenzhydroxamic acid, m.p. 161°, is produced, and with *p*-nitrobenzoyl chloride it yields bis-*p*-nitrobenzoylbenzhydroxamic acid and *p*-nitrobenzoylbenzhydroxamic acid (Holleman, Rec. trav. chim. 1896, 15, 356, 365), whilst its sodium salt on treatment in aqueous solution with hydrochloric acid yields benzhydroxamic acid (Bamberger and Rust, Ber. 1902, 35, 45).

ω -Dinitrotoluene, phenyldinitromethane, large white prisms, m.p. 79° (Ponzio, Gazz. chim. ital. 1901, 31, 133; 1908, 38, 417; Ponzio and Charrier, Atti R. Accad. Sci. Torino, 1908, 43, 475).

DINITROTOLUENES.

Commercial dinitrotoluene is chiefly a mixture of the α -, β -, and γ -dinitrotoluenes, and forms a cake of yellow crystals, m.p. 66°–68°, b.p. about 300° (partial decomp.). The 2:4-dinitro-compound is present in the greatest proportion in the dinitrotoluene used in the explosive industry.

2:3-Dinitrotoluene; by heating 2:3-dinitro-*p*-toluic acid with 5 p.c. hydrochloric acid for 6 hours at 265° (Rozánski, Ber. 1889, 22, 2681); from 3-nitro-*o*-toluidine by replacing the amino-group by a nitro-group (Grell, Ber. 1895, 28, 2565). It is best obtained by nitrating aceto-*o*-toluidide with nitric acid in presence of acetic acid and treating the mixture of 3- and 5-nitro-aceto-*o*-toluidides with hydrochloric acid, the separation of the isomeric amines being accomplished by diluting the acid solution largely with water when the very feebly basic 3-nitro-*o*-toluidine is precipitated. The latter is converted into 3-nitro-2-nitrosotoluene, which is then transformed into 2:3-dinitrotoluene (Meisenheimer and Hesse, Ber. 1919, 52, 1161); also from 5:6-dinitro-*m*-toluidine by the diazo-reaction (Brady, Day and Rolt, Chem. Soc. Trans. 1922, 121, 531). M.p. 61° (M. and H.) or 63° (Rozánski).

(a) 2:4-Dinitrotoluene; by nitration of toluene (Deville, Ann. 1842, 44, 307; Cahours, Compt. rend. 1847, 24, 555; Noetting and Witt, Ber. 1885, 18, 1336; Beilstein and Kuhlberg, Ann. 1870, 155, 13; Limpricht, Ber. 1885, 18, 1402), and of *o*- and *p*-nitrotoluene; by boiling 2:4-toluylenediamine with sodium peroxide solution (O. Fischer and Trost, Ber. 1893, 26, 3085); from dinitrotoluidine by elimination of the amino-group (Staedel, Ann. 1898, 259, 220). Long monoclinic needles, m.p. 70.5° (Deville), or 69.21°–69.57° (Milla, Phil. Mag. 1882, [5] 14, 27), or 69.9°–70.2° (Rintoul, J. Soc. Chem. Ind. 1915, 34, 160). When treated for a long time with fuming nitric acid it yields 2:4-dinitrobenzoic acid. Partial reduction with ammonium sulphide in the cold yields 2-nitro-*p*-toluidine, whilst

at higher temperatures 4-nitro-*o*-toluidine is also formed (Graeff, Ann. 1885, 229, 343; Limpricht, Ber. 1885, 18, 1400). Alcoholic stannous chloride, on the other hand, yields 4-nitro-*o*-toluidine (Anschütz and Heussler, Ber. 1886, 19, 2161). When reduced completely it yields *m*-toluylenediamine (Baeyer, Ber. 1874, 7, 1638). On electrolytic oxidation it yields 2:4-dinitrobenzoic acid (Sachs and Kempf, Ber. 1902, 35, 2704). It does not react with chromium oxychloride (Richter, Ber. 1886, 19, 1062). It condenses with benzaldehyde in presence of piperidine to form stilbene derivatives (Thiele and Escales, Ber. 1901, 34, 2842); with dimethylaminobenzaldehyde to form 2':4'-dinitro-4-dimethylaminostilbene (Sachs and Steinert, Ber. 1904, 37, 1733); with nitrosodimethylamine in presence of sodium carbonate to form 2:4-dinitrobenzaldehyde-*p*-dimethylaminoanil (Sachs and Kempf, *ibid.* 1902, 35, 1224).

(B) 2:5-Dinitrotoluene; from 5-nitro-*o*-toluidine by the diazo-reaction (Grell, Ber. 1895, 28, 2565); by the action of nitrogen peroxide on toluquinonediimine in ethereal solution (Oliveri and Tortorici, Gazz. chim. ital. 1900, 30, i, 534); by treating '*p*-dinitrosotoluene' with cold fuming nitric acid (Nietzki and Guitermann, Ber. 1888, 21, 433); readily from 5-nitro-2-nitrosotoluene by oxidation with nitric acid (Meisenheimer and Hesse, Ber. 1919, 52, 1161); by heating 2:5-dinitro-*p*-toluic acid with 3 parts of 5 p.c. hydrochloric acid for 6 hours at 250° (Rozanski, Ber. 1889, 22, 2679). It appears to occur also among the products of the nitration of toluene (Limpricht, Ber. 1885, 18, 1402).

Needles or large wedge-shaped crystals, m.p. 50°-51° (Meisenheimer and Hesse), 52-5° (Rozanski) or 48° (Nietzki and Guitermann). It is reduced by alcoholic ammonium sulphide to 6-nitro-*m*-toluidine (Limpricht). On reduction with stannous chloride in presence of alcoholic hydrochloric acid it yields a mixture (m.p. 97°) of monoamines, consisting of 62 p.c. of 5-nitro-*o*-toluidine and 38 p.c. of 6-nitro-*m*-toluidine, a little 2:5-diaminotoluene being formed also (Burton and Kenner, Chem. Soc. Trans. 1921, 119, 1053).

2:6-Dinitrotoluene; from 2:6-dinitro-*p*-toluidine by the diazo-reaction (Staedel, Ann. 1883, 217, 206; Rosenstiehl, Ann. Chim. 1872, [4] 27, 470; Cunerth, Ann. 1874, 172, 222; Claus and Becker, Ber. 1883, 16, 1597; Holleman and Boeseken, Rec. trav. chim. 1897, 16, 427); together with other products during the manufacture of trinitrotoluene (Molinari and Giua, Zeit. ges. Schiess. Sprengstoffw. 1914, 9, 239; cf. Haeussermann and Grell, Ber. 1894, 27, 2209). Glistening needles, m.p. 60°-61° (Staedel), or 65-6° (H. and G.). On reduction with sulphuretted hydrogen in alcoholic ammonia a mixture, m.p. 66°, of 6-nitro-2-amino-*m*-cresol and 6-nitro-*o*-toluidine is formed, the former being produced by the action of the boiling hydrochloric acid (used to extract the amine) on the intermediate 6-nitro-*o*-tolylhydroxylamine (Cohen and Marshall, Chem. Soc. Trans. 1904, 85, 527). It condenses with dimethylaminobenzaldehyde to form a condensation product, bluish-violet lles (Sachs and Steinert, Ber. 1904, 37, 1745).

(γ) 3:4-Dinitrotoluene; together with 2:3-, 1:5-, and 3:6-dinitrotoluene by nitration of

m-nitrotoluene, and is readily separated from the mixture by fractional distillation *in vacuo* and freezing the distillate (Beilstein and Kuhlberg, Ann. 1870, 155, 25; Haeussermann and Grell, Ber. 1894, 27, 2209; Holleman and Sirks, Proc. K. Akad. Wetensch. Amsterdam, 1906, 9, 280; Sirks, Rec. trav. chim. 1907, 27, 208); from 3:4- or 4:5-dinitro-*o*-toluidine by elimination of the amino-group (Brady and Williams, Chem. Soc. Trans. 1920, 117, 1139); from 5:6-dinitro-*m*-toluidine in a similar manner (Brady, Day and Rolt, *ibid.* 1922, 121, 531); from 3-nitro-*p*-toluidine by the diazo-reaction (Haeussermann and Grell, *l.c.*); conveniently by oxidising 3-nitro-*p*-toluidine by Caro's acid to 3-nitro-4-nitrosotoluene and completing the oxidation of the latter with nitric acid (Meisenheimer and Hesse, Ber. 1919, 52, 1161). Long needles, m.p. 59°-60° (M. and H.), or 61° (H. and G.). On reduction with stannous chloride in presence of absolute alcoholic hydrochloric acid, it yields a eutectic mixture (m.p. 70°) of 4-nitro-*m*-toluidine and 3-nitro-*p*-toluidine together with a little diamine (Burton and Kenner, Chem. Soc. Trans. 1921, 119, 1053).

3:5-Dinitrotoluene; from 3:5-dinitro-*o*- or *p*-toluidine by elimination of the amino-group (Staedel, Ann. 1883, 217, 189; Ber. 1881, 14, 909; Hübner, Ann. 1884, 222, 74; Nevile and Winther, Ber. 1882, 15, 2984; Chem. Soc. Trans. 1882, 41, 416; Hönig, Ber. 1887, 20, 2418; Cohen and McCandlish, Chem. Soc. Trans. 1905, 87, 1270; Brady, Day and Rolt, *ibid.* 1922, 121, 528). It is best prepared by adding aceto-*p*-toluidide slowly to 8 times its weight of nitric acid (D. 1.79) below 0°, purifying the dinitro-derivative by extracting with hot benzene, hydrolysing with concentrated sulphuric acid (below 90°), diazotising the resulting base at -10° in concentrated sulphuric acid in presence of alcohol, warming and purifying the dinitrotoluene by extraction with alcohol (Kreman, Hönigsberg and Mauermann, Monatsch. 1923, 44, 65). Monoclinic needles or prisms readily volatile with steam, m.p. 92°-93°.

TRINITROTOLUENE.

The following method gives satisfactory results for the preparation of trinitrotoluene from toluene of about 99 p.c. purity. 50 grms. of toluene are added gradually with constant stirring to a mixture of 73.4 grms. of nitric acid (D. 1.42), and 146.8 grms. of sulphuric acid (D. 1.84), the temperature not being allowed to rise above 30°. The reaction is allowed to continue for half an hour after the addition of the toluene, and, after keeping, the spent acid is drawn off. The crude product (80-83 grms., consisting of about 60 p.c. of mono- and 40 p.c. of dinitrotoluene) is dissolved in 109.2 grms. of sulphuric acid (D. 1.84), the solution is heated to 50°, and a mixture of 54.6 grms. each of nitric acid (D. 1.5) and sulphuric acid (D. 1.84) is added gradually during a period of at least 1 hour, the temperature not exceeding 100°. The mixture is then heated for 2 hours at 90°-100°, after which it is cooled to 90°, and 145.6 grms. of oleum (15 p.c.) are added slowly followed by a mixture of 72.8 grms. each of oleum (15 p.c.) and nitric acid (D. 1.5). The addition of the acid takes 2 hours, and the temperature is not allowed

to exceed 115°. The mixture is then heated at 90°–117° for 2 hours. After keeping for at least 8 hours, the spent acid is drawn off, and the crude trinitrotoluene crushed and washed first with cold water and then several times in the molten state with hot water. A yield of 75 p.c. is obtained and the product melts at 78°–80°, a further yield of 8.5 p.c. (m.p. 69°–75°) can be recovered from the spent acid. If the product be purified by crystallising from, or washed with, a mixture of 9 volumes of 95 p.c. alcohol and 1 volume of benzene the yield is 69 p.c. (m.p. 79°–81°) and 7.5 p.c. (m.p. 78°–81°) (Hoffman, U.S. Bureau of Mines, Met. and Chem. Eng. 1916, 14, 467; cf. Humphrey, J. Ind. Eng. Chem. 1916, 8, 998; Langenscheidt, Z. ges., Schiess. u. Sprengstoffw. 1912, 7, 425). For the manufacture of TNT (trinitrotoluene) and its intermediate products, see Technical Methods of Explosives Supply, 1915–1918, No. 2, Ministry of Munitions and Department of Scientific and Industrial Research. An account of the minimum amount of water required to precipitate trinitrotoluene from its acid mother liquor is given by McHutchison and Wright (J. Soc. Chem. Ind. 1915, 34, 781).

For freezing-point solubility diagram of TNT and picric acid, see Taylor and Rinkenbach (J. Ind. Eng. Chem. 1923, 15, 795).

The specific heats of trinitrotoluene, tetryl and picric acid have been determined by Taylor and Rinkenbach (J. Amer. Chem. Soc. 1924, 46, 1504).

For quantitative experiments on the trinitration of toluene, see Gibson, Duckham and Fairbairn (Chem. Soc. Trans. 1922, 121, 282).

A review of the preparation of the six isomeric trinitrotoluenes up to date is given by Brunswig (Zeitsch. angew. Chem. 1923, 36, 75).

(a) 2:4:6-Trinitrotoluene; by prolonged boiling of toluene with nitric and sulphuric acids (Wilbrand, Ann. 1863, 128, 178) or from α - or β -dinitrotoluene in a similar manner; by treating 1 part of 2:4-dinitrotoluene dissolved in 4 parts of sulphuric acid (95–96 p.c. H_2SO_4) with 1½ parts of nitric acid (90–92 p.c. HNO_3), the mixture being heated gradually to 90°–95° with agitation for about 4–5 hours (Haeussermann, Zeitsch. angew. Chem. 1891, 5, 661); by boiling trinitrophenylacetic acid with water or alcohol (Jackson and Phinney, Ber. 1895, 28, 3067; Amer. Chem. J. 1899, 21, 431).

Pseudo-rhombic crystals, belonging to the prismatic class of the monoclinic system (Artini, Atti R. Accad. Lincei, 1915, [v.] 24, ii. 274; cf. Friedländer, Zeitsch. Kryst. Min. 1879, 3, 168), m.p. 80.52° (Mills, Phil. Mag. 1882, [5] 14, 27), 80.5° (Brunswig, Zeitsch. angew. Chem. 1923, 36, 75), 80.6° (Will, Ber. 1914, 47, 704), or 80.8°–80.85° (Rintoul, J. Soc. Chem. Ind. 1915, 34, 60). Electrical conductivity in liquid ammonia (Franklin and Kraus, Amer. Chem. J. 1900, 23, 294); cryoscopic behaviour (Bruni and Berti, Atti R. Accad. Lincei. 1900, [v.] 9, i. 274; Gazz. chim. ital. 1900, 30, 76); behaviour with methyl alcohol, &c. (Hantzsch and Kissel, Ber. 1899, 32, 3140); solubility in organic solvents (Taylor and Rinkenbach, J. Amer. Chem. Soc. 1923, 45, 44). It forms additive compounds with hydrocarbons and with aniline (Hepp, Ann. 1882, 215, 365). On reduction with alcoholic ammonium sulphide it yields 2:6-dinitro-*p*-

toluidine (Tiemann, Ber. 1869, 3, 218), whilst in hydrochloric acid solution in presence of cupric chloride it is reduced at a copper cathode to 2:6-dinitro-*p*-toluidine and 4:6-dinitro-*o*-toluidine (Brand and Eisenmenger, J. pr. Chem. 1913, ii. 87, 487). On oxidation with nitric acid at 180° it yields 1:3:5-trinitrobenzene with evolution of carbon dioxide (Claus and Becker, Ber. 1883, 16, 1597). With acetone and ammonia it gives a deep red coloration, and is not so sensitive to alkalis as the β - and γ -compounds. In alkaline alcoholic solutions it forms coloured salts which, under the simultaneous action of oxidising agents, yield a hexanitrodiphenylethane (m.p. 212°) (Will, l.c.; Giua, Atti R. Accad. Lincei. 1914, [v.] 23, ii. 484; Gazz. chim. ital. 1915, 45, 345). When exposed to light 2:4:6-trinitrotoluene forms two substances of the formula $C_7H_5O_6N_3$ (Schultz and Ganguly, Ber. 1925, 58, 702; see also Wichert and Donat, Zeitsch. ges. Schiess-Sprengstoffw. 1925, 20, 69).

2:4:6-Trinitrotoluene condenses with diazomethane (Heinke, Ber. 1894, 31, 1399); with nitroso-dimethylaniline to form the compound $C_6H_2(NO)_3 \cdot CH \cdot N \cdot C_6H_4 \cdot N(CH_3)_2$ (Sachs and Everding, Ber. 1903, 36, 959); it combines with dimethylaminobenzaldehyde (Sachs and Steinert, *ibid.* 1904, 37, 1733); and with α - and β -naphthylamine it yields compounds which melt at 113.5° and 141.5° respectively (Sudborough, Chem. Soc. Trans. 1901, 79, 522).

(β) 2:3:4-Trinitrotoluene; together with 3:4:6-trinitrotoluene by nitration of *m*-nitrotoluene (Hepp, Ann. 1882, 215, 366); by nitration of 2:3-dinitrotoluene, and to the extent of 17 parts together with 83 parts of 3:4:6-trinitrotoluene by the nitration of 3:4-dinitrotoluene (Brady; see also Gibson, Duckham and Fairbairn, Chem. Soc. Trans. 1922, 121, 282); by oxidation of 2:3-dinitro-*p*-toluidine in 80 p.c. sulphuric acid with Caro's acid, followed by treatment of the nitroso-derivative with nitric acid (Scott and Robinson, Chem. Soc. Trans. 1922, 121, 846); from 3:4-dinitro-*o*-toluidine in a similar manner (Brady and Williams, *ibid.* 1920, 117, 1140). Slender leaflets or flaky needles from alcohol or thick trimetric plates from acetone, m.p. 112°. On oxidation with chromic acid mixture it yields 2:3:4-trinitrobenzoic acid, m.p. 202° (Giua; Hepp; Brunswig). With acetone and ammonia it yields a greenish-yellow coloration (Will; Giua).

2:3:4-Trinitrotoluene when boiled with hydrazine hydrate in alcoholic solution yields 4-nitro-1-hydroxy-5 (or 7)-methyl-1:2:3-benzotriazole, pale yellow hexagonal prisms + H_2O , m.p. 205° (decomp.) when anhydrous. On methylation this forms exclusively the *O*-ether, brownish-yellow needles, m.p. 152°, and on acetylation an acetyl-derivative, colourless monoclinic prisms, m.p. 182° (decomp.), is formed (Brady and Bowman, Chem. Soc. Trans. 1921, 119, 894; Brady and Day, *ibid.* 1923, 123, 2258). Converted by aqueous sodium sulphite into sodium 2:4-dinitrotoluene 3-sulphonate (Brady, Hewetson and Klein, Chem. Soc. Trans. 1924, 125, 2400).

(γ) 3:4:6-Trinitrotoluene; (see above); in a yield of 80 p.c. by adding a solution of 2 grms. of 4:5-dinitro-*o*-toluidine in 10 c.c. of 80 p.c.

sulphuric acid to Caro's acid, prepared from 10 grms. of ammonium persulphate and 7 c.c. of concentrated sulphuric acid, and pouring on to 20 grms. of crushed ice. On keeping over night and on further dilution the dinitro-nitrosotoluene separates and is oxidised by warming with 10 times its weight of nitric acid (D 1.5) (Brady and Williams, Chem. Soc. Trans. 1920, 117, 1139); from 2:5-dinitro-*p*-toluidine in a similar manner (Scott and Robinson, *ibid.* 1922, 121, 845). Yellowish rhombohedral crystals from alcohol or rhombic plates from acetone, m.p. 104°. With alcoholic ammonia it yields 4:6-dinitro-*m*-toluidine, and with aniline, phenyl-dinitrotoluidine. With aqueous sodium sulphite it yields sodium 4:6-dinitrotoluene 3-sulphonate (Brady, Hewetson and Klein, *l.c.*). On oxidation with chromic acid mixture it yields 3:4:6-trinitrobenzoic acid, laminae, m.p. 190°–191° (decomp.) (Hepp; Giua). For the action of alkalis, aldehydes, and amines on α -, β -, and γ -trinitrotoluenes, see O'Riordan (Proc. Roy. Irish Acad. 1918, 34, 175). β - and γ -Trinitrotoluene react even with 1 p.c. sodium carbonate solution or lead oxide and alcohol with the formation of dinitrotolyl oxides. In all three cases the salts are very explosive. With acetone and ammonia it yields a blue coloration (Will, Ber. 1914, 47, 704; Giua, Atti R. Accad. Lincei, 1914, [v.] 23, ii. 484; Gazz. chim. ital. 1915, 5, 345).

3:4:6-Trinitrotoluene when treated in boiling alcoholic solution with an excess of hydrazine hydrate yields 6-nitro-1-hydroxy-5-methyl-1:2:3-benzotriazole, yellow prisms, i.p. 194° (decomp.). The latter compound on methylation yields a mixture of the *O*-methyl ether, long, pale canary-yellow needles, m.p. 35°, and the *N*-methyl ether, canary-yellow aethery tufts, m.p. 265° (decomp.), and on acetylation an acetyl derivative, faintly pink monoclinic needles, m.p. 166° (decomp.), is formed (Brady and Day, Chem. Soc. Trans. 1923, 123, 2258; cf. Brady and Bowman, *ibid.* 1921, 119, 894).

(ξ) 2:3:5-Trinitrotoluene; from 3:5-dinitro-*o*-toluidine. Large, slightly yellow prisms, belonging to the bi-pyramidal class of the rhombic system. It melts at 97° (Brunswick, Zeitsch. angew. Chem. 1923, 36, 75). It dissolves in acetone containing a few drops of ammonia giving a rose-red coloured solution, which changes to red, then brown, and finally black. With chromic acid it yields 2:3:5-trinitrobenzoic acid, m.p. 82° (+2H₂O) or 171° (anhydrous) (Körner and Contardi, Atti R. Accad. Lincei, 1915, [v.] 24, i. 888). With aqueous sodium sulphite it yields sodium 3:5-dinitrotoluene 2-sulphonate (Brady, Hewetson and Klein, *l.c.*).

2:3:5-Trinitrotoluene when boiled with hydrazine hydrate in alcoholic solution forms nitro-1-hydroxy-4-methyl-1:2:3-benzotriazole, pale yellow prisms, m.p. 225° (decomp.). The latter on methylation yields a mixture of *O*-ether, needles, m.p. 137°, and the *N*-ether, low needles, m.p. 220° (decomp.), and on acetylation an acetyl-derivative, almost colourless cubic crystals, m.p. 142°, is formed (Brady and Day, Chem. Soc. Trans. 1923, 123, 2258; Brady and Bowman, *ibid.* 1921, 119, 894).

(ϵ) 2:3:6-Trinitrotoluene; by direct nitra-

tion of toluene (Drew, Chem. Soc. Trans. 1920, 117, 1615); together with 2:3:4- and 3:4:6-trinitrotoluene by nitration of *m*-nitrotoluene (Marqueyrol, Koehler and Jovinet, Bull. Soc. chim. 1920, [v.] 27, 420; Drew, *l.c.*; Brady, Chem. Soc. Trans. 1922, 121, 328); in a yield of 15 p.c. together with other products by nitration of 2:3- and 2:5-dinitrotoluene (Drew); from 2:4:6-trinitrotoluene by reduction, bromination, elimination of the amino-group, and replacement of the bromine atom by an amino-group, followed by conversion of the 2:6-dinitro-*m*-toluidine into 2:3:6-trinitrotoluene via the diazo-nitrate (Körner and Contardi, Atti R. Accad. Lincei, 1916, [v.] 25, ii. 339); from 3:6- or 5:6-dinitro-*o*-toluidine by treatment with Caro's acid and oxidation of the dinitro-nitroso-toluene produced (Brady and Taylor, Chem. Soc. Trans. 1920, 117, 876); from 2:6-dinitro-*m*-cresol (Drew).

Molinari and Giua (Zeitsch. ges. Schiess-Sprengstoffw. 1914, 9, 239) obtained in the manufacture of trinitrotoluene a compound, m.p. 79.5°, which they stated might be 2:3:6-trinitrotoluene, together with 3- and 4-nitrotoluene, 2:4-, 2:5-, 2:6-, 3:4-dinitrotoluenes, and 2:4:6-trinitrotoluene. Brady and Taylor, however, showed that this compound was probably a mixture of 2:3:4- and 3:4:6-trinitrotoluenes.

The formation of 2:3:6-trinitrotoluene by the direct nitration of toluene has been questioned by Giua (Gazz. chim. ital. 1921, 51, ii. 113), but Drew's contention that 2:3:4-, 2:4:5-, and 2:3:6-trinitrotoluene are formed by the nitration of *m*-nitrotoluene is further supported by Brady (*l.c.*).

Shining white needles belonging to the prismatic class of the monoclinic system, m.p. 111°. By treatment with alcoholic ammonia in a sealed tube at 110°–120° it yields 3:6-dinitro-*o*-toluidine, m.p. 151°, and a complex mixture of substances, m.p. 128°. It yields 2:3:6-trinitrobenzoic acid, m.p. 55° (+2H₂O) or 160° (anhydrous), on oxidation with chromic acid (Körner and Contardi; cf. Brunswick, *l.c.*).

(δ) 3:4:5-Trinitrotoluene; from 3:5-dinitro-*p*-toluidine. Greenish-yellow transparent prisms or plates, belonging to the prismatic class of the monoclinic system, m.p. 137.5°. With chromic acid it yields 3:4:5-trinitrobenzoic acid (Körner and Contardi, Atti R. Accad. Lincei, 1914, [v.] 23, ii. 464; 1915, [v.] 24, i. 888; cf. Brunswick, Zeitsch. angew. Chem. 1923, 36, 75). With aqueous sodium sulphite it forms sodium 3:5-dinitrotoluene 4-sulphonate (Brady, Hewetson and Klein, Chem. Soc. Trans. 1924, 125, 2400).

3:4:5-Trinitrotoluene when boiled with hydrazine hydrate in alcoholic solution yields 4-nitro-1-hydroxy-6-methyl-1:2:3-benzotriazole, yellow needles, m.p. 241° (decomp.), the monohydrate of which, deep orange prisms, loses water at 90°–95°. The triazole on methylation yields exclusively the *O*-ether, yellow plates, m.p. 183°, and on acetylation an acetyl-derivative, colourless prismatic crystals, m.p. 210° (decomp.), is formed (Brady and Day, Chem. Soc. Trans. 1923, 123, 2258; cf. Brady and Bowman, *ibid.* 1921, 119, 894).

Up to the present, the formation of higher nitro-derivatives by the nitration of toluene has

failed, for if the reaction is promoted by heat or pressure either trinitrobenzoic acid or even tetranitromethane is obtained, whilst 3:5-dinitrotoluene could not be nitrated to yield any trinitro-derivative (Will, Ber. 1914, 47, 704).

o-Nitrobenzyl chloride; together with the *p*-isomeride by nitration of benzyl chloride (Noelting, Ber. 1884, 17, 385; Kumpf, Ann. 1884, 224, 100; Ber. 1884, 17, 1073; cf. Beilstein and Geitner, Ann. 1866, 139, 337); from *o*-nitrobenzyl alcohol and phosphorus pentachloride (Geigy and Königs, Ber. 1885, 18, 2401; Gabriel and Borgmann, Ber. 1883, 16, 2066); by the action of chlorine on a mixture of *o*-nitrotoluene and sulphur at 130°–140° (Haeussermann and Beck, Ber. 1892, 25, 2445). Calcspar-like crystals, m.p. 47.9°; $n_D^{25} 1.5557$ (Holleman, Vermeulen and de Mooy, Rec. trav. chim. 1914, 33, 1). With potassium iodide it yields *o*-nitrobenzyl iodide. With stannous chloride and hydrochloric acid it is reduced to *o*-benzylene-imide (Lellmann and Stickel, Ber. 1886, 19, 1604; Thiele and Weil, Ber. 1895, 28, 1650), whilst on reduction with stannous chloride in presence of alcoholic hydrochloric acid *o*-aminobenzyl ethyl ether is obtained: By reduction with excess of stannous chloride in aqueous or ethereal solution in presence of hydrogen chloride, followed by treatment with hydrogen sulphide, *o*-diaminobenzyl sulphide is produced (Thiele and Dimroth, Ann. 1899, 305, 112, 122; Ber. 1895, 28, 914). With aluminium chloride in presence of benzene it yields *o*-nitrodiphenylmethane and other products (Freund, Monatsh. 1896, 17, 395). When reduced with sodium in methyl alcoholic solution *o*-nitrobenzyl chloride yields *o*-nitrobenzyl methyl ether (Thiele and Dimroth).

m-Nitrobenzyl chloride; from *m*-nitrobenzyl alcohol and phosphorus pentachloride (Gabriel and Borgmann, Ber. 1883, 16, 2064); together with *o*- and *p*-nitrobenzyl chloride by treating benzyl chloride in the cold with nitric acid (D 1.5) (Abelli, Gazz. chim. ital. 1883, 13, 98; Kumpf, l.c.). Yellow needles, volatile with steam, m.p. 44.8°, $n_D^{25} 1.5577$ (Holleman, Vermeulen and de Mooy, Rec. trav. chim. 1914, 33, 1). When treated with sodium sulphite it yields the sodium salt of *m*-nitrobenzyl sulphonic acid (Purgotti and Monti, Gazz. chim. ital. 1900, 30, ii, 246).

p-Nitrobenzyl chloride; by nitration of benzyl chloride (Beilstein and Geitner, Ann. 1866, 139, 337; Strakosch, Ber. 1873, 6, 1056); by the action of 1 mol. of chlorine on *p*-nitrotoluene at 185°–190° (Wachendorff, Ann. 1877, 185, 271). Needles, m.p. 72.4°, $n_D^{25} 1.5647$ (Holleman, Vermeulen and de Mooy, l.c.). Chlorine at 190°–190° is without any action. It is oxidised by alkaline pyrogallol to *p*-nitrotoluene (Pellizzari, Gazz. chim. ital. 1884, 14, 481). For its reduction with stannous chloride under various conditions, see Thiele and Dimroth (l.c.); Roser, (Ann. 1887, 238, 364). With zinc and hydrochloric acid it is reduced to *p*-toluidine (Rudolph, D.R.P. 34234 of 1885). With sodium acetoxime in warm alcohol it yields *p*:*p*-dinitrostilbene (Schröter and Peschkes, Ber. 1900, 33, 1981). It forms colouring matters with primary, secondary, and tertiary amines, as well as with phenols in the presence of oxidising agents

(Greiff, D. R. P. 15120 of 1881; Lembach and Schleicher, D. R. P. 14945 of 1880).

2:4:6-Trinitrobenzyl chloride; m.p. 85° (Ganguly, Ber. 1925, 59, 708).

2:3:4-Trichloro-6-nitro-benzyl chloride. Needles, m.p. 122° (Ganguly, l.c.).

o-Nitrobenzylidene chloride; in a yield of 23.3 p.c. by nitration of benzylidene chloride. M.p. 25.7° (Holleman, Vermeulen and de Mooy, Rec. trav. chim. 1914, 33, 1; cf. Kliegel, Ber. 1907, 40, 4937).

m-Nitrobenzylidene chloride; m.p. 64.5°. Yield 33.8 p.c. (Holleman, &c.).

p-Nitrobenzylidene chloride; m.p. 42.8°. Yield 42.9 p.c. (Holleman, &c.).

CHLORONITROTOLUENES.

The nitration of *o*-chlorotoluene leads to formation of all the possible chloromononit derivatives, 2:3-, 2:4-, 2:5-, and 2:6-, although the 2:4-isomeride is difficult to detect. Using 10 grms. of *o*-chlorotoluene and nitrating with 40 grms. of nitric acid (D 1.52) at 0°, the percentage yields of the products in the above order are 19.2, 17.0, 43.3, and 20.5 respectively. In the case of *m*-chlorotoluene the 3:6-, 3:5-, 3:4-, and 3:2-chloromononitrotoluenes are obtained in a yield of 58.9 p.c., very little, 32.3 p.c. and 8.8 p.c. respectively (Holleman and Wibaut, Proc. K. Akad. Wetensch. Amsterdam, 1912, 15, 594). The nitration of *o*-chlorotoluene with nitric and sulphuric acids primarily at 8°–10°, and finally at the temperature of the water-bath, leads to the formation of four isomeric dinitro-derivatives in the following proportions: 2-chloro-3:5-dinitrotoluene, 55–60 p.c.; 2-chloro-5:6-dinitrotoluene, 18–20 p.c.; 2-chloro-4:5-dinitrotoluene, 18–20 p.c.; 2-chloro-4:6-dinitrotoluene, 1–2 p.c. (Morgan and Drew, Chem. Soc. Trans. 1921, 117, 793).

2-Chloro-3-nitrotoluene; from 3-nitro-*o*-toluidine by the diazo-reaction (Wynne and Greeves, Chem. Soc. Proc. 1895, 11, 151; cf. Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1127). M.p. 21° (Holleman, Rec. trav. chim. 1908, 27, 455), $n_D^{20} 1.5327$ (Wibaut, *ibid.* 1913, 32, 244).

2-Chloro-4-nitrotoluene; from *p*-nitrotoluene and phosphorus pentachloride (Lellmann, Ber. 1884, 17, 534) or antimony pentachloride (Wachendorff, Ann. 1877, 185, 273); in a yield of 95 p.c. by chlorination of *p*-nitrotoluene at 65°–75° in presence of antimony trichloride (Davies, Chem. Soc. Trans. 1921, 119, 868; 1922, 121, 809); from 4-nitro-*o*-toluidine (Green and Lawson, *ibid.* 1891, 59, 1017), or 6-chloro-4-nitro-*m*-toluidine (Morgan and Drew, *ibid.* 1920, 117, 789), or 2-chloro-4-nitro-*m*-toluidine (Morgan and Glover, *ibid.* 1921, 119, 1704) by the diazo-reaction. Long white pointed needles, m.p. 68° (Green and Lawson), or m.p. 62.3°, $n_D^{20} 1.5470$ (Wibaut, Rec. trav. chim. 1913, 32, 244), b.p. 257°–260°/756 mm. (Davies, l.c.). Volatile with steam and develops an intense red coloration with hot alcoholic sodium hydroxide.

2-Chloro-5-nitrotoluene; by nitration of *o*-chlorotoluene; from 5-nitro-*o*-toluidine (Goldschmidt and Hönig, Ber. 1886, 19, 2439; 1887, 20, 199), or 2-chloro-5-nitro-*p*-toluidine (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1334); together with 4-chloro-7-nitroindazole from

6-chloro-3-nitro-*o*-toluidine (Morgan and Drew, *ibid.* 1920, 117, 787) by the diazo-reaction. Yellowish pyramids, m.p. 44°, b.p. 248°/711 mm. (G. and H.), or m.p. 42-43°, n_D^{20} 1.5511 (Wibaut, *Rec. trav. chim.* 1913, 32, 244).

2-Chloro-6-nitrotoluene; from 6-nitro-*o*-toluidine (Green and Lawson, *l.c.*; Morgan and Drew, *Chem. Soc. Trans.* 1920, 117, 787) by the diazo-reaction; by the reduction of 2:6-dinitrotoluene by means of hydrogen sulphide in ammoniacal solution followed by the diazo-reaction (Wibaut, *Rec. trav. chim.* 1913, 32, 244); together with considerable amounts of 4-chloro-2-nitrotoluene by chlorination of *o*-nitrotoluene (Cohn, *Monatsh.* 1901, 22, 471; cf. Janson, D. R. P. 107505 of 1898). Needles, m.p. 35-37°, n_D^{20} 1.5377 (Wibaut), or m.p. 37° (Green and Lawson), b.p. 236°-238° (Janson). Readily volatile with steam. On reduction with zinc dust and sodium hydroxide it yields 6-chloro-*o*-toluidine, *o*-*o'*-dichloroazotoluene, and *o*-*o'*-dichlorotolidine (Cl:CH₃:NH₂=2:3:4) (Cohn, *l.c.*; cf. Akt. Ges. f. Anilfabr., D. R. P. 82140 of 1894).

3-Chloro-2-nitrotoluene; by chlorination of 6-nitro-aceto-*o*-toluidine in glacial acetic acid, followed by hydrolysis and elimination of the amino-group (Cohen and Hodsman, *Chem. Soc. Trans.* 1907, 91, 974). M.p. 23-24° (Holleman and Wibaut, *Proc. K. Akad. Wetensch. Amsterdam*, 1912, 15, 594), n_D^{20} 1.5204 (Wibaut, *Rec. trav. chim.* 1913, 32, 244). It may also exist in a metastable form. It is oxidised to 3-chloro-2-nitrobenzoic acid (Brand and Zöller, *Ber.* 1907, 40, 3324).

3-Chloro-4-nitrotoluene; from 5-chloro-4-nitro-*o*-toluidine. M.p. 24-25°, n_D^{20} 1.5428 (Wibaut, *l.c.*).

3-Chloro-5-nitrotoluene; from 5-nitro-*m*-toluidine by the diazo-reaction (Hönig, *Ber.* 1887, 20, 2419). Yellow needles, volatile with steam m.p. 55° (Hönig), m.p. 58-60°, n_D^{20} 1.5404 (Wibaut, *Rec. trav. chim.* 1913, 32, 244), m.p. 61° (Wynne and Greeves, *Chem. Soc. Proc.* 1895, 11, 151).

3-Chloro-6-nitrotoluene; from 6-nitro-*m*-toluidine (Cohen and Hodsman, *Chem. Soc. Trans.* 1907, 91, 975) or 2-nitro-5-chloro-*p*-toluidine (Brand and Zöller, *l.c.*). It appears to exist in a stable form, m.p. 24-25°, and a metastable form, m.p. 24-25°, n_D^{20} 1.5495 (Wibaut, *l.c.*).

4-Chloro-2-nitrotoluene; together with the 4:3-isomeride by nitration of *p*-chlorotoluene (Engelbrecht, *Ber.* 1874, 7, 797; Goldschmidt and Hönig, *ibid.* 1886, 19, 2440; cf. Wroblewsky, *Ann.* 1873, 168, 203); from 2-nitro-*p*-toluidine by the diazo-reaction (Beilstein and Kuhlberg, *Ann.* 1871, 158, 336; Green and Lawson, *Chem. Soc. Trans.* 1891, 59, 1019). Long needles, m.p. 38°, b.p. 239-240°/718 mm., readily volatile with steam. On reduction it yields *p*-chloro-*o*-toluidine (Goldschmidt and Hönig).

4-Chloro-3-nitrotoluene; together with the 4:3-isomeride by nitrating *p*-chlorotoluene (see under 4-chloro-2-nitrotoluene); from 3-nitro-*p*-toluidine by the diazo-reaction (Gattermann and Kaiser, *Ber.* 1888, 12, 2800). Oil which solidifies in a freezing mixture, m.p. 7°, b.p. 260°/745 mm. n_D^{20} 1.297 (Gattermann and Kaiser).

2-Chloro-3:4-dinitrotoluene; from 3:4-di-

nitro-*o*-toluidine by the Sandmeyer reaction. Colourless needles, m.p. 89°. With warm aqueous sodium hydroxide the following colour-changes occur: yellow, yellowish-brown, brownish-red; with alcoholic sodium hydroxide, pale green, dark green, greenish-blue, brownish-black, and after heating and keeping for 2 hours, pale red; with alcoholic ammonia, faint yellow (Morgan and Glover, *Chem. Soc. Trans.* 1921, 119, 1703).

2-Chloro-3:5-dinitrotoluene; from 3:5-dinitro-*o*-toluidine by the diazo-reaction (Körner and Contardi, *Atti R. Accad. Lincei*, 1915, [v.] 24, i. 888; Rabaut, *Bull. Soc. chim.* 1895, [3] 13, 634; *Compt. rend.* 1895, 120, 1123); together with other products by nitration of *o*-chlorotoluene (Nietzki and Rehe, *Ber.* 1892, 25, 3005; Borsche and Fiedler, *ibid.* 1911, 45, 270; Morgan and Drew, *Chem. Soc. Trans.* 1920, 117, 784); best prepared by heating 2-chloro-3-nitrotoluene or 2-chloro-5-nitrotoluene with a mixture of equal parts of sulphuric and fuming nitric acids for 2 hours on the water-bath (Borsche and Fiedler, *l.c.*). Stout yellow rhombs, or large prisms; m.p. 63°-64.5° (Borsche and Fiedler). With anhydrous liquid ammonia it yields an intense violet to bluish-violet colour (red by transmitted light) changing to greenish-black; with alcoholic ammonia a greenish to azure-blue colour changing to red; with alcoholic sodium hydroxide a pale yellow colour changing through greenish-blue to intense rose-red and on heating to bright orange-red (Morgan and Drew).

2-Chloro-4:5-dinitrotoluene; from 4:5-dinitro-*o*-toluidine by the Sandmeyer reaction (Morgan and Glover, *Chem. Soc. Trans.* 1921, 119, 1703); in 85 p.c. yield together with upwards of 4 p.c. of 2-chloro-4:6-dinitrotoluene by nitration of 2-chloro-4-nitrotoluene (Morgan and Challenor, *ibid.* 1921, 119, 1539); in 18-20 p.c. yield by direct nitration of *o*-chlorotoluene (Morgan and Drew, *ibid.* 1920, 117, 786, 792). Colourless hexagonal leaflets or prismatic needles, m.p. 88-89°. It yields a transparent orange-red colour with anhydrous liquid ammonia which changes to bluish- and brownish-black, a transparent orange-red coloration with alcoholic ammonia, and with alcoholic sodium hydroxide a pale yellow colour which changes through emerald-green to brownish-red (Morgan and Drew).

2-Chloro-4:6-dinitrotoluene; in a yield of about 1-2 p.c. by nitration of *o*-chlorotoluene; in a yield of 12 p.c. by nitration of 2-chloro-4-nitrotoluene (Morgan and Drew, *Chem. Soc. Trans.* 1920, 117, 786, 792); in small yield, together with 2-chloro-5:6-dinitrotoluene by nitration of 2-chloro-6-nitrotoluene (Morgan and Jones, *ibid.* 1921, 119, 187). Colourless rectangular prisms or prismatic needles, m.p. 49°. With anhydrous liquid ammonia it yields an intense violet coloration which changes to bluish-violet, magenta, and finally deep crimson; with alcoholic ammonia a bright red colour which changes to bluish-green, intense azure blue, red by transmitted light to deep crimson, and with alcoholic sodium hydroxide an intense blue changing to greenish-blue and finally black, and on heating to reddish-black and finally to transparent deep orange-red (Morgan and Drew).

2-Chloro-5:6-dinitrotoluene; as the chief product, together with a small amount of 2-chloro-4:6-dinitrotoluene, by the gradual addition of 2-chloro-6-nitrotoluene to a mixture of nitric acid (D 1.42) and sulphuric acid at 20°, the temperature being raised subsequently to 70° for 1 hour (Morgan and Jones, Chem. Soc. Trans. 1921, 119, 187; cf. Janson, D. R. P. 107805 of 1898; Cohn, Monatsh. 1901, 22, 475; Morgan and Drew, Chem. Soc. Trans. 1920, 117, 787). Colourless needles or prisms, m.p. 106.5°. With anhydrous liquid ammonia it yields a transparent yellow colour which changes to orange-red, with alcoholic ammonia a transparent yellow colour, and with alcoholic sodium hydroxide a faint transparent yellow colour which on heating changes from orange to deep orange-red, fading to transparent brownish-yellow and finally to light orange (Morgan and Drew).

3-Chloro-2:4-dinitrotoluene; by the action of cupric chloride on 2:4-dinitro-*m*-tolyl-hydrazine. Long silky pale yellow needles, m.p. 92° (Brady and Bowman, Chem. Soc. Trans. 1921, 119, 897). These authors consider that the compound, m.p. 73°, obtained by Borsche and Fiedler (Ber. 1913, 46, 2117) is identical with 3-chloro-2:6-dinitrotoluene.

3-Chloro-2:6-dinitrotoluene; large, almost colourless prisms, m.p. 75° (Körner and Contardi, Atti R. Accad. Lincei, 1916, [v.] 25, ii. 339; cf. Borsche and Fiedler, *l.c.*).

3-Chloro-4:6-dinitrotoluene; from 6-nitro-*m*-toluidine by replacement of the amino-group by chlorine, followed by nitration with fuming nitric acid and sulphuric acid; or by nitration of *m*-chlorotoluene (Reverdin and Crépeux, Ber. 1900, 33, 2506; Bull. Soc. chim. 1900, (3) 23, 838). Pale yellow needles, or shining leaflets, volatile with steam, m.p. 91°. When reduced with an alcoholic solution of ammonium sulphite it yields a *chloronitrotoluidine* (3:4:6- or 3:6:4-), yellow leaflets, m.p. 120°, *acetyl derivative*, m.p. 262° (Reverdin and Crépeux; cf. Borsche and Fiedler, Ber. 1913, 46, 2117). On nitration it yields 3-chloro-2:4:6-trinitrotoluene.

4-Chloro-2:3-dinitrotoluene; by nitration of *p*-chlorotoluene with nitric acid (D 1.4). Small yellow needles, m.p. 76° (Goldschmidt and Hönig, Ber. 1886, 19, 2439; Hönig, *ibid.* 1887, 20, 2420).

4-Chloro-2:5-dinitrotoluene; by oxidation of 4-chloro-2:5-dinitrosotoluene with warm concentrated nitric acid. Short amber-yellow prisms, m.p. 107° (Kahrmann, Silva and Keleti, Ber. 1915, 48, 2021).

4-Chloro-2:6-dinitrotoluene; by nitration of 4-chloro-2-nitrotoluene with mixed acid. Long white needles, m.p. 101° (Hönig, Ber. 1887, 20, 2420).

4-Chloro-3:5-dinitrotoluene; by nitration of 4-chloro-3-nitrotoluene (Hönig, Ber. 1887, 20, 2420; Borsche and Fiedler, Ber. 1912, 45, 1839; 1913, 46, 2117); in small quantity by the action of toluene *p*-sulphonyl chloride on 3:5-dinitro-*p*-cresol in presence of diethylaniline (Borsche and Fiedler). In preparing the compound by the first method, a substance, m.p. 106°, probably 4-chloro-2:5-dinitrotoluene, is formed simultaneously. 4-Chloro-3:5-dinitrotoluene is prepared also from the corresponding nitrate by the

action of cuprous or cupric chloride (Körner and Contardi, Atti R. Accad. Lincei, 1914, [v.] 22, ii. 464). Colourless needles, m.p. 115°-116° (Borsche and Fiedler), or stout yellow rhombic prisms, m.p. 114.5° (Körner and Contardi). Hönig gave the melting point as 48°.

3-Chloro-2:4:6-trinitrotoluene; by nitration of 3-chloro-4:6-dinitrotoluene at 150°-175°, or of 3-chlorotoluene with sulphuric acid (D 1.84) and nitric acid (D 1.51) (Reverdin, Drosel and Delétra, Bull. Soc. chim. 1904, [3] 31, 631); by condensation of trinitro-*m*-cresol with toluene *p*-sulphonyl chloride in presence of diethylaniline (Ullmann and Náday, Ber. 1908, 41, 1870). Long colourless needles or spangles, m.p. 148.5°.

2:3-Dichloro-4-nitrotoluene; by the action of cold fuming nitric acid on 2:3-dichlorotoluene. Fine needles, m.p. 50.5°-51.5° (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1128; 1902, 81, 1327, 1347; cf. Seelig, Ann. 1887, 237, 163).

2:3-Dichloro-5-nitrotoluene; from 3-chloro-5-nitro-*o*-toluidine by the diazo-reaction (Wyne and Greeves, Chem. Soc. Proc. 1895, 11, 151). Pale yellow needles, m.p. 83°.

2:4-Dichloro-5-nitrotoluene; by nitration of 2:4-dichlorotoluene with cold fuming nitric acid. Needles, m.p. 54°-55° (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1129; 1902, 81, 1334, 1348; cf. Seelig, *l.c.*).

2:5-Dichloro-3-nitrotoluene; from 5-chloro-3-nitro-*o*-toluidine by the diazo-reaction. Long slender needles, volatile with steam, m.p. 54°-55° (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1330).

2:5-Dichloro-4-nitrotoluene; by nitration of 2:5-dichlorotoluene (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1130; 1902, 81, 1347); from 6-chloro-4-nitro-*m*-toluidine by the diazo-reaction (Morgan and Drew, *ibid.* 1920, 117, 789). Fine needles, m.p. 50°-51° (C. and D.).

2:5-Dichloro-6-nitrotoluene, m.p. 68°-70°, from 5-chloro-6-nitro-*o*-toluidine by the diazo-reaction (Cohen and Hodsman, *ibid.* 1907, 81, 975).

2:6-Dichloro-3-nitrotoluene; m.p. 52°-53°, by nitrating 2:6-dichlorotoluene in the cold with fuming nitric acid (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1346).

2:6-Dichloro-4-nitrotoluene; together with other products in a yield of more than 30 p.c. by the monochlorination of 2-chloro-4-nitrotoluene in the presence of antimony trichloride or ferric chloride. Thick colourless faintly odorous blunt needles, m.p. 65°, b.p. 278°-279°/760 mm. It is very stable towards potassium permanganate solution (Davies, Chem. Soc. Trans. 1922, 121, 810).

3:4-Dichloro-5-nitrotoluene; from 3-chloro-5-nitro-*p*-toluidine by the diazo-reaction. Pale yellow needles, volatile with steam, m.p. 49°-50°. On further nitration it yields a *dinitro-derivative*, m.p. 80°-81° (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1338, 1349).

3:4-Dichloro-6-nitrotoluene; by nitration of 3:4-dichlorotoluene. Fine long needles, m.p. 63°-64° (Cohen and Dakin, *ibid.* 1902, 81, 1349).

3:5-Dichloro-2-nitrotoluene; by nitration of 3:5-dichlorotoluene. Needles, m.p. 62° (Cohen and Dakin, *ibid.* 1902, 81, 1348).

A *dichloro-4-nitrotoluene*, m.p. 16°, b.p. 274°, is obtained from dichlorotoluene and fuming nitric acid as described by Wroblewsky (Ann. 1873, 166, 212).

The following dichlorodinitro-derivatives are obtained by nitrating the corresponding dichlorotoluene (Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1111; 1902, 81, 1224, 1344; Cohen and Hodman, *ibid.* 1907, 91, 975; Davies, *ibid.* 1922, 121, 812; Seelig, Ann. 1887, 237, 129).

2:3-Dichloro-4:6-dinitrotoluene; m.p. 71°-72° (C. and D.).

2:4-Dichloro-3:5-dinitrotoluene; prisms, m.p. 103°-104° (C. and D.; S.).

2:5-Dichloro-4:6-dinitrotoluene; m.p. 100°-101° (C. and D.; C. and H.).

2:6-Dichloro-3:4-dinitrotoluene; by nitrating 2:6-dichloro-4-nitrotoluene with nitric acid (D 1.5) and concentrated sulphuric acid at the temperature of the water-bath for 1 hour. Long colourless needles, m.p. 130°-131° (D).

2:6-Dichloro-3:5-dinitrotoluene; colourless needles, m.p. 121° (C. and D.); also prepared from 2:6-dichloro-3-nitro-*p*-toluidine by eliminating the amino-group followed by nitration (D).

3:4-Dichloro-2:6-dinitrotoluene; long, most colourless needles, m.p. 91.5°-92.5° (C. and D.).

3:5-Dichloro-2:6-dinitrotoluene, long white needles, m.p. 99°-100° (C. and D.).

3:5-Dichloro-2:4:6-trinitrotoluene; by heating ethyldichlorotrinitrophenyl acetate in a sealed tube with concentrated hydrochloric acid at 150°-160°. Long flat white prisms, m.p. 200°-201° (Jackson and Smith, Amer. Chem. J. 1904, 32, 168).

2:6-Dichloro-3:4:5-trinitrotoluene; by prolonged nitration of 2:6-dichloro-3:5-dinitrotoluene with a mixture of nitric acid (D 1.5) and fuming sulphuric acid (20 p.c. SO₃) at 155°-160°. Small colourless needles, m.p. 160°-161° (Davies, Chem. Soc. Trans. 1922, 121, 812).

The following trichloronitrotoluenes have been obtained by nitrating the corresponding dichlorotoluenes (Seelig, Ann. 1887, 237, 140; Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1224, 1344).

2:3:4-Trichloronitrotoluene; white needles, m.p. 60°-61° (S.).

2:3:5-Trichloronitrotoluene; felted needles, m.p. 58°-59° (C. and D.).

2:3:6-Trichloronitrotoluene; long needles, m.p. 57°-58° (C. and D.).

3:4:5-Trichloronitrotoluene; needles or prisms, m.p. 91°-92° (S.) (cf. Beilstein and Kahlberg, Ann. 1869, 152, 240; Schultz, Ann. 1871, 167, 277).

3:4:6-Trichloro-3-nitrotoluene; m.p. 54° (Beilstein) (C. and D.).

3:4:5-Trichloro-3-nitrotoluene; prisms, m.p. 51°-52° (C. and D.).

The following trichlorodinitrotoluenes have been obtained by nitrating the corresponding dichlorotoluenes (Seelig, Ann. 1887, 237, 140; Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1224, 1344).

2:3:4-Trichloro-4:6-dinitrotoluene; small needles, m.p. 141° (S.).

2:3:5-Trichloro-4:5-dinitrotoluene; prisms, m.p. 140°-142° (C. and D.).

2:4:5-Trichloro-3:6-dinitrotoluene; small needles, m.p. 227° (S.).

2:4:6-Trichloro-3:5-dinitrotoluene; m.p. 178°-180° (C. and D.).

3:4:5-Trichloro-2:6-dinitrotoluene, prismatic needles, m.p. 163°-164° (C. and D.).

The following tetrachloronitrotoluenes have been obtained in a similar manner (Cohen and Dakin, *ibid.* 1904, 85, 1274; 1906, 89, 1483).

2:3:4:5-Tetrachloro-6-nitrotoluene; m.p. 159°.

2:3:4:6-Tetrachloro-5-nitrotoluene; m.p. 131°-134° (not pure).

2:3:5:6-Tetrachloro-4-nitrotoluene; small hexagonal plates, m.p. 150°-152°.

2-Bromo-4-nitrotoluene, by elimination of the amino-group from 6-bromo-4-nitro-*m*-toluidine (Neville and Winther, Chem. Soc. Trans. 1881, 39, 85; Ber. 1881, 14, 418); by heating *p*-nitrotoluene with bromine in presence of ferrous bromide (Scheufelen, Ann. 1885, 231, 171); by the action of hydrobromic acid on *p*-nitrotoluene-*o*-diazopiperidide (Wallach, Ann. 1886, 235, 248). Needles, m.p. 77.5° (S.) or 74°-75° (N. and W.).

2-Bromo-5-nitrotoluene; from 5-nitro-*o*-toluidine (Neville and Winther, Chem. Soc. Trans. 1880, 37, 429); by heating *m*-nitrotoluene with bromine in presence of ferrous bromide (Scheufelen, Ann. 1885, 231, 180); from 2-bromo-5-nitro-*p*-toluidine or 6-bromo-3-nitro-*o*-toluidine by the diazo-reaction (Blankma, Chem. Weekblad. 1912, 9, 968). It melts at 78° (S.).

2-Bromo-6-nitrotoluene; from 6-nitro-*o*-toluidine (Friedländer, Bruckner and Deutsch, Ann. 1912, 388, 23; Nölting, Ber. 1904, 37, 1915). Yellowish-white needles, m.p. 41° (N.) or 35° (F. B. and D.).

3-Bromo-2-nitrotoluene; from 2-nitro-3-bromo-*m*-toluidine by the diazo-reaction. Liquid (Neville and Winther, Chem. Soc. Trans. 1880, 37, 630; Ber. 1880, 13, 1945).

3-Bromo-5-nitrotoluene; from 3-bromo-5-nitro-*p*-toluidine, 5-bromo-3-nitro-*o*-toluidine, or 3-bromo-5-nitro-*o*-toluidine by the diazo-reaction. Prisms, m.p. 81.4°-81.5° (Neville and Winther, Chem. Soc. Trans. 1880, 37, 429; Ber. 1880, 13, 564) or m.p. 86°, b.p. 269°-270° (Wroblewsky, Ann. 1878, 192, 203).

4-Bromo-2-nitrotoluene; from 2:4-dinitrotoluene by replacing the *p*-nitro-group by bromine (Beilstein and Kahlberg, Ann. 1871, 158, 340); together with 4-bromo-3-nitrotoluene by nitrating *p*-bromotoluene (Wroblewsky, Ann. 1873, 168, 176); by the action of bromine on *o*-nitrotoluene in presence of iron (Gland, Ber. 1915, 48, 432). Slender yellowish needles or large monoclinic tables, m.p. 45° (Beilstein and Roes, Ber. 1873, 6, 609), m.p. 43°, b.p. 257° (Wroblewsky), m.p. 157.5° (Hodman, Rec. trav. chim. 1915, 34, 262). Its reaction with sulphuric acid on electrolysis yields 4-bromo-2-amino-3-creosol (Gattermann, Ber. 1904, 37, 1921).

4-Bromo-3-nitrotoluene; together with 4-bromo-2-nitrotoluene by nitrating *p*-bromotoluene (Wroblewsky, Ann. 1873, 168, 176).

(D 1.52) cooled in ice a mixture of 4-bromo-2-nitrotoluene and 4-bromo-3-nitrotoluene, in the relative proportions of 56.3 : 43.7, is obtained. Analysis by decomposition with sodium methoxide showed the mixture to contain 41.5 p.c. of the 3:4-isomeride, whilst calculation from theoretical considerations gave the relative proportions as 2:4/3 = 52.4 : 47.6 (Holleman, Rec. trav. chim. 1915, 34, 283); from 3-nitro-*p*-toluidine by the diazo-reaction (Neville and Winther, Chem. Soc. Trans. 1880, 37, 442; Ber. 1880, 13, 972); by treating *m*-nitrotoluene with bromine in presence of ferrous bromide (Scheufelen, Ann. 1885, 231, 180). M.p. 33°.

η_D^{20} 1.5682 (Holleman; cf. Hübner and Rods), b.p. 255°–256°, D_{20}^{20} 1.631 (Wroblewsky). By the electrolysis of its solution in sulphuric acid, 4-bromo-5-amino-2-cresol is obtained (Gatterman, Ber. 1893, 27, 1931).

2-Bromo-3:5-dinitrotoluene; slender white prisms or large prisms, m.p. 86.2° (Körner and Contardi, Atti R. Accad. Lincei, 1916, [v.] 25, ii. 339; Blanksma, Rec. trav. chim. 1901, 20, 425).

3-Bromo-4:6-dinitrotoluene; by nitrating *m*-bromotoluene or *m*-bromomononitrotoluene with fuming nitric acid (Grete, Ann. 1873, 168, 258; Ber. 1875, 8, 567; Bentley and Warren, Amer. Chem. J. 1890, 12, 1); by the decomposition of ethyl bromodinitrophenylmalonate (Jackson and Robinson, Amer. Chem. J. 1889, 11, 541). Long pale yellow prisms or needles, m.p. 103°–104° (G.).

4-Bromo-3:5-dinitrotoluene; from 3:5-dinitro-*p*-toluidine by the diazo-reaction; by nitration of 4-bromo-3-nitrotoluene with nitric acid (D 1.52). Yellow prisms, m.p. 118.4° (Jackson and Ittner, Amer. Chem. J. 1897, 19, 7, 199, 205; Körner and Contardi, Atti R. Accad. Lincei, 1914, [v.] 23, ii. 464).

3-Bromo-2:4:6-trinitrotoluene; by boiling 10 grms. of 3-bromo-4:6-dinitrotoluene with 20 c.c. of a mixture of 1 vol. of concentrated sulphuric acid and 2 vols. of concentrated nitric acid (Bentley and Warren, Amer. Chem. J. 1890, 12, 4); from 3-bromo-2:6-dinitro-*p*-toluidine (Körner and Contardi, Atti R. Accad. Lincei, 1916, [v.] 25, ii. 339). Small needles, m.p. 143°. With alcoholic ammonia it yields 2:4:6-trinitro-*m*-toluidine.

2:3-Dibromo-4- (or 6) nitrotoluene; by nitrating 2:3-dibromotoluene. Needles, m.p. 56.5°–57.5° (Neville and Winther, Chem. Soc. Trans. 1880, 37, 434; Ber. 1881, 14, 419) or 59° (Wroblewsky, Ann. 1873, 168, 184).

2:3-Dibromo-5-nitrotoluene; from 3-bromo-5-nitro-*o*-toluidine by the diazo-reaction. It melts at 105.4° (Neville and Winther, Chem. Soc. Trans. 1880, 37, 429; Ber. 1880, 13, 965; Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 512).

2:4-Dibromo-5-nitrotoluene; by nitration of 2:4-dibromotoluene (Davis, Chem. Soc. Trans. 1902, 81, 872; cf. Neville and Winther, l.c.); from 2-bromo-5-nitro-*p*-toluidine by the diazo-reaction. Colourless needles, m.p. 85° (Blanksma, Chem. Weekblad. 1912, 9, 968) or 81°–82° (Davis).

2:4-Dibromo-6-nitrotoluene (?); by nitrating dibromotoluenes derived from dibromo-*m*-toluidine (m.p. 75°). It melts at 80°–81° (Neville and Winther, Chem. Soc. Trans. 1880, 37, 441; Ber. 1881, 14, 419).

2:5-Dibromo-3-nitrotoluene; from 5-bromo-3-nitro-*o*-toluidine by the diazo-reaction. It melts at 69.5°–70.2° (Neville and Winther, Chem. Soc. Trans. 1880, 37, 448; Ber. 1881, 14, 419).

2:5-Dibromo-4-nitrotoluene; by nitrating 2:5-dibromotoluene; from 6-bromo-4-nitro-*m*-toluidine by the diazo-reaction (Neville and Winther, Chem. Soc. Trans. 1880, 37, 445; Ber. 1881, 14, 419); together with other products by treating dibromo-*p*-cymene with a mixture of nitric and sulphuric acids (Claus, J. pr. Chem. 1888, [2] 37, 18). Needles, m.p. 87°–89° (N. and W.), 89° (C.).

2:6-Dibromo-3-nitrotoluene; by nitration of 2:6-dibromotoluene with nitric acid (D 1.45) the 3-nitro-compound is formed and not the 4-nitro-derivative as stated by Neville and Winther; from 6-bromo-3-nitro-*o*-toluidine. Pale yellow crystals, m.p. 50° (Blanksma, l.c.; cf. Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 502).

2:6-Dibromo-4-nitrotoluene; from *p*-nitrotoluene by the action of bromine in presence of ferrous bromide (Scheufelen, Ann. 1885, 231, 178); from 2:6-dibromo-4-nitro-*m*-toluidine (Neville and Winther). Needles, m.p. 57°–58° (S.) or 56.8°–57° (N. and W.).

3:4-Dibromo-5-nitrotoluene; from 3-bromo-5-nitro-*p*-toluidine. Leaflets, m.p. 62°–63.6° (Neville and Winther, l.c.) or 63°–65° (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 510).

3:4-Dibromo-6-nitrotoluene; by nitration of 3:4-dibromotoluene (Wroblewsky, Ann. 1873, 168, 184; Neville and Winther, Chem. Soc. Trans. 1880, 37, 429; Ber. 1881, 14, 417); from 5-bromo-2-nitro-*p*-toluidine (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 515). Needles, m.p. 86.5°–87.5° (Neville and Winther) or 83.5°–84.5° (Cohen and Dutt).

3:5-Dibromonitrotoluene; by nitration of 3:5-dibromotoluene. Prisms, m.p. 124° (Wroblewsky, Ann. 1873, 168, 189).

3:5-Dibromo-2-nitrotoluene; obtained together with a *by-product* of higher melting-point by the diazotisation of 3:5-dibromo-2-nitro-*p*-toluidine. It melts at 67°, and on nitration with nitric acid (D 1.52) it yields a mixture of 3:5-dibromo-2:4-dinitrotoluene and 3:5-dibromo-2:6-dinitrotoluene, but in presence of sulphuric acid 3:5-dibromo-2:4:6-trinitrotoluene is obtained (Blanksma, Chem. Weekblad, 1909, 6, 728).

3:5-Dibromo-4-nitrotoluene; obtained together with a *compound*, m.p. about 250°, from 3:5-dibromo-4-nitro-*o*-toluidine by the diazo-reaction. Colourless crystals, m.p. 84° (Blanksma, l.c.).

2:4-Dibromo-3:5-dinitrotoluene; by nitration of 2:4-dibromotoluene or 2:4-dibromo-5-nitrotoluene. Light yellow prisms, m.p. 127.5° (Davis, Chem. Soc. Trans. 1902, 81, 873) or 130° (Blanksma, Chem. Weekblad, 1912, 9, 968).

2:5-Dibromo-4:6-dinitrotoluene; by treating dibromo-*p*-cymene with a mixture of nitric and sulphuric acids. Small acicular needles, or large yellow prisms, m.p. 142°. It sublimes readily in leaflets (Claus, J. pr. Chem. 1888, [2] 37, 16).

2:6-Dibromodinitrotoluene; by nitration of 2:6-dibromotoluenes. It melts at 161.6°–162.2°

(Neville and Winther, *Chem. Soc. Trans.* 1880, 37, 437; *Ber.* 1880, 13, 967).

2:6-Dibromo-3:5-dinitrotoluene; by nitration of 2:6-dibromo-3-nitrotoluene. Colourless crystals, m.p. 161° (Blanksma, *l.c.*).

3:5-Dibromo-2:4-dinitrotoluene; when 3:5-dibromotoluene is added slowly to four times its weight of nitric acid (D 1.52) and the mixture is warmed for 10 minutes at 100°, 3:5-dibromo-2:4-dinitrotoluene, needles, m.p. 157°, is obtained, together with a product, cubes, m.p. 106°–108°, which appears to be a mixture of the above substance with the 2:6-isomeride (Blanksma, *Rec. trav. chim.* 1904, 23, 125; *cf.* Neville and Winther, *l.c.*); also prepared by nitration of 3:5-dibromo-4-nitrotoluene and, together with the 2:6-isomeride, by nitration of 3:5-dibromo-2-nitrotoluene (Blanksma, *Chem. Weekblad*, 1909, 6, 728).

3:5-Dibromo-2:6-dinitrotoluene; (*see above*); from 3:5-dibromo-2:6-dinitro-*p*-toluidine. White needles or flat plates, m.p. 120° (Körner and Contardi, *Atti R. Accad. Lincei*, 1916, [v.] 25, ii. 339) or 117° (Blanksma, *l.c.*).

3:5-Dibromo-2:4:6-trinitrotoluene; by nitration of 3:5-dibromotoluene in presence of sulphuric acid (Blanksma, *Rec. trav. chim.* 1904, 23, 125); by nitration of 3:5-dibromo-4-nitrotoluene, 3:5-dibromo-2:4-dinitrotoluene, and of 3:5-dibromo-2-nitrotoluene, the nitration in the last case being carried out in presence of sulphuric acid (Blanksma, *Chem. Weekblad*, 1909, 6, 728); from 3:5-dibromo-2:6-dinitro-*p*-toluidine by the action of nitrous gases on a suspension in concentrated nitric acid at 0° (Körner and Contardi, *l.c.*). White flat needles, m.p. 240°; Palmer (*Ber.* 1888, 21, 3501; 1896, 29, 1346) describes it as long yellow prisms, m.p. 229°–230°.

2:3:4-Tribromonitrotoluene; by nitration of 2:3:4-tribromotoluene. M.p. 107°–108° (Neville and Winther, *Chem. Soc. Trans.* 1880, 37, 446; Cohen and Dutt, *l.c.*).

2:3:5-Tribromonitrotoluene; on nitration 2:3:5-tribromotoluene yields two mononitroderivatives, m.p. 67°–68° and 88.5°–89° respectively, the former in greater quantity (Cohen and Dutt, *l.c.*).

2:3:6-Tribromonitrotoluene; m.p. 91°–92° (C. and D.; N. and W.).

2:4:5-Tribromonitrotoluene; colourless crystals, m.p. 131°–131.5° (C. and D.).

2:4:6-Tribromonitrotoluene; m.p. 215° (Wroblewsky, *Ann.* 1873, 168, 195).

2:4:6-Tribromonitrotoluene; colourless crystals, m.p. 74°–75.5° (C. and D.).

2:5:6-Tribromo-4-nitrotoluene; from 2:6-dibromo-4-nitro-*m*-toluidine. It melts at 106.5°–107° (C. and D.; N. and W.).

3:4:5-Tribromonitrotoluene; colourless crystals, m.p. 104°–105° (C. and D.).

3:5:6-Tribromo-2-nitrotoluene; from 3:5-dibromo-6-nitro-*o*-toluidine. It melts at 93° (Blanksma, *Chem. Weekblad*, 1914, 11, 185).

2:3:4-Tribromodinitrotoluene; m.p. 197°–199° (C. and D.).

2:2:5-Tribromodinitrotoluene; m.p. 209°–210° (C. and D.).

2:3:6-Tribromodinitrotoluene; light yellow prisms, m.p. 202°–203° (C. and D.).

2:4:5-Tribromodinitrotoluene; colourless crystals, m.p. 276°–278° (C. and D.).

2:4:6-Tribromodinitrotoluene; colourless crystals, m.p. 217°–218° (C. and D.; N. and W.).

3:4:5-Tribromodinitrotoluene; colourless prisms, m.p. 211.5° (C. and D.).

3:5:6-Tribromodinitrotoluene; by nitration of 3:5:6-tribromo-2-nitrotoluene. Colourless crystals, m.p. 208° (Blanksma, *Chem. Weekblad*, 1914, 11, 185).

2:3:4:5-Tetrabromo-6-nitrotoluene, m.p. 212° (N. and W.).

2:3:4:6-Tetrabromo-5-nitrotoluene, m.p. 215°–216° (N. and W.).

2:3:5:6-Tetrabromo-4-nitrotoluene; by nitration of 2:3:5:6-tetrabromotoluene (Neville and Winther, *Chem. Soc. Trans.* 1880, 37, 450); from 2-bromo-4-nitrotoluene by bromination in presence of ferrous bromide (Scheufelen, *Ann.* 1885, 231, 179). It melts at 213° (Neville and Winther) or 227° (Scheufelen).

m-Chloro-*p*-bromonitrotoluene; by nitration of chlorinated *p*-bromotoluene. Needles, m.p. 61° (Willgerodt and Salzmann, *J. pr. Chem.* 1889, [2] 39, 478).

o-Chlorobromonitrotoluene; by nitration of brominated *o*-chlorotoluene. Needles, m.p. 68° (W. and S.).

Dichloro-*p*-bromonitrotoluene; by nitration of dichloro-*p*-bromotoluene. Pearly leaflets, m.p. 106° (W. and S.).

Trichloro-*p*-bromonitrotoluene; by nitration of trichloro-*p*-bromotoluene. Needles, m.p. 162° (W. and S.).

2-Iodonitrotoluene; by nitration of 2-iodotoluene. Microscopic needles, m.p. 103°–104° (Beilstein and Kuhlberg, *Ann.* 1871, 158, 347).

2-Iodo-3-nitrotoluene; from 3-nitro-*o*-toluidine. Light yellow plates, m.p. 67°–68° (Wheeler and Liddle, *Amer. Chem. J.* 1909, 42, 441).

2-Iodo-4-nitrotoluene; from 4-nitro-*o*-toluidine. Yellowish plates, m.p. 51° (Reverdin, *Ber.* 1897, 30, 3000) or rhombic plates, m.p. 58° (Willgerodt and Kok, *Ber.* 1908, 41, 2077). It yields a dichloride, sulphur-yellow prisms, m.p. 83°, which on treatment with sodium carbonate or sodium hydroxide yields 2-iodo-4-nitrotoluene, yellowish-white powder, exploding at 180°–181°. The latter on treatment with hypochlorous acid is converted into 2-iodoxy-4-nitrotoluene, white flocculent precipitate, exploding at 204° (Willgerodt and Kok, *l.c.*).

2-Iodo-5-nitrotoluene; from 5-nitro-*o*-toluidine by the diazo-reaction (Reverdin); by gradual treatment of *o*-iodo-toluene with nitric acid (D 1.51) (Reverdin; Beilstein and Kuhlberg, *Ann.* 1871, 158, 347). It melts at 103°–104° and forms a dichloride, m.p. 102° (decomp.), when chlorine is passed into a saturated solution in chloroform (McCrae, *Chem. Soc. Trans.* 1878, 73, 693).

2-Iodo-6-nitrotoluene; from 6-nitro-*o*-toluidine. It forms thick yellowish-white crystals, m.p. 35.5° (Nölting, *Ber.* 1904, 37, 1015) or yellow needles, m.p. 34°–35° (Cohen and Miller, *Chem. Soc. Trans.* 1904, 85, 1627).

3-Iodo-2-nitrotoluene; from 5-iodo-6-nitro-*o*-toluidine. Colourless prismatic plates, m.p. 65°, volatile with steam (Wheeler and Brautlecht, *Amer. Chem. J.* 1910, 44, 126).

3-Iodo-5-nitrotoluene; from 5-nitro-*m*-toluidine. Yellow rectangular prisms, m.p. 77°

(Wheeler and Scholes, Amer. Chem. J. 1910, 44, 126).

3-Iodo-6-nitrotoluene; from 6-nitro-*m*-toluidine. Orange needles, volatile with steam, m.p. 84° (Artmann, Monatsh. 1905, 26, 1091).

3-Iodo-nitrotoluene; by nitration of 3-iodotoluene. Small needles, m.p. 108°–109° (Beilstein and Kuhlberg).

4-Iodo-2-nitrotoluene; from 2:4-dinitrotoluene by replacing the *p*-nitro-group by iodine (Heynemann, Ann. 1871, 158, 337); together with other products by the nitration of *p*-iodotoluene (Reverdin, Ber. 1897, 30, 3001). Pale yellow crystals, m.p. 60.5°–61°, b.p. 286° (decomp.).

4-Iodo-3-nitrotoluene; from 3-nitro-*p*-toluidine. Flat yellow needles, m.p. 55°–56° (Beilstein and Kuhlberg, Ann. 1871, 158, 344). Yields a *dichloride*, large yellow plates, m.p. 71° (Willgerodt and Simonis, Ber. 1906, 39, 269).

2-Iodo-3:5-dinitrotoluene; from 3:5-dinitrotoluene-2-diazonium nitrate and cupric iodide. Small lemon-yellow plates or long prisms, m.p. 119.5° (Körner and Contardi, Atti R. Accad. Lincei, 1915, [v.] 24, i. 888).

3-Iodo-2:4-dinitrotoluene; by boiling an alcoholic solution of 2:4-dinitro-3-tolylhydrazine with excess of iodine. Yellow leaflets, m.p. 117° (Brady and Bowman, Chem. Soc. Trans. 1921, 119, 897).

3-Iodo-2:6-dinitrotoluene; large aggregates of small colourless plates, m.p. 90° (Körner and Contardi, Atti R. Accad. Lincei, 1916, [v.] 25, ii. 339).

4-Iodo-3:5-dinitrotoluene; by nitration of *p*-iodotoluene (Glassner, Ber. 1875, 8, 561); from 3:5-dinitro-*p*-toluidine. Lemon-yellow needles, m.p. 158° (Körner and Contardi, Atti R. Accad. Lincei, 1914, [v.] 23, ii. 464); Glassner gave m.p. 137°–138°.

Di-iodonitrotoluene (?); formed together with other products by nitration of *p*-iodotoluene with nitric acid (D 1.51); m.p. 112° (Reverdin, l.c.).

2:3-Di-iodo-4-nitrotoluene; from 3-iodo-5-nitro-*o*-toluidine. Light brown prismatic needles, m.p. 143° (Wheeler, etc., Amer. Chem. J. 1910, 44, 126, 493).

2:5-Di-iodo-3-nitrotoluene; from 5-iodo-3-nitro-*o*-toluidine. Colourless prisms, m.p. 95° (Wheeler, etc.).

2:5-Di-iodo-4-nitrotoluene; from 5-iodo-4-nitro-*o*-toluidine. Buff coloured prismatic plates, m.p. 117° (Wheeler, etc.).

2:5-Di-iodo-6-nitrotoluene; from 5-iodo-6-nitro-*o*-toluidine. Colourless needles, m.p. 105° (Wheeler, etc.).

3:4-Di-iodo-5-nitrotoluene; from 3-iodo-5-nitro-*p*-toluidine. Rectangular orange prisms, m.p. 84°–85° (Wheeler, etc.).

3-Bromo-2-iodonitrotoluene; by nitration of 3-bromo-2-iodotoluene. Prisms (Wroblewsky, Ann. 1873, 168, 165).

2-Bromo-4-iodonitrotoluene; by nitration of *o*-bromo-*p*-iodotoluene. Yellow needles, m.p. 92° (Hirtz, Ber. 1896, 29, 1405).

3-Bromo-4-iodonitrotoluene; by nitration of 3-bromo-4-iodotoluene. Needles, m.p. 118° (Wroblewsky, Ann. 1873, 168, 160).

3:5-Dibromo-4-iodo-2-nitrotoluene; by nitration of 3:5-dibromo-4-iodotoluene. Large needles, volatile with steam, m.p. 69° (Wroblewsky, Ann. 1878, 192, 210).

3:5-Dibromo-2:4-di-iodonitrotoluene; by nitration of 3:5-dibromo-2:4-di-iodotoluene (m.p. 68°). Plates, m.p. 129° (Wroblewsky).

SULPHINIC AND SULPHONIC ACID DERIVATIVES.

Toluene *o*-sulphinic acid; by boiling *o*-tolyltoluenesulphazide with baryta water (Limpricht, Ber. 1887, 20, 1241); by dropping toluene *o*-sulphonyl chloride into a warm mixture of zinc dust and water (Troeger and Voigtländer, J. pr. Chem. 1896, [2] 54, 513); by treating an ice-cold solution of *o*-toluenediazonium sulphate in sulphuric acid saturated with sulphur dioxide with copper (Gattermann, Ber. 1899, 32, 1140; Fr. Bayer & Co., Eng. Pat. 26139 of 1896; Fr. Pat. 252787 and addn.; D. R. P. 95830 of 1896); by the action of sulphur dioxide on an ethereal solution of *o*-tolyl magnesium bromide (Rosenheim and Singer, Ber. 1904, 37, 2152). Long needles, m.p. 80° (Limpricht). $\text{NaA}' + 4\text{H}_2\text{O}$, glistening plates; $\text{CaA}'_2 + 3\text{H}_2\text{O}$, crystalline powder; $\text{BaA}'_2 + 3\text{H}_2\text{O}$, nodules; $\text{SrA}'_2 + 3\text{H}_2\text{O}$, crystalline powder. On passing hydrogen sulphide into the methyl alcoholic solution, a mixture of *o*-tolyl tetra- and pentasulphide is formed. On boiling with water for about 3 hours, the sulphinic acid is converted into *o*-toluic disulphoxide and toluene *o*-sulphonic acid (T. and V.). For its behaviour with diazo-compounds, see Troeger and Ewers (J. pr. Chem. 1900, [2] 62, 369).

Toluene *m*-sulphinic acid; from diazotised *m*-toluidine, sulphur dioxide and copper powder. Unstable oil (Troeger and Hill, J. pr. Chem. 1905, (2) 71, 201).

Toluene *p*-sulphinic acid; prepared as in the case of the *o*-sulphinic acid (Limpricht); by treating toluene *p*-sulphonyl chloride with sodium amalgam, zinc-dust or sodium sulphite (Otto, Ann. 1867, 142, 92; 1868, 145, 19; Ber. 1876, 9, 1586; Bloomstrand, Ber. 1869, 3, 965); by Gattermann's reaction (Ber. 1899, 32, 1141); by the action of sulphur dioxide and aluminium chloride on toluene or its halogen derivatives at low temperatures (Knoevenagel and Kenner, Ber. 1908, 41, 3315). Plates, m.p. 86°–87° (Thomas, Chem. Soc. Trans. 1909, 95, 344). $\text{KA}' + 2\text{H}_2\text{O}$, leaflets (Casanova, Ber. 1887, 20, 2088); $\text{CaA}'_2 + 4\text{H}_2\text{O}$; BaA'_2 , small leaflets; $\text{ZnA}'_2 + 2\text{H}_2\text{O}$ (Otto); $\text{NH}_4\text{A}'$, small needles, m.p. 175°; *hydrazine salt*, glistening plates, decomposing at 140°; *aniline salt*, m.p. 118°; *o*-toluidine salt, m.p. 124°; *p*-toluidine salt, m.p. 140°; *m*-xylylidine salt, m.p. 129.5° (Hälsig, J. pr. Chem. 1897, [2] 56, 213); *phenylhydrazine salt*, m.p. 114° (Köhler and Reimer, Amer. Chem. J. 1904, 31, 163; cf. Hälsig). On electrolytic oxidation it yields *p*-sulphobenzonic acid (Sehor, Zeitsch. Elektrochem. 1903, 9, 370). When treated with an excess of thionyl chloride, it yields the *sulphonyl chloride*, m.p. 54°–58° (Hilditch and Smiles, Ber. 1908, 41, 4113). When ammonia is passed into an alcoholic or ethereal solution of toluene *p*-sulphinic acid, the corresponding ammonium salt is formed, whilst in benzene solution a mixture of *p*-tolyl disulphoxide and toluene *p*-sulphonic acid is produced (Heiduschka, Verh. Ges. deut. Naturforsch. Aerzte, 1907, 11, 170; Hälsig, J. pr. Chem. 1897, 56, 213).

For the action of toluene *p*-sulphinic acid on nitrobenzene and phenylhydroxylamine, see

Bamberger and Rising (Ber. 1901, 34, 228, 241), and for further reactions, see Kohler and Macdonald (Amer. Chem. J. 1899, 22, 235), von Meyer, Nacke and Gmeiner (J. pr. Chem. 1901, 63, 167), von Meyer (*ibid.* 1903, 68, 263), Hälsig (*ibid.* 1897, 56, 213), Troeger and Ewers (*ibid.* 1900, 62, 369), Hantzsch and Horn (Ber. 1902, 35, 877), Ullmann and Lehner (*ibid.* 1905, 38, 729), Kohler and Reimer (Amer. Chem. J. 1904, 31, 163).

Toluene p-sulphinic anhydride; melts at 75° (Knoevenagel and Polack, Ber. 1908, 41, 3323).

Methyl ester; a very unstable yellow oil. Oxidation yields the corresponding sulphonate (Otto, J. pr. Chem. 1893, [2] 47, 166).

Ethyl ester; from sodium toluene *p*-sulphinate and ethyl chlorocarbonate. Oil, D₂₀^o 1.1212. On treatment with hydrogen sulphide, (CH₃)C₆H₄SO₃H, C₂H₅SH, (CH₃)C₆H₄SH, [(CH₃)C₆H₄]₂S₂ and sulphur are produced (Otto and Rössing, Ber. 1885, 18, 2504; 1886, 19, 1226; 1887, 20, 2278; 1893, 26, 310).

Nitrotoluene sulphinic acid; from *o*(?)-nitrotoluene *p*(?)-sulphonic acid and sodium amalgam in ethereal solution. Crystals, NaA' + $\frac{1}{2}$ H₂O (Otto and Grüber, Ann. 1868, 145, 24).

2:6-Dinitrotoluene 4-sulphinic acid; from the corresponding sulphonyl chloride and zinc dust. Solidifies after prolonged keeping over sulphuric acid. KA', crusts; BaA'₂ + xH₂O, pearly leaflets; PbA'₂ + 3H₂O, microscopic prisms (Perl, Ber. 1885, 18, 71).

Toluene 2:4-disulphinic acid; obtained as its zinc salt by the action of zinc dust on the corresponding disulphonyl chloride. The free acid is an oil, zinc salt, white needles, sodium and barium salts, white crystals. When heated with water the free acid yields toluene 2:4-disulphonic acid and tolylene-toluene-2:4-dithio-sulphonate, C₆H₄(SO₂)₂:C₆H₄ (Tröger and Meine, J. pr. Chem. 1903, [2] 68, 313).

Benzyl sulphinic acid; by treating benzyl sulphonyl chloride with zinc dust or sodium amalgam. The free acid is very unstable and is readily decomposed with evolution of sulphur dioxide; NaA', small leaflets (Otto and Lüders, Ber. 1880, 13, 1287).

Sulphonation of toluene: The quantities of the three isomeric monosulphonic acids produced are dependent upon the temperature, the concentration, and the amount of the sulphonating agent. Increase of temperature favours the production of toluene *p*- and *m*-sulphonic acids. The concentration of acid between the limits of 96–100 p.c. appears to be without influence. Increase in the amount of acid favours the production of the *o*-isomeride at low temperatures, but this influence is neutralised at higher temperatures by the effect due to rise of temperature. The addition of potassium sulphate, mercurous sulphate, and silver sulphate has no effect. At 35° and 75° the transformation of the *o*- and *p*-isomerides into one another occurs very slowly, whilst toluene *m*-sulphonic acid is unaltered after heating with sulphuric acid for 6 hours at 100°. With chlorosulphonic acid the chief product is also the *p*-isomeride (Holleman, Culand, van der Linden and Wibaut, Ber. 1911, 44, 2504). If fuming sulphuric acid be used and the temperature of the reaction is kept at the b.p.

of toluene, the main product is the *p*-acid, but if the temperature be not allowed to rise above 100° and ordinary concentrated acid is employed, 40–50 p.c. of the *o*-sulphonic acid is obtained (Fahlberg, Fr. Pat. 163797; D. R. P. 35211 of 1884; Fabr. de Thann, Eng. Pat. 14390 of 1901; Fr. Pat. 312797; D. R. P. 137935 of 1901; Eng. Pat. 10810 of 1897; Norton and Otten, Amer. Chem. J. 1885, 10, 140; Bourgeois, Chem. Zentr. 1900, i, 253; Reverdin, Ber. 1909, 42, 1523).

Toluene o-sulphonic acid; in small quantity together with the *p*-isomeride by dissolving toluene in hot fuming sulphuric acid (Engelhardt and Latschinoff, Zeit. f. Chem. 1869, (2) 5, 617; Wolkoff, *ibid.* (2) 6, 321; Bourgeois, Rec. trav. chim. 1899, 18, 436); by gradual addition of concentrated sulphuric acid to boiling toluene only the *p*-isomeride is formed (Chrutschoff, Ber. 1874, 7, 1167), whilst, according to Fahlberg (Ber. 1879, 12, 1048) no *m*-sulphonic acid is produced; in a yield of 40–50 p.c. by sulphonating below 100° with concentrated sulphuric acid with efficient agitation (Fahlberg and List; cf. D. R. PP. 35211, 35717 of 1884, and 137935 of 1901); from the sulphonyl chloride obtained together with the *m*- and *p*-isomerides by the action of chlorosulphonic acid on toluene (Klason and Vallin, Ber. 1879, 12, 1848; Noyes, Amer. Chem. J. 1886, 8, 176; Gilliard, Monnet and Cartier, D. R. P. 98030 of 1894); from 4-bromotoluene 2-sulphonic acid by reduction with sodium amalgam (Terry, Ann. 1873, 169, 27); from 4-nitrotoluene 2-sulphonic acid by elimination of the nitro-group (Jenssen, Ann. 1874, 172, 235); by treating diazo-derivatives of *o*-toluidine with sulphurous acid (Müller and Wiesinger, Ber. 1879, 12, 1348); by treatment of *p*-diazo-toluene *o*-sulphonic acid with sodium methoxide in methyl alcoholic solution (Moale, Amer. Chem. J. 1898, 20, 298); by warming the salts of *o*-sulphotoluene-*p*-hydrazine sulphonie acid, (CH₃)C₆H₄(SO₂H)·NH·NH·SO₃H, with potassium hydroxide (Ges. f. Chem. Ind. D. R. P. 68708 of 1892). For separation of the *o*- and *p*-acids by means of magnesium and zinc salts, see Fahlberg (Eng. Pat. 17401 of 1896; D. R. PP. 103299 of 1898, and 103943 of 1895), or by means of sulphuric acid, see Lange (Fr. Pat. 232539; D. R. P. 57391 of 1890).

Free acid, thin leaflets containing 2H₂O; NH₄A', thin leaflets; NaA' + H₂O, tables; KA' + H₂O, monoclinic plates; KA', needles; CaA'₂, leaflets; BaA'₂ + H₂O, plates; ZnA'₂ + 7H₂O; CdA'₂ + 2H₂O; PbA'₂ + 4H₂O, needles (Terry; Hübner and Post); +H₂O (Klason and Vallin); MnA'₂ + 2H₂O; CuA'₂ + 4H₂O; AgA'; MnA'₂ + 2H₂O; ZnA'₂ + 7H₂O; MgA'₂ + 7H₂O (Klason and Vallin, *loc. cit.*; Hübner and Post, Ann. 1873, 169, 1).

Chloride, by the action of chlorine on toluene *o*-sulphinic acid in presence of dilute sodium hydroxide or hydrochloric acid at temperatures below 35° (Basler Chemische Fabrik, Eng. Pat. 4525 of 1900, and 12585 of 1900; U.S. Pat. 667861; D. R. P. 124407 of 1900), or on potassium toluene *o*-sulphinate in aqueous solution (Ullmann and Lehner, Ber. 1905, 38, 729). Oil, b.p. 126°/10 mm., D₁₇^o 1.3443 (U. and L.), or b.p. 151°/33 mm., 154°/36 mm. (Davies, Chem.

Soc. Trans. 1921, 119, 878). See also Fahlberg and List (*l.c.*), and Majert and Ebers (D. R. P. 95338 of 1898); Fabr. de Thann, Eng. Pat. 14390 of 1901; U.S. Pat. 692598; Fr. Pat. 312797; D. R. P. 142116 of 1901; Eng. Pat. 2304 of 1905; M. L. B., D. R. P. 154493 of 1902; Eng. Pat. 6581 of 1897; 4525 of 1900; 11077 and 11078 of 1898; 16299 of 1903.

Bromide; by the action of bromine on an aqueous solution of toluene *o*-sulphinic acid. M.p. 13°, b.p. 137.5°–138°/10 mm.

Tröger's compound (J. pr. Chem. 1896, [2] 54, 523) contains some of the *p*-isomeride (Ullmann and Lehner, *l.c.*).

Amide; octahedra, m.p. 154° (Noyes), m.p. 156.3° (McKie, Chem. Soc. Trans. 1918, 113, 799; cf. Wolkoff, *l.c.*; Klason and Vallin, Ber. 1879, 12, 1850; Heffter, Ann. 1883, 221, 208; Miller, Chem. Soc. Trans. 1892, 61, 1030; Thomas, *ibid.* 1909, 95, 343; Noyes, *l.c.*; Fahlberg and List, *l.c.*). It can be separated from the *p*-isomeride by fractional precipitation from an alkaline solution by means of acids or by fractional crystallisation of the sodium salts (von Heyden, D. R. P. 76881 of 1892, and 77435 of 1894; cf. Barger and Givaudan, Eng. Pat. 848 of 1903; D. R. P. 154655 of 1903). When oxidised in alkaline solution with potassium manganate or potassium permanganate it yields *o*-sulphaminobenzoic acid, in neutral solution benzoic sulphinide is the chief product, whilst in acid solution the product is *o*-sulphobenzoic acid (Fahlberg and List, Ber. 1888, 21, 242; cf. Fahlberg and Remsen, Ber. 1879, 12, 469). It is converted in 4*N*-ammoniacal solution in the presence of ammonium sulphate at 40° at a platinum gauze anode into 'saccharin'; the material yield being 43.7 p.c. and the current yield 9.2 p.c. The most favourable results, however, (material yield 75.4 p.c., current yield 42.6 p.c.) are obtained by the electrolysis of a suspension in 2*N*-sodium carbonate solution at about 60° with a platinum gauze anode and a rotating lead cathode (Fichter and Löwe, Helv. Chim. Acta, 1922, 5, 60; vide SACCHARIN).

Methylamide, thin striated plates, m.p. 73°–75°, when oxidised with alkaline potassium permanganate yields potassium *o*-methylsulphaminobenzoate (Remsen and Clark, Amer. Chem. J. 1903, 30, 247).

Toluene *m*-sulphonic acid; in small quantities by sulphonation of toluene (Holleman and co-workers, *l.c.*); from *o*-bromotoluene *m*-sulphonic acid, (Müller, Ann. 1873, 169, 47) or 4-bromotoluene 3-sulphonic acid (Neville and Winther, Chem. Soc. Trans. 1880, 37, 628) and sodium amalgam; or from 2-bromotoluene 5-sulphonic acid and zinc dust in alkaline solution (Miller, Chem. Soc. Trans. 1892, 61, 1030); from *p*-toluidine 3-sulphonic acid (Pechmann, Ann. 1874, 173, 202; Neville and Winther, *l.c.*), *o*-toluidine *m*-sulphonic acid (Pagel, Ann. 1875, 176, 297) or *o*-toluidine 5-sulphonic acid (Neville and Winther, *l.c.*); by treating *m*-toluidine diazo-salts with sulphur dioxide (Müller and Wiesinger, Ber. 1879, 12, 1348); from *p*-diazo-toluene *m*-sulphonic acid by treatment with zinc dust in ethyl alcoholic solution (Griffin, Amer. Chem. J. 1897, 19, 173, 189).

The free acid forms thin deliquescent scales +H₂O (Klason and Vallin); NH₄A', scales;

NaA' + ½H₂O (Miller); + ½H₂O (Vallin, Ber. 1886, 19, 2953), +H₂O (G.); KA' + ½H₂O, scales (M.), +H₂O (K. and V.); CaA' + 2½ or 5H₂O (V.), +3H₂O (K. and V.), +2H₂O, tables (G.); BaA', +H₂O, rectangular tables (G.); ZnA', +7H₂O, thin rectangular plates (K. and V.), +6H₂O, long thin prisms; CdA', +6H₂O (V.), +7H₂O, tables (K. and V.); PbA', +H₂O (Pechmann), +2H₂O (M.; Pagel; V.), +3H₂O (K. and V.); MnA', +6H₂O (V.), +7H₂O (K. and V.); CuA', +7H₂O (V.), +4H₂O (K. and V.), +½H₂O (G.); AgA', glistening prisms (V.), rectangular tables (G.).

Chloride; oil.

Amide; monoclinic needles or tables (Noyes and Walker, Amer. Chem. J. 1886, 8, 188), hexagonal scales, fernlike aggregates from water, or monoclinic prisms from alcohol (Griffin); m.p. 108° (Klason and Vallin, *l.c.*; Klason, Ber. 1886, 19, 2887; Griffin, Amer. Chem. J. 1897, 19, 176) or 91° (Noyes, Amer. Chem. J. 1886, 8, 177). According to Noyes, the amide, m.p. 108°, is a mixture of the *o*- and *p*-isomerides. On oxidation with potassium permanganate or chromic acid mixture it yields *m*-sulphaminobenzoic acid.

Toluene *p*-sulphonic acid; chief product of sulphonation of boiling toluene (Deville, Ann. Chim. 1841, (3) 3, 172; Fittig and Tollens, Ann. 1864, 131, 310; Märcker, *ibid.* 1865, 136, 85; Engelhardt and Latschinoff, Zeit. f. chem. 1869 (2) 5, 617; Jaworski, *ibid.* 1865, 221; Otto and Grüber, Ann. 1867, 142, 92; 1868, 145, 10; Chrustchoff, Ber. 1874, 7, 1167; Fahlberg, Ber. 1879, 12, 1048); from toluene and chlorosulphonic acid (Klason and Vallin, Ber. 1879, 12, 1848); by the action of sulphurous acid on *p*-diazo-toluene salts (Müller and Wiesinger). Thick plates or flat prisms +H₂O (K. and V.), m.p. 92° (Norton and Otten, Amer. Chem. J. 1888, 10, 140), or 35°, b.p. 146°–147°/0 mm. (Krafft and Wilke, Ber. 1900, 33, 3208). Fusion with potash yields *p*-cresol and *p*-hydroxybenzoic acid. Fusion with sodium formate yields *p*-toluic acid (Remsen, Ber. 1875, 8, 1412). Hydrolysis with steam commences at 150° (Armstrong and Miller, Chem. Soc. Trans. 1884, 45, 148). On electrolytic oxidation in 10–20 p.c. sulphuric acid using a lead anode at 70°, it yields *p*-sulphobenzoic acid (Sebor, Zeitsch. Elektrochem. 1903, 9, 370).

NH₄A' (K. and V.); NaA' + 2H₂O, or +4H₂O, rectangular tables (Vallin, Ber. 1886, 19, 2953); KA' + H₂O, six-sided plates, prisms or trimetric crystals (Otto and Köbig, Ber. 1886, 19, 1834); BaA', crystallises in anhydrous leaflets above 30° and as needles +3H₂O below 30° (Kelbe, Ber. 1883, 16, 622); CaA', +4H₂O, monoclinic prisms (K. and V.); MgA', +6H₂O, large tables (K. and V.); ZnA', +6H₂O, tables (K. and V.); CdA', +6H₂O, tables (K. and V.); PbA', long needles (K. and V.); MnA', +6H₂O, tables (K. and V.); CuA', +6H₂O, tables or needles (K. and V.); AgA', large tables (K. and V.).

The following salts with organic bases are described by Norton and Otten (*l.c.*): NH₄(CH₃)C₆H₄SO₃, rosettes, m.p. 128°; NH(CH₃)C₆H₄SO₃, m.p. 78°; N(CH₃)C₆H₄SO₃, m.p. 92°; NH₄(C₂H₅)C₆H₄SO₃, m.p. 111°; NH(C₂H₅)C₆H₄SO₃, m.p. 85°; N(C₂H₅)C₆H₄SO₃, m.p. 65°.

Chloride; rhombic tablets or triclinic crystals (Otto and Köbig, Ber. 1888, 19, 1835), m.p. 69°, b.p. 145°-146°/15 mm. (Krafft and Roos, Ber. 1892, 25, 2259), 136°-1°/11 mm., 151°-6°/20 mm. (Bourgeois, Rec. trav. chim. 1899, 18, 436), 164°/33 mm. (Davies, Chem. Soc. Trans. 1921, 119, 878), 80°/0 mm. (Krafft and Wilke, l.c.). On warming with alkaline solutions, or better, by boiling with 80 p.c. sulphuric acid, it yields *o*-chloro-toluene (Ges. für. Chem. Ind., D. R. P. 133000 of 1901). Toluene *p*-sulphonyl chloride when heated with ethylene chlorohydrin yields β -chloroethyltoluene *p*-sulphonate, b.p. 210°/21 mm., which is a valuable reagent for introducing the chloroethyl-group into amines and phenols (Clemo and W. H. Perkin, Chem. Soc. Trans. 1922, 121, 642; B. D. C., W. H. Parkin and Clemo, Eng. Pat. 193618 of 1922).

Toluene *p*-sulphonyl chloride when treated at 70°-75° with antimony pentachloride yields a mixture of the 2:6-di- and 2:3:6-trichloro-derivatives, converted on hydrolysis into the corresponding sulphonic acids, or, on removing the acyl-group into a mixture of 2:6-di- and 2:3:6-trichlorotoluene (Geigy & Co., D. R. P. 210856 of 1908). When electrolysed in 2*N*. alcoholic hydrochloric acid solution it yields as the main product, the corresponding sulphonic acid, which is partially converted into its ethyl-ester, and decomposed thus:

In the presence of titanium trichloride using a nickel gauze cathode, the main product is *p*-tolyl mercaptan, which is also produced by reducing a suspension of the sulphonyl chloride in aqueous sulphuric acid at 80° at a lead cathode (Fichter and Bernouilli, Zeitsch. Elektrochem. 1907, 13, 310). Toluene *p*-sulphonyl chloride on nitration on the water-bath with fuming nitric and concentrated sulphuric acids yields 2:6-dinitrotoluene 4-sulphonic acid in almost theoretical yield (Reverdin and Crépieux, Ber. 1901, 34, 2992).

Bromide; from toluene *p*-sulphonic acid and bromine. Monoclinic prisms, m.p. 96° (Otto, Ann. 1867, 142, 98) or 93°-94° (Zincke and Frohberg, Ber. 1910, 43, 837).

Iodide; from sodium toluene *p*-sulphinate and iodine. Yellow powder, m.p. 84°-85°. By heating with water or alcohol it is decomposed into toluene *p*-sulphonic acid, iodine and little *p*-toluene disulphoxide, whilst by heating with potassium hydroxide it yields toluene *p*-sulphonic acid. Zinc-ethyl yields the zinc sulphinate (Otto and Trüger, Ber. 1891, 24, 479).

Ethyl ester; from the chloride (Jaworski, Zeit. f. chem. 1865, 1221) or the bromide (Otto, Ann. 1867, 142, 100); by treating the ethyl ester of toluene *p*-sulphonic acid with potassium permanganate and acetic acid (Otto and Rössing, 1890, 19, 1236). Monoclinic crystals, m.p. 32°-33°, b.p. 73°/15 mm., $D_{20}^{25} 1.1736$, $n_D^{20} 1.5776$ (Krafft and Roos, Ber. 1892, 25, 2259).

The phenyl, *o*-, *m*-, and *p*-tolyl esters melt at 95°-96°, 54°-55°, 51°, and 69°-70° respectively (Reverdin and Crépieux, Bull. Soc. chim. 1901, (3) 25, 1044; 1902, (3) 27, 741; Ber. 1902, 35, 214, 1422). For other esters, see Reverdin and Crépieux (l.c.); Bamberger and Rietz (Ber. 1901, 34, 338). For the use of

methyl- and ethyl-toluene *p*-sulphonates as alkylating agents, see Ullmann and Wenner (Ann. 1903, 327, 120); Finzi (Annali. Chim. Appl., 1925, 15, 41).

Anhydride; formed together with the chloride by heating toluene *p*-sulphonic acid with pure thionyl chloride. Crystals, m.p. 122°-125° (Meyer and Schlegel, Monatsh. 1913, 34, 561).

Amide; leaflets, m.p. 137°-137.5° (Claesson and Wallin, Ber. 1879, 12, 1853; McKie, Chem. Soc. Trans. 1918, 113, 799). It forms a potassium salt, $C_6H_4SO_3NHK$ (Wolkoff, Ber. 1872, 5, 140; Zeit. f. Chem. 1870, (2) 6, 323, 580). **Methylamide**, m.p. 76°-77°; **ethylamide**, m.p. 64°; **dimethylamide**, m.p. 76°; **diethylamide**, m.p. 59°-60°; **anilide**, m.p. 103°; **methylanilide**, m.p. 95°; **ethylanilide**, m.p. 88°; ***p*-toluidide**, m.p. 118° (van Romburgh, Proc. K. Akad. Wetensch. Amsterdam, 1902, 616; cf. Rec. trav. chim. 1884, 3, 7; Jaeger, Proc. K. Akad. Wetensch. Amsterdam, 1920, 23, 347; Remsen and Palmer, Amer. Chem. J. 1886, 8, 241; Marckwald and von Droste-Hulshoff, Ber. 1898, 31, 3262; 1899, 32, 561; D. R. P. 105870 of 1897); **propylamide**, m.p. 52° (Marckwald, Ber. 1899, 32, 3509); **propylisobutylamide**, m.p. 59° (M.); **bromoallylamide**, m.p. 45°-46° (Rudziak, Ber. 1901, 34, 3543); **benzylamide**, m.p. 116° (Chattaway, Chem. Soc. Trans. 1905, 87, 145); **benzylmethylamide**, m.p. 95° (Holmes and Ingold, Chem. Soc. Trans. 1925, 127, 1813); **anilide**, m.p. 103° (R. and P.); **3-iodoanilide**, m.p. 128° (Ullman, Ann. 1904, 332, 38); **2:4-dinitroanilide**, m.p. 219°; ***o*-toluidide**, m.p. 108°, on nitration yields the 5-nitro-*o*-toluidide, and a little 3-nitro-*o*-toluidide and 3:5-dinitro-*o*-toluidide, which, on hydrolysis, yield 5-nitro-*o*-toluidine, 3-nitro-*o*-toluidine, and 3:5-dinitro-*o*-toluidine, respectively; ***m*-toluidide**, m.p. 114°; ***p*-toluidide**, m.p. 117°, on nitration yields the 3-nitro-*p*-toluidide; ***p*-phenetide**, m.p. 106°-107°; the amides with *o*-, *m*-, and *p*-phenylenediamine melt at 201°-202°, 172° and above 250°, respectively; ***di-p*-toluene-sulphonbenzide**, m.p. 243°, and its **dimethyl-derivative**, m.p. 235° (Reverdin and Crépieux; Willstätter and Kalb, Ber. 1904, 37, 3761). For other derivatives, see Esch and Marckwald (Ber. 1900, 33, 762); Howard and Marckwald (l.c.); von Meyer (J. pr. Chem. 1901, 63, 167). For *N*-halogen derivatives of the amides see Chattaway (Chem. Soc. Trans. 1905, 87, 145).

Benzylsulphonic acid; by oxidising benzyl disulphide with nitric acid (Barbaglia, Ber. 1872, 5, 270, 688); by boiling benzyl chloride with aqueous potassium or sodium sulphite (Böhler, Ann. 1870, 154, 50; 1883, 221, 216; Mohr, ibid. 1883, 221, 216; Otto and Lüden, Ber. 1890, 13, 1286); by heating benzyl methyl ketone with sulphuric acid (Krocker, Ber. 1888, 19, 2625). Very hygroscopic crystals. The potassium salt when heated with phosphorus pentachloride yields benzotrichloride; with potassium cyanide it yields benzyl cyanide (Barbaglia, l.c.), and on fusion with potassium hydroxide it yields toluene and benzoic acid (Otto, Ber. 1890, 13, 1288).

NH_4A' ; $KA' + H_2O$, rhombic, m.p. 104°; $CaA' + 2H_2O$, crystalline scales; $FeA' + 2H_2O$, $PbA' + Pb(OH)_2$, crystalline powder.

tate; PbA' , plates; AgA' , crystalline scales (Böhler, *l.c.*).

The *o*-chloro-derivative, obtained by treating *o*-chlorobenzyl chloride with sulphites, forms a dinitro-derivative whose calcium salt forms needles. The free acid on heating with ammonia at 135° – 140° yields a nitroaminohydroxybenzyl sulphonic acid (Kalle and Co., D. R. P. 141783 of 1902).

Chloride; prisms, m.p. 92° . Decomposes on heating into benzyl chloride and sulphur dioxide (Pechmann, Ber. 1873, 6, 534; Otto and Lüders, Ber. 1880, 13, 1286).

Amide; small prisms, m.p. 102° (O. and L.) or 105° (P.).

(a) *Toluene 2:4-disulphonic acid*; by sulphonation of toluene, toluene-*o*- or *p*-sulphonic acid (Hakansson, Ber. 1872, 5, 1085; Claesson and Berg, *ibid.* 1880, 13, 1170; Gnehm and Forrer, *ibid.* 1877, 10, 542, 1276; Klason, *ibid.* 1887, 20, 354; Senhofer, Ann. 1872, 164, 126); by the action of iodine and potassium iodide on potassium toluene disulphinate (Tröger and Meine, J. pr. Chem. 1903, (2) 68, 313); by heating toluene *p*-sulphonyl chloride with sulphuric acid (Fahlberg, Ber. 1879, 12, 1052; Amer. Chem. J. 1879, 1, 170; 1880, 2, 182); from *p*-toluidine 2-sulphonic acid and *o*-toluidine 4-sulphonic acid by the xanthate method (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 754).

$(\text{NH}_4)_2\text{A}'' + \text{H}_2\text{O}$; $\text{K}_2\text{A}'' + \text{H}_2\text{O}$; $\text{BaA}'' + \text{H}_2\text{O}$, silky needles (W. and B.) or $\text{BaA}'' + (?)2\text{H}_2\text{O}$, prisms (H.); $\text{ZnA}'' + 8\text{H}_2\text{O}$; $\text{CuA}'' + 8\text{H}_2\text{O}$, four-sided prisms; $\text{As}_2\text{A}'' + 2\text{H}_2\text{O}$ (Senhofer).

Chloride; elongated prisms or prismatic needles, m.p. 56° (W. and B.) or 51° – 52° (H.).

Bromide; white solid, m.p. 78° (Tröger and Meine).

Amide; prisms, m.p. 185° – 186° . On oxidation with potassium permanganate it yields disulphaminobenzoic acid (Fahlberg).

Anilide; small prisms or tufts of needles, m.p. 187° (W. and B.).

o-Toluidide; m.p. 170° – 171° (T. and M.).

m-Toluidide; m.p. 138° (T. and M.).

(β) *Toluene 2:5-disulphonic acid*; by sulphonation of toluene; by heating toluene *o*-sulphonic acid with fuming sulphuric acid at 160° (Hakansson, *l.c.*), or toluene *m*-sulphonic acid with sulphuric acid at 180° (Klason, *l.c.*); from *o*-toluidine 5-sulphonic acid by replacing the amino-group by a mercaptan group and oxidising the thiocresol sulphonic acid obtained with permanganate (Klason, Ber. 1887, 20, 354); from *p*-toluidine 2:5-disulphonic acid by conversion into the hydrazine and treatment of the latter with copper sulphate, or from *o*-toluidine 5-sulphonic acid by the xanthate method (Wynne and Bruce).

$\text{K}_2\text{A}'' + \text{H}_2\text{O}$; $\text{BaA}'' + \text{H}_2\text{O}$.

Chloride; four-sided plates or prisms, m.p. 98° (W. and B.).

Amide; microscopic prisms, m.p. 224° (K.).

Anilide; slender prismatic needles, m.p. 178° (W. and B.).

(c) *Toluene 2:6-disulphonic acid*; by reduction of 4-bromo- or 4-chlorotoluene 2:6-disulphonic acid with sodium amalgam (Kornatzki, Ann. 1883, 221, 199; Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 771).

$\text{K}_2\text{A}''$, anhydrous flat prisms; $\text{BaA}'' + 2\text{H}_2\text{O}$,

rhombs (above 50°), or $+4\text{H}_2\text{O}$, flat needles (below 50°).

Chloride; monoclinic prisms, m.p. 88° .

Amide; long slender needles, melting above 260° (Kornatzki).

Anilide; minute diamond-shaped prisms, m.p. 162° (W. and B.).

Toluene 3:4-disulphonic acid; from *p*-toluidine 3-sulphonic acid by conversion into *p*-thiocresol 3-sulphonic acid and oxidation of the latter with potassium permanganate (Klason Ber. 1887, 20, 356), or by diazotisation, treatment with potassium xanthate, saponification and oxidation with potassium permanganate (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 751).

$\text{K}_2\text{A}'' + \text{H}_2\text{O}$, needles; $\text{BaA}'' + 2\text{H}_2\text{O}$, prisms.

Chloride; scales, m.p. 111° , or prismatic crystals, m.p. 70° – 80° , from benzene, containing benzene of crystallisation, which is lost rapidly on exposure to air when the melting-point rises to 111° (Klason; Wynne and Bruce).

Amide; m.p. 235° – 239° (slight decomp.) (Klason).

Anilide; small prisms or clusters of minute plates, m.p. 190° (W. and B.).

(γ or δ) *Toluene 3:5-disulphonic acid*; from *o*-toluidine 3:5-disulphonic acid by conversion into the hydrazine and treatment with copper sulphate (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 748); together with the 2:5-acid by sulphonation of toluene *m*-sulphonic acid (Klason, Ber. 1886, 19, 2889; 1887, 20, 352); by treatment of *p*-iodotoluene disulphonic acid with sodium amalgam (Limpricht and Richter, Ber. 1885, 18, 2179; Richter, Ann. 1885, 230, 326).

$\text{K}_2\text{A}''$, anhydrous microscopic scales; $\text{BaA}'' + 3\frac{1}{2}\text{H}_2\text{O}$, small scales, becoming anhydrous on exposure to air (W. and B.). The product obtained by Richter is the 3:5-disulphonic acid and not the 2:6- or 2:3- isomeride, as he was led to believe from the experiments of Hasse (Ann. 1885, 230, 286), whilst the compound described by Hasse is not the 3:5-acid.

Chloride; pale yellow prismatic crystals, m.p. 95° (W. and B.) (Hasse gives m.p. 132°).

Amide; short prisms, m.p. 214° (K.) or 216° (R.) (Hasse gives m.p. above 230°).

Anilide; thin scales, m.p. 153° (W. and B.).

Toluene 2:4:6-trisulphonic acid; by heating 1 mol. of potassium toluene 2:4-disulphonate with 3 mols. of chlorosulphonic acid at 240° . The product is converted, *via* the barium and potassium salts, into the sulphonyl chloride, which is then heated with 12 parts of water at 130° – 140° .

Long slender needles $+6\text{H}_2\text{O}$, which lose $3\text{H}_2\text{O}$ at 100° and melt at 145° .

$\text{KA}''' + 3\frac{1}{2}\text{H}_2\text{O}$, large rhombic tables; $\text{Ba}_2\text{A}_2''' + 14\text{H}_2\text{O}$; $\text{Pb}_2\text{A}_2''' + 8\text{H}_2\text{O}$, amorphous crystals (Klason, Ber. 1881, 14, 307).

Chloride; tables, m.p. 153° (K.).

Amide; microscopic crystals, m.p. above 300° (K.).

4-Fluorotoluene 2-sulphonic acid; from *p*-toluidine 2-sulphonic acid.

$\text{KA}' + 2\text{H}_2\text{O}$, large scales; $\text{BaA}' + \text{H}_2\text{O}$, small scales.

Chloride; oil, b.p. 145° – $150^{\circ}/20$ mm.

Amide; large prisms or long white needles, m.p. 140° or 155° . When oxidised with per-

manganate it yields *p*-chlorobenzoic sulphinide, 'fluoraccharin,' colourless needles or rhombs, m.p. 200°, which is very sweet but has a somewhat bitter after-taste (Roode, Amer. Chem. J. 1891, 13, 219; Holleman, Rec. trav. chim. 1906, 25, 330).

p-Chlorotoluene on sulphonation yields chiefly 4-chlorotoluene 3-sulphonic acid together with 4-chlorotoluene 2-sulphonic acid (Wynne, Chem. Soc. Trans. 1892, 61, 1082; Wynne and Bruce, Chem. Soc. Proc. 1895, 11, 152; Vogt and Henninger, Ann. Chim. 1865, (4) 27, 133; Ann. 1873, 165, 362), whilst toluene *o*-sulphonic acid or its soluble salts when chlorinated in cold aqueous solution yields a mixture of 4- and 6-chlorotoluene *o*-sulphonic acids. The latter mixture is readily separable owing to the much greater insolubility of the salts of the 4-chloro-acid. Chlorination in more dilute solution at a temperature not exceeding 60° yields a mixture of dichloro- and trichlorotoluene *o*-sulphonic acids (B. D. C., Green and Herbert, Eng. Pat. 170056 of 1920).

On disulphonation with 20 p.c. fuming sulphuric acid *p*-chlorotoluene yields a mixture of the 2:6- and 2:5-disulphonic acids in the proportion of about 3 parts of the former to 1 part of the latter, together with some of the 3:5-disulphonic acid. A similar mixture is obtained also when 4-chlorotoluene 2-sulphonic acid is treated in this manner (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 768).

3-Chlorotoluene *o*-sulphonic acid; from *m*-chlorotoluene and 100 p.c. sulphuric acid.

$\text{NaA}' + \text{H}_2\text{O}$, monosymmetric rhombs; KA' , monosymmetric rhombs; $\text{BaA}'_2 + \text{H}_2\text{O}$, small nacreous plates (Wynne, Chem. Soc. Trans. 1892, 61, 1075).

Chloride; orthorhombic prisms, m.p. 53° (W.).

Amide; thin scales, m.p. 182° (W.).

4-Chlorotoluene 2-sulphonic acid; sulphonation of *p*-chlorotoluene (above) or chlorination of toluene *o*-sulphonic acid (above); from *p*-toluidine 2-sulphonic acid by the diazo-reaction (Jonsen, Ann. 1874, 172, 239; Roode, Amer. Chem. J. 1891, 13, 221; Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 761; cf. Wynne, *ibid.* 1892, 61, 1078).

$\text{NaA}' + \frac{1}{2}\text{H}_2\text{O}$, rectangular scales; KA' , anhydrous prismatic needles (W. and B.; R.), $+ \text{H}_2\text{O}$ (Hübner and Majert, Ber. 1873, 6, 793); $\text{BaA}'_2 + \text{H}_2\text{O}$, microscopic plates (H. and M.), or prismatic aggregates (W. and B.; Jonsen); $\text{CaA}'_2 + 6\text{H}_2\text{O}$ (H. and M.); $\text{PbA}'_2 + 8\text{H}_2\text{O}$ (H. and M.); $\text{CuA}'_2 + 7\text{H}_2\text{O}$ (H. and M.).

Chloride; large four-sided elongated plates, m.p. 24° (W. and B.).

Amide; slender needles, m.p. 142° (W. and B.; Heffter, Ann. 1883, 221, 209, gives m.p. 128°).

Anilide; monosymmetric plates, m.p. 144° (W. and B.).

When oxidised with potassium permanganate it yields *p*-chlorobenzoic sulphinide, pearly scales, m.p. 218°, with a sweet taste but bitter after-taste (R.). On heating at 150° with 20 p.c. fuming sulphuric acid the free acid yields a mixture of the 2:5- and 2:6-disulphonic acids in the approximate proportions of 1:3 (W. and B.).

4-Chlorotoluene 3-sulphonic acid; by sul-

phonation of *p*-chlorotoluene (Vogt and Henninger, *l.c.*); from *p*-toluidine 3-sulphonic acid by diazotisation and treatment with cuprous chloride (Wynne and Bruce, *l.c.*).

$\text{NaA}' + \text{H}_2\text{O}$, long needles or flat prisms (Wynne); $\text{NaA}' + 5\text{H}_2\text{O}$ (Hübner and Majert, *l.c.*); $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$ (Wynne), $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$, laminae, $\text{KA}' + \text{H}_2\text{O}$, rectangular plates or prismatic needles (W. and B.); $\text{BaA}'_2 + \frac{1}{2}\text{H}_2\text{O}$ (H. and M.), $\text{BaA}'_2 + \text{H}_2\text{O}$, thin scales, $\text{BaA}'_2 + 2\text{H}_2\text{O}$, rectangular prisms (W. and B.), $\text{BaA}'_2 + 7\text{H}_2\text{O}$ (Engelbrecht, Ber. 1874, 7, 796); $\text{CdA}'_2 + 2\text{H}_2\text{O}$; $\text{PbA}'_2 + 6\text{H}_2\text{O}$; $\text{CuA}'_2 + 10\text{H}_2\text{O}$. When heated with 20 p.c. fuming sulphuric acid at 150° it yields a mixture of the 2:5- and 3:5-disulphonic acids.

Chloride; large elongated hexagonal plates, m.p. 56° (W. and B.).

Amides; spear-shaped crystals, m.p. 156° (W. and B.).

Anilide; small monosymmetric prisms or needles, m.p. 188° (W. and B.).

6-Chlorotoluene 2-sulphonic acid; non-deliquescent laminae, m.p. about 72°, is obtained from the sulphonyl chloride which is produced in a yield of 38.6 p.c., together with other isomerides, by chlorinating toluene *o*-sulphonyl chloride at 75°-90° in presence of antimony pentachloride.

$\text{NaA}' + \text{H}_2\text{O}$, large laminae; $\text{BaA}'_2 + \text{H}_2\text{O}$, small lustrous flakes.

Chloride; large thick white prisms or plates, softening at 71°, m.p. 72°.

Amide; glistening scales, m.p. 180°. On oxidation with alkaline permanganate at 96°-97° in the presence of carbon dioxide, it yields 6-chloro-*o*-benzoic sulphinide ('6-chloro-saccharin'), small plates, m.p. 210°-212°. The latter product is more than half as sweet as saccharin, but has a somewhat astringent taste except in very great dilution (Davies, Chem. Soc. Trans. 1921, 119, 878).

6-Chlorotoluene 3-sulphonic acid; from *o*-chlorotoluene and fuming sulphuric acid (Hübner and Majert, *l.c.*; Wynne, Chem. Soc. Trans. 1892, 61, 1073); from *o*-toluidine 5-sulphonic acid by the diazo-reaction (Wynne, *l.c.*, 1040). It crystallises with $\frac{1}{2}\text{H}_2\text{O}$.

$\text{NH}_4\text{A}' + \text{H}_2\text{O}$; $\text{NaA}' + \frac{1}{2}\text{H}_2\text{O}$, thin plates; $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$, large quadrate tables or scales; $\text{CaA}'_2 + 2\text{H}_2\text{O}$; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, leaflets or long thin prisms; $\text{PbA}'_2 + 2\text{H}_2\text{O}$; $\text{CuA}'_2 + \frac{1}{2}\text{H}_2\text{O}$.

The potassium salt on sulphonation with 20 p.c. fuming sulphuric acid at 150° yields *o*-chlorotoluene 3:5-disulphonic acid, which is also produced by sulphonating *o*-chlorotoluene under similar conditions.

Chloride; long, pearly prisms, m.p. 60° or 65°.

Bromide; thin flat prisms, m.p. 67.5°.

Amide; thin glistening scales, m.p. 128°.

Anilide; thin irregular scales or anorthic plates, m.p. 92° (Wynne, *l.c.*; Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 731).

2-Chlorotoluene 4-sulphonic acid; from *o*-toluidine 4-sulphonic acid by diazotisation and treatment with cuprous chloride (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 764); by hydrolysis of the amide with hydrochloric acid at 150° (Payson, Ann. 1883, 221, 213).

$\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$, large hexagonal (W. and B.) or anhydrous pearly leaflets (P.

small scales; $\text{BaA}'_2 + \text{H}_2\text{O}$, thin scales (W. and B.), anhydrous (P.); CaA'_2 , glistening rhombic leaflets (P.).

Chloride; long massive prisms, m.p. 37° , b.p. $178^\circ/36$ mm. (W. and B.; Davies, Chem. Soc. Trans. 1921, 119, 860).

Amide; in the usual manner (W. and B.) or by treating the sulphonamide of diazoaminotoluene with hydrochloric acid (P.). Long slender needles, m.p. 137° (Davies).

Anilide; rhomb-shaped plates, m.p. 96° (W. and B.).

On sulphonation with 35 p.c. fuming sulphuric acid at 150° potassium *o*-chlorotoluene 4-sulphonate yields a mixture of the 4:5- and 4:6-disulphonic acids (W. and B.).

2:3-Dichlorotoluene sulphonic acid; 2:3-dichlorotoluene is stated by Wynne and Greeves (Chem. Soc. Proc. 1895, 11, 151) and Wynne (Chem. Soc. Trans. 1892, 61, 1045) to yield two sulphonic acids on sulphonation, which are separated by their barium salts. The acid from the less soluble barium salt yields a very soluble *chloride*, radiating needles, m.p. 45° , and an *amide*, m.p. 221° , whilst that from the more soluble barium salt is the 5-sulphonic acid, and yields a *chloride*, prisms, m.p. 85° , *amide*, m.p. 183° . Cohen and Dakin (Chem. Soc. Trans. 1901, 79, 1129) could only isolate one sulphonic acid, forming the sulphonamide, m.p. 222° .

$\text{NaA}' + \text{H}_2\text{O}$, large pearly leaflets; $\text{CaA}'_2 + \text{H}_2\text{O}$, leaflets; $\text{BaA}'_2 + \text{H}_2\text{O}$, leaflets (Seelig, Ann. 1887, 237, 159).

2:4-Dichlorotoluene 5-sulphonic acid; by sulphonation of 2:4-dichlorotoluene.

$\text{NaA}' + 1\frac{1}{2}\text{H}_2\text{O}$, long thin needles; $\text{CaA}'_2 + 3\text{H}_2\text{O}$, long thin needles; $\text{BaA}'_2 + 2$ or $4\text{H}_2\text{O}$ (Seelig; Wynne and Greeves, Chem. Soc. Proc. 1895, 11, 151; Cohen and Dakin).

Chloride; elongated scales or hard prisms, m.p. 71° (W. and G.; C. and D.); *amide*, m.p. 176° – 177° (W. and G.; C. and D.).

2:5-Dichlorotoluene *p*-sulphonic acid; (see 2:3:6-trichlorotoluene *p*-sulphonic acid): by chlorination of toluene *p*-sulphonic acid (B. D. C., Green and Clibbens, Eng. Pat. 169025 of 1920). *Chloride* is formed together with 2:6-dichlorotoluene *p*-sulphonyl chloride by chlorination of 2-chlorotoluene *p*-sulphonyl chloride (Davies, Chem. Soc. Trans. 1921, 119, 874).

2:5-Dichlorotoluene sulphonic acid; by sulphonation of 2:5-dichlorotoluene.

KA' , long needles which break up into a crystalline powder; $\text{NaA}' + 1\frac{1}{2}\text{H}_2\text{O}$, long slender needles; $\text{BaA}'_2 + \text{H}_2\text{O}$, diamond-shaped plates and large prismatic needles (Wynne, l.c.).

Chloride; brownish coloured tables, m.p. 43° (W.) or colourless plates, m.p. 46° (C. and D.).

Amide; long thin flat needles, m.p. 191° – 192° (W.; C. and D.; cf. Seelig, Ann. 1887, 237, 159).

2:6-Dichlorotoluene *p*-sulphonic acid; colourless deliquescent plates.

$\text{NaA}' + \text{H}_2\text{O}$, colourless fan-like needles; $\text{BaA}'_2 + 3\text{H}_2\text{O}$, minute silky needles.

Chloride; by chlorinating at 65° – 70° a fused mass of 2-chloro-*p*-toluene sulphonyl chloride for 2 hours until the necessary increase in weight has been attained. Large flat plates, m.p. 69° . A substance, hair-like colourless needles, m.p. 218° , apparently pentachlorotoluene, is obtained as a by-product.

Amide; scales, m.p. 191° (Davies, Chem. Soc. Trans. 1921, 119, 871).

2:6-Dichlorotoluene sulphonic acid; by sulphonation of 2:6-dichlorotoluene.

Chloride; prismatic needles, m.p. 60° .

Amide; m.p. 204° (Wynne and Greeves, l.c.; cf. Cohen and Dakin, l.c.).

3:4-Dichlorotoluene sulphonic acid; from 3:4-dichlorotoluene and 5 p.c. fuming sulphuric acid.

KA' , long thin prismatic needles; NaA' , long slender brittle needles; $\text{BaA}'_2 + 2(?)\text{H}_2\text{O}$, long slender needles.

Chloride; long monosymmetric prisms, m.p. 82° .

Amide; elongated prisms, m.p. 189° (Wynne, Chem. Soc. Trans. 1892, 61, 1060) or 190° – 191° (Cohen and Dakin, l.c.).

3:5-Dichlorotoluene sulphonic acid; by sulphonation of 3:5-dichlorotoluene.

Chloride; thick prisms, m.p. 45° .

Amide; needles, m.p. 168° – 169° (Wynne and Greeves; Cohen and Dakin).

2-Chlorotoluene 3:5-disulphonic acid; by sulphonating 2-chlorotoluene 5-sulphonic acid and from *o*-toluidine 3:5-disulphonic acid by the diazo-reaction. Very small needles.

$\text{K}_2\text{A}'' + 2\frac{1}{2}\text{H}_2\text{O}$, massive irregular crystals, or $+2\text{H}_2\text{O}$, small needles; $\text{BaA}'' + 4\frac{1}{2}\text{H}_2\text{O}$, minute needles.

Chloride; short slender needles, m.p. 85° .

Anilide; small elongated flat prisms, m.p. 183° (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 750).

2-Chlorotoluene 4:5-disulphonic acid; by sulphonation of potassium *o*-chlorotoluene-4-sulphonate and from *o*-toluidine 4:5-disulphonic acid by the diazo-reaction.

$\text{K}_2\text{A}'' + \text{H}_2\text{O}$, long prismatic needles; $\text{BaA}'' + 2\text{H}_2\text{O}$, small rectangular prisms (W. and B.).

Chloride; plates or monosymmetric prisms, m.p. 158° .

Anilide; small prisms, m.p. 183° (W. and B.).

2-Chlorotoluene 4:6-disulphonic acid; from 2-chlorotoluene 4-sulphonic acid and 35 p.c. fuming sulphuric acid at 150° .

$\text{K}_2\text{A}'' + 2\text{H}_2\text{O}$, large prisms; $\text{BaA}'' + 6\text{H}_2\text{O}$, microscopic prisms; $\text{BaA}'' \cdot \text{K}_2\text{A}'' + 3\text{H}_2\text{O}$, very small needles.

Chloride; octahedral prisms or four-sided plates, m.p. 88° .

Anilide; small plates, m.p. 180° (W. and B.).

4-Chlorotoluene 2:5-disulphonic acid; from *p*-toluidine 2:5-disulphonic acid. Small scales.

$\text{K}_2\text{A}'' + 2\text{H}_2\text{O}$, small scales; $\text{BaA}'' + \text{H}_2\text{O}$, minute prisms.

Chloride; very small prisms, m.p. 144° .

Anilide; small diamond-shaped scales or large prisms, m.p. 245° (W. and B.).

4-Chlorotoluene 2:6-disulphonic acid; by sulphonation of 4-chlorotoluene 2-sulphonic acid with 20 p.c. fuming sulphuric acid at 150° .

$\text{K}_2\text{A}''$, anhydrous scales; $\text{BaA}'' + 3\frac{1}{2}\text{H}_2\text{O}$, small prisms.

Chloride; large prisms or large pale-yellow monosymmetric plates, m.p. 108° .

Anilide; small lustrous scales, m.p. 188° (W. and B.).

4-Chlorotoluene 3:5-disulphonic acid; from *p*-toluidine 3:5-disulphonic acid. Long colourless needles.

$\text{K}_2\text{A}'' + 6\text{H}_2\text{O}$, long thin needles, which

rapidly becomes anhydrous on exposure to air; $\text{BaA}'' + 3\text{H}_2\text{O}$, prisms.

Chloride; small monosymmetric prisms from benzene, containing $\frac{1}{2}\text{O}_2\text{H}_2$, which is lost rapidly at 140° , or plates from light petroleum. Both forms melt at 118° with previous softening (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 740; Pope, Z. f. Krist., 1900, 31, 128).

2:3:4-Trichlorotoluene; when shaken with fuming sulphuric acid at 60° yields two sulphonic acids, α -acid, $\text{NaA}' + 4\frac{1}{2}\text{H}_2\text{O}$, fine needles or leaflets, and the β -acid, $\text{NaA}' + \text{H}_2\text{O}$, leaflets (Seelig, Ann. 1887, 237, 136).

2:3:6-Trichlorotoluene 4-sulphonic acid; obtained together with the 2:5-dichloro-isomeride by neutralising 680 grams of toluene *p*-sulphonic acid with sodium hydroxide dissolved in sufficient water to make about 11 litres and chlorinating until 10 c.c. of the solution have acquired an acidity equivalent to 5.5 c.c. of N-alkali. Nearly the whole of the sodium trichlorosulphonate crystallises, and the dichloro-sulphonate is recovered practically pure by evaporating the mother-liquor (B. D. C., Green and Clibbens, Eng. Pat. 169025 of 1920).

3:4:5-Trichlorotoluene sulphonic acid; $\text{NaA}' + \frac{1}{2}\text{H}_2\text{O}$, needles; KA' , scales; $\text{BaA}'_2 + \text{H}_2\text{O}$, scales.

Chloride; short needles, m.p. 88° (Wynne, Chem. Soc. Trans. 1892, 61, 1069).

2-Bromotoluene 4-sulphonic acid; from *o*-toluidine 4-sulphonic acid by the diazo-reaction (Hayduck, Ann. 1874, 172, 205); together with *p*-bromotoluene and *p*-bromobenzyl bromide by brominating potassium toluene *p*-sulphonate (Miller, Chem. Soc. Trans. 1892, 61, 1027).

KA' , white plates (M.); $\text{BaA}'_2 + 2\text{H}_2\text{O}$, plates (M.) or microscopic tables (H.);

$\text{PbA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$ (H.).

Chloride; m.p. 54° (H.).

Amide; microscopic prisms, m.p. 151° (H.).

2-Bromotoluene 5-sulphonic acid; from *o*-bromotoluene by sulphonation (Miller, Chem. Soc. Trans. 1892, 61, 1029; Hübner and Post, Ann. 1873, 169, 31; cf. Dmochowsky, Ber. 1872, 5, 333); from brominated *p*-toluidine 3-sulphonic acid by elimination of the amino-group (Pechmann, Ann. 1874, 173, 212); from *o*-toluidine by sulphonation and replacement of the amino-group by bromine (Pagel, Ann. 1875, 176, 394; Neville and Winther, Chem. Soc. Trans. 1880, 37, 628; Ber. 1880, 13, 1943; Wynne, Chem. Soc. Trans. 1892, 61, 1041; cf. Gerver, Ann. 1873, 169, 384).

$\text{NaA}' + \frac{1}{2}\text{H}_2\text{O}$, striated prisms; $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, rhomboidal tables; $\text{PbA}'_2 + 2\text{H}_2\text{O}$ (H. and P.) or $3\text{H}_2\text{O}$ (P.).

Chloride; elongated flat prisms, m.p. 61° (W.), 56° (N. and W.), 53° (P.).

Bromide; glistening scales, m.p. 63.5° (W.).

Amide, needles, m.p. 147° (W.; N. and W.) or 135° (P.).

2-Bromotoluene 6-sulphonic acid; in small yield, together with 2-bromotoluene 5-sulphonic acid by sulphonating *o*-bromotoluene. The two acids are separated by means of their barium salts, when the barium salt of the 5-acid crystallises first.

KA' ; $\text{BaA}'_2 + \text{H}_2\text{O}$, minute scales (Miller, l.c.).

According to Wroblewsky (Ann. 1873, 188, 186), *m*-bromotoluene when dissolved in fum.

sulphuric acid yields three sulphonic acids of which the α -acid is formed in greatest quantity. Separation is effected by means of their barium salts.

Grete (Ber. 1874, 7, 795; 1875, 8, 565; Ann. 1875, 177, 233) only obtained one acid corresponding to the α -acid of Wroblewsky.

α -Acid or 3-bromotoluene 2-sulphonic acid; $\text{BaA}'_2 + \text{H}_2\text{O}$; $\text{CaA}'_2 + 2\text{H}_2\text{O}$; $\text{SrA}'_2 + \text{H}_2\text{O}$; $\text{MgA}'_2 + 6\text{H}_2\text{O}$; $\text{PbA}'_2 + 3\text{H}_2\text{O}$; $\text{CuA}'_2 + 4\text{H}_2\text{O}$.

β -Acid or 3-bromotoluene 6-sulphonic acid; KA' ; $\text{CaA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$; $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$; $\text{PbA}'_2 + 3\text{H}_2\text{O}$.

γ -Acid; formed in smallest quantity; $\text{BaA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$.

m-Bromotoluene *o*-sulphonic acid; by bromination of *p*-toluidine 2-sulphonic acid, followed by elimination of the amino-group (Weckwarth, Ann. 1874, 172, 191).

$\text{NaA}' + \frac{1}{2}\text{H}_2\text{O}$, scales or nodules; $\text{KA}' + \text{H}_2\text{O}$, yellow rhombic plates; $\text{SrA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$, yellow needles; $\text{BaA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$, scales or plates; $\text{PbA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, grouped prisms; $\text{PbA}'_2 + 5\text{H}_2\text{O}$, yellow prisms; $\text{CuA}'_2 + \frac{1}{2}\text{H}_2\text{O}$; yellowish-green plates or thick prisms.

Chloride; liquid, solidifying in a freezing mixture.

Amide; thick yellow needles from chloroform, m.p. 162° – 165° .

This acid appears to be identical with Wroblewsky's β -acid, although some of the salts differ in the content of water of crystallisation.

3-Bromotoluene 5-sulphonic acid; from 3-bromo-*o*-toluidine 5-sulphonic acid or 5-bromo-*p*-toluidine 3-sulphonic acid by elimination of the amino-group (Neville and Winther, Chem. Soc. Trans. 1880, 41, 420; Ber. 1880, 13, 1944).

Chloride; m.p. 52° (N. and W.).

Amide; m.p. 138° – 139° (N. and W.).

Bromotoluene sulphonic acid; from toluene by sulphonation, nitration, reduction and replacement of the amino-group by bromine (Weckwarth, Ann. 1874, 172, 193; Hayduck, *ibid.* 1875, 177, 57). $\text{BaA}'_2 + \text{H}_2\text{O}$.

Chloride; oil, solidifying on cooling.

Amide; nodules, which do not melt at 230° .

4-Bromotoluene 2-sulphonic acid; chief product, together with the 3-acid by sulphonating *p*-bromotoluene (Hübner and Post, Ann. 1873, 169, 6; Zeit. f. Chem. 1871, (2) 7, 618; Miller, Chem. Soc. Trans. 1892, 61, 1026) from *p*-toluidine 2-sulphonic acid by the diazo-reaction (Jensen, Ann. 1874, 172, 237). Free acid, large plates. Oxidised by chromic acid mixture to *p*-bromosulphobenzoic acid and reduced to toluene *o*-sulphonic acid by sodium amalgam.

$\text{NaA}' + \text{H}_2\text{O}$; $\text{KA}' + \text{H}_2\text{O}$, scales (Roode, Amer. Chem. J. 1891, 13, 222); $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$ (Miller); $\text{MgA}'_2 + 8\frac{1}{2}\text{H}_2\text{O}$ (?); $\text{CaA}'_2 + 4\text{H}_2\text{O}$, rhombic needles; $\text{SrA}'_2 + \text{H}_2\text{O}$; $\text{BaA}'_2 + \text{H}_2\text{O}$; $\text{BaA}'_2 + 2\text{H}_2\text{O}$ (M.); $\text{PbA}'_2 + 3\text{H}_2\text{O}$, needles; $\text{PbA}'_2 + 2\text{H}_2\text{O}$ (M.); $\text{CuA}'_2 + 7\text{H}_2\text{O}$.

Chloride; plates, m.p. 35° (H. and P.).

Amide; long fine needles, m.p. 165° – 167° (H. and P.). When oxidised with permanganate it yields *p*-bromobenzoic sulphamide, which is somewhat sweet with a bitter after-taste (R.).

4-Bromotoluene 3-sulphonic acid; (see above); by sulphonation of *p*-bromotoluene; from *p*-toluidine 3-sulphonic acid by replacing the amino-group by bromine (K. Richter, Ann. 1873, 188, 186; Post and Reibey, *ibid.* 1874, 177, 57).

169, 7; Pechmann, *ibid.* 1874, 173, 208; Neville and Winther, Chem. Soc. Trans. 1880, 37, 631). Laminee + H_2O , m.p. $105^\circ\text{--}110^\circ$ (P.). Oxidation with chromic acid mixture yields *p*-bromobenzoic-*m*-sulphonic acid.

$\text{BaA}'_2 + 7\text{H}_2\text{O}$, long rhombic needles; $\text{SrA}'_2 + 7\text{H}_2\text{O}$; $\text{PbA}'_2 + 3\text{H}_2\text{O}$.

Chloride; oil, solidifying on keeping, m.p. 62° (P.; N. and W.).

Amide; long needles, m.p. $151^\circ\text{--}152^\circ$ (H. and P.).

2-Bromotoluene 3:5-disulphonic acid; from *o*-toluidine 3:5-disulphonic acid by the Sandmeyer reaction (Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 749; Hasse, Ann. 1885, 230, 295).

$\text{K}_2\text{A}'' + \text{H}_2\text{O}$, small needles; $\text{BaA}'' + 4\text{H}_2\text{O}$, short slender needles (W. and B.).

Chloride; white needles, m.p. 102° .

Anilide; small square prisms or irregular needles, m.p. 194° (W. and B.); the products obtained by Hasse were impure).

4-Bromotoluene disulphonic acid; by passing sulphur trioxide into a mixture of *p*-bromotoluene and sulphuric acid (Kornatzki, Ann. 1883, 221, 192). Very deliquescent crystals. On boiling with nitric acid it yields dibromonitrotoluene disulphonic acid, nitrotoluene disulphonic acid, and disulphobromobenzoic acid.

$\text{K}_2\text{A}'' + \text{H}_2\text{O}$, fine needles or large rhombic prisms; $\text{BaA}'' + 5\text{H}_2\text{O}$, thick prisms or fine needles or plates; $\text{PbA}'' + 2\text{H}_2\text{O}$, glistening needles.

Chloride; large rhombic plates, m.p. 99° (K.).

Amide; irregular crystals, m.p. above 260° (K.).

p-Bromotoluene disulphonic acid; from *p*-toluidine disulphonic acid by replacement of the amino-group by bromine (Limpriht, Ber. 1885, 18, 2179; Richter, Ann. 1885, 230, 324). Crystalline mass.

$\text{K}_2\text{A}'' + \text{H}_2\text{O}$, silky felted needles; $\text{BaA}'' + 6\text{H}_2\text{O}$, silky needles.

Chloride; prisms, m.p. 133° (R.).

Amide; long prisms, m.p. above 240° .

2:1-Dibromotoluene 5-sulphonic acid; from 2-bromotoluene 5-sulphonic acid by nitration and replacement of the nitro-group by bromine (Schäfer, Ann. 1874, 174, 365). Syrup.

$\text{NaA}' + 2\text{H}_2\text{O}$; $\text{BaA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$ (S.).

5:6-Dibromotoluene 3-sulphonic acid; from 3-bromo-*o*-toluidine 5-sulphonic acid by the Sandmeyer reaction (Wynne, Chem. Soc. Trans. 1892, 61, 1038).

$\text{NaA}' + \text{H}_2\text{O}$, long flat needles; KA' , long needles; $\text{BaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, long thin needles.

Chloride; small four-sided prisms or needles, m.p. 93° (W.).

Bromide; needles, m.p. 97° (W.).

Amide; small prisms, m.p. 214° (W.).

2:3:5-Tribromotoluene 4-sulphonic acid; from *o*-toluidine *p*-sulphonic acid by dibromination and replacement of the amino-group by bromine (Hayduck, Ann. 1874, 174, 354); or from 3:5-dibromo-*o*-toluidine 4-sulphonic acid by replacement of the amino-group by bromine (Claus and Immel, Ann. 1891, 265, 677). Free acid is deliquescent.

KA' , white needles; $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$, white mammillary mass (H.).

Chloride; syrup.

Amide; amorphous powder, charring without melting when heated.

2-(or 6)-Nitrotoluene 3-sulphonic acid; from *p*-toluidine *m*-sulphonic acid by nitration, reduction and elimination of the amino-group (Pechmann, Ann. 1874, 173, 214).

$\text{BaA}'_2 + 2\text{H}_2\text{O}$, plates.

Chloride, m.p. 58.5° (Foth, Ann. 1885, 230, 308).

Amide; m.p. 163.5° (F.).

2-Nitrotoluene 4-sulphonic acid; together with other products by nitrating *o*-nitrotoluene *p*-sulphonamide (Reverdin and Crépieux, Ber. 1901, 34, 2992); by sulphonating *o*-nitrotoluene or nitrating toluene *p*-sulphonic acid (Beilstein and Kuhlberg, Ann. 1871, 155, 18; Engelhardt and Bck, Zeit. f. Chem. 1869, (2) 5, 209; Kornatzki, Ann. 1883, 221, 180).

$\text{BaA}'_2 + 2\text{H}_2\text{O}$, scales; $\text{PbA}'_2 + 2\text{H}_2\text{O}$. On electrolysis in sulphuric acid solution it yields 6-amino-3-cresol 4-sulphonic acid (Gattermann, Ber. 1894, 27, 1938).

Chloride, by nitration of toluene *p*-sulphonyl chloride. M.p. 45° (van Romburgh, Proc. K. Akad. Wetensch. Amsterdam, 1902, 616; cf. Otto and Grüber, Ann. 1868, 145, 23) or 36° (Reverdin and Crépieux). A suspension in alcoholic sulphuric acid is readily reduced at a lead electrode below 20° . The product is 2-aminotolyl-4-mercaptan sulphate which readily changes to the sulphate of 2-aminotolyl-4-disulphide on keeping in a loosely closed vessel (Fichter and Bernouilli, Ber. 1909, 42, 4308).

Amide; four-sided rhombic columns, m.p. 128° (O. and G.), 139° (K.), 144° (Reverdin and Crépieux, Ber. 1901, 34, 2992, 2996; Neale, Ann. 1880, 203, 73). When heated with fuming nitric acid two mononitrotoluene sulphonic acids, of which one is 2-nitrotoluene 4-sulphonic acid, and a dinitrotoluene sulphonic acid are obtained (Reverdin and Crépieux, *l.c.*).

For the preparation and properties of the *anilide*, *p*-toluidide, 2:4-dinitroanilide, α - and β -naphthalide, the diamide of *o*-, *m*-, and *p*-phenylenediamine; and also the esters of phenol, *o*-, *m*-, and *p*-cresol, *p*-nitrophenol, resorcinol and nitroresorcinol, &c., see Reverdin and Crépieux (Ber. 1901, 34, 2992, 2996; 1902, 35, 314, 1439; Bull. Soc. chim. 1901, (3) 25, 1044; 1902, (3) 27, 745). For the *N*-halogen derivative of the amides, see Chattaway (Chem. Soc. Trans. 1905, 87, 145).

2-Nitrotoluene 5-sulphonic acid; by heating the diazo-compound of 2-nitro-*p*-toluidine 5-sulphonic acid with absolute alcohol at 100° (Foth, Ann. 1885, 230, 305).

KA' , reddish-yellow thick prisms; barium and lead salts, readily soluble in water and alcohol.

Chloride; thick prisms, m.p. 50° (F.).

Amide; long glistening needles, m.p. 133.5° (F.).

m-Nitrotoluene sulphonic acid; by sulphonating *m*-nitrotoluene (Beilstein and Kuhlberg, Ann. 1870, 155, 27).

$\text{BaA}'_2 + 2\text{H}_2\text{O}$, nodules; $\text{PbA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$, small granules.

von Pagel (Ann. 1875, 176, 304) has described a nitrotoluene sulphonic acid obtained by nitrating *p*-toluidine *o*-sulphonic acid and eliminating the amino-group.

$\text{BaA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$, tufts of red needles.

4-Nitrotoluene 2-sulphonic acid; by nitrating toluene *o*-sulphonic acid or by sulphonating

p-nitrotoluene (Jaworsky, Zeit. f. Chem. 1865, 1, 222; Beilstein and Kuhlberg, l.c.; Jenssen, Ann. 1874, 172, 230; Hart and Remsen, Ber. 1877, 10, 1046; Amer. Chem. J. 1879, 1, 349; Schwanert, Ann. 1877, 186, 351; Ber. 1877, 10, 29; Noyes, Amer. Chem. J. 1886, 8, 168; Haussner, Bull. Soc. chim. 1890, (3) 3, 797); by sulphonating *p*-cymene to its *o*-sulphonic acid and treating the sulphonation mixture at 40°–60° with nitric and sulphuric acids (Hintikka, Eng. Pat. 123548 of 1918; Can. Pat. 200291; cf. Osakeyhtio, D. R. P. 327051 of 1918). Prisms or rhombic tables + 2½H₂O, or prisms + aq., m.p. 133°–5° (Hintikka, Ann. Acad. Sci. Fennicae, 1917 (A), 10, 1).

For the action of sodium hydroxide, see Fischer and Hepp, Ber. 1893, 26, 2233; 1895, 28, 2281; Bender, *ibid.* 1895, 28, 422; Green and Wahl, *ibid.* 1897, 30, 3099; Kalle & Co., D. R. P. 79241 of 1892; Cassella & Co., D. R. P. 75369 of 1893; Leonhardt & Co., D. R. PP. 96107 of 1893, 46252 of 1888, and 38735 of 1886; for the action of zinc and sodium hydroxide, see Neale, Ann. 1880, 203, 80; Kornatzki, Ann. 1883, 221, 182; Bender and Schultz, Ber. 1886, 19, 3235; for the action of sodium hypochlorite, see Ris and Simon, Ber. 1897, 30, 2618; 1898, 31, 354; Geigy & Co., Fr. Pat. 269466; D. R. P. 98760 of 1897; Green and Wahl, Ber. 1897, 30, 3097; 1898, 31, 1078; Levinstein, D. R. P. 106961 of 1897; Green, Chem. Soc. Trans. 1904, 85, 1424; for dye formation by condensation with *p*-diamines in presence of alkalis, see Geigy & Co., Eng. Pat. 15671 of 1890; U.S. Pat. 455952; Fr. Pat. 208626; D. R. PP. 99290 of 1890, 75326 of 1893.

NH₄A', long prisms not decomposed by sulphuric acid at 100°; NaA' + 2H₂O, prisms (Haussner); KA' (Noyes); CaA'₂ + H₂O (Schwanert), or + 4H₂O, needles (H. and R.), or + 6H₂O (Hart); BaA'₂ + 3H₂O (Jaworsky); PbA'₂ + 3H₂O, needles (Beilstein and Kuhlberg), or + 2H₂O (Schwanert).

Chloride; rhombic tables, m.p. 43°–44°–5°.

Amide; long needles, m.p. 186°. With permanganate it is oxidised to anhydro-*p*-nitro-sulphaminobenzoic acid (Noyes).

o-Nitrobenzyl sulphonic acid; by boiling *o*-nitrobenzyl chloride with sodium sulphite solution (Eug. Fischer, Fr. Pat. 193686; D. R. P. 8722 of 1888; Marckwald and Frahne, Ber. 1898, 31, 1855). Very hygroscopic crystals.

NaA' + H₂O, silver-white scales; BaA'₂ - 3H₂O; AgA' + H₂O, needles.

m-Nitrobenzyl sulphonic acid; from *m*-nitrobenzyl chloride and sodium sulphite (Purgotti and Monti, Gazz. chim. ital. 1900, 30, ii. 247). White crystals + H₂O, m.p. 74°.

NaA' + H₂O, needles; BaA'₂ + 3H₂O; PbA'₂, needles; AgA', leaflets.

Chloride; m.p. 100°.

Amide; m.p. about 159° (decomp.).

Methyl ester; m.p. 77°.

p-Nitrobenzyl sulphonic acid; from *p*-nitrobenzyl chloride and alkali sulphites (Dahl & Co., R. P. 55138 of 1889; Purgotti and Monti, *ibid.*); by nitration of barium nitrobenzyl sulphonic acid (Böhler, Ann. 1870, 154, 55). A little acid is formed also (Mohr, *ibid.* 1883, 221, 16). If the crude mixture is oxidised with potassium permanganate *p*-nitrobenzoic acid and a little *o*-nitrobenzoic acid are formed.

The following salts are described by Böhler, and are probably those of *p*-nitrobenzyl sulphonic acid.

BaA'₂ + 2H₂O, needles; PbA'₂ + 3H₂O, needles; PbOHA', crystals.

Chloride; oil.

Amide; prisms, m.p. 204° (Mohr).

Nitrotoluene disulphonic acid; together with other acids by boiling *p*-bromotoluene disulphonic acid with fuming nitric acid (Kornatzki, Ann. 1883, 221, 198).

K₂A', fine needles.

The same acid (?) is obtained by warming toluene disulphonic acid, obtained from *p*-bromotoluene disulphonic acid and sodium amalgam, with nitric acid for 2 hours (Kornatzki, l.c., 201).

K₂A'', fine needles; BaA'' + 3H₂O, small needles.

2:6-Dinitrotoluene 4-sulphonic acid; by nitration of toluene *p*-sulphonic acid (Beilstein and Kuhlberg, Ann. 1870, 155, 21; Schwanert, Ann. 1877, 186, 342; Ber. 1877, 10, 28; cf. Marckwald, Ann. 1893, 274, 349); in almost theoretical yield by nitrating toluene *p*-sulphonyl chloride with fuming nitric and concentrated sulphuric acids (Reverdin and Crépieux, Ber. 1901, 34, 2992; Bull. Soc. chim. 1901, (3) 25, 1043).

Pale yellow flat rhombic prisms + 2H₂O, m.p. 165° (anhydrous) (Schwanert).

NH₄A', flat rhombic prisms; KA'; CaA'₂ + 2H₂O, needles or scales; BaA'₂ + 4H₂O, prisms; PbA'₂ + 2H₂O, clumps of needles; PbA'₂ + 3H₂O, laminæ (Schwanert).

Chloride; rhombic needles, m.p. 125° (S.).

Amide; white needles or laminæ, m.p. 203° (S.).

Dinitrobenzyl sulphonic acid; by warming nitrobenzyl sulphonic acid with nitric and sulphuric acids (Mohr, Ann. 1883, 221, 225).

KA', yellow leaflets; BaA'₂ + 4H₂O, yellowish nodules; PbA'₂ + 4H₂O, yellow crystals.

Chloronitrotoluene sulphonic acid; from liquid (α)-chloronitrotoluene and fuming sulphuric acid (Wroblewsky, Ann. 1873, 168, 204).

BaA'₂ + 4H₂O, needles.

5-Chloro-4-nitrotoluene 2-sulphonic acid; by successive sulphonation and nitration of *m*-chlorotoluene.

BaA'₂ + 2H₂O, yellowish-brown plates or needles (Schraube and Romig, Ber. 1893, 26, 579).

6-Chloro-4-nitrotoluene 2-sulphonic acid; slightly hygroscopic, colourless flattened needles (Davies, Chem. Soc. Trans. 1921, 119, 881, 885).

NaA' + H₂O, plates; BaA'₂ + H₂O, needles.

Chloride; formed in about 60 p.c. yield together with about 40 p.c. of 6-chloro-3-nitrotoluene *o*-sulphonyl chloride by nitrating 6-chlorotoluene *o*-sulphonyl chloride at 20°–30° (D.).

Amide; minute needles, m.p. 161°. A red colour is formed by boiling for a few minutes with ammonia solution (D.).

6-Chloro-3-nitrotoluene o-sulphonic acid (see above). Very deliquescent microscopic prisms.

NaA' + 3½ or 4H₂O, needles; BaA'₂ + 7H₂O, small needles, decomposing at about 140°.

Chloride; long colourless needles, m.p. 60°. When boiled with sodium hydroxide the sulphonyl group is replaced by hydroxyl (Davies, l.c.).

2-Chloro-5-nitrotoluene *p*-sulphonic acid; small non-deliquescent crystals which after drying at 120° melt at 123°–128° (Davies).

$\text{NaA}' + 2\text{H}_2\text{O}$, pale yellow or colourless needles; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, colourless scales.

Chloride; formed together with 2-chloro-6-nitrotoluene *p*-sulphonyl chloride, by gradual addition of 2-chlorotoluene *p*-sulphonyl chloride with stirring to a cold mixture of nitric acid (D 1.5) and sulphuric acid.

Large colourless prisms, m.p. 99.2° (D.).

Amide, small needles, m.p. 181° (D.).

2-Chloro-6-nitrotoluene *p*-sulphonic acid (see above); deliquescent plates.

NaA' , colourless microscopic plates; KA' , colourless laminæ; $\text{BaA}'_2 + 3\text{H}_2\text{O}$, colourless leaflets (Davies).

Chloride; long colourless needles, m.p. 70° (D.).

Amide; needles or scales, m.p. 182° (D.).

***o*-Bromonitrotoluene *m*-sulphonic acid**; by nitration of barium-*o*-bromotoluene sulphonate (Müller, Ann. 1873, 169, 42; Pagel, *ibid.* 1875, 176, 299).

Free acid is crystalline and very deliquescent.

$\text{NaA}' + \text{H}_2\text{O}$; KA' ; $\text{BaA}'_2 + \text{H}_2\text{O}$, small needles or nodules; $\text{PbA}'_2 + 2\text{H}_2\text{O}$, microscopic crystals.

***o*-Bromonitrotoluene *p*-sulphonic acid**; by nitration of barium *o*-bromotoluene-*p*-sulphonate with nitric acid (D 1.5) (Hayduck, Ann. 1874, 174, 347); from *o*-toluidine *p*-sulphonic acid by nitration and replacement of the amino-group by bromine (Hayduck, *ibid.* 1874, 172, 219). Microscopic needles.

$\text{BaA}'_2 + 3\text{H}_2\text{O}$, needles.

Chloride; crystals which do not melt at 220°.

Amide; does not melt at 200°.

***m*-Bromonitrotoluene *o*-sulphonic acid**; by nitration of barium (β) *m*-bromotoluene *o*-sulphonate (Wroblewsky, Ann. 1873, 168, 169).

$\text{CaA}'_2 + 4\frac{1}{2}\text{H}_2\text{O}$, large prismatic crystals; $\text{BaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, needles; $\text{PbA}'_2 + 3\text{H}_2\text{O}$, prismatic crystals.

***m*-Bromonitrotoluene *o*-sulphonic acid**; by nitration of *m*-bromotoluene *o*-sulphonic acid (Weckwarth, Ann. 1874, 172, 200).

NaA' , yellow granules; $\text{CaA}'_2 + 5\text{H}_2\text{O}$, pale yellow prisms; $\text{BaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, yellow needles.

Nitro-*p*-bromotoluene *o*-sulphonic acid; by nitrating *p*-bromotoluene *o*-sulphonic acid (Hässelbarth, Ann. 1873, 169, 22). Deliquescent laminæ.

$\text{BaA}'_2 + 2\text{H}_2\text{O}$; $\text{SrA}'_2 + 7\text{H}_2\text{O}$; $\text{PbA}'_2 + 3\text{H}_2\text{O}$; $\text{CuA}'_2 + 6\text{H}_2\text{O}$; AgA' .

Nitro-*p*-bromotoluene *m*-sulphonic acid; by nitrating barium *p*-bromotoluene *m*-sulphonate (Hässelbarth, *l.c.*). Small deliquescent needles.

$\text{BaA}'_2 + 5\text{H}_2\text{O}$ or H_2O ; $\text{SrA}'_2 + 5\text{H}_2\text{O}$;

$\text{PbA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$.

Dibromonitrotoluene sulphonic acid; together with other acids by boiling *p*-bromotoluene disulphonic acid with nitric acid (Kornatzki, Ann. 1883, 221, 197).

$\text{KA}' + \text{H}_2\text{O}$, nodules; $\text{BaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, thin plates.

AMINO DERIVATIVES.

***o*-Toluidine**; by reduction of *o*-nitrotoluene (Beilstein and Kuhlberg, Ann. 1871, 158, 77);

by catalytic reduction by passing the vapours mixed with hydrogen over heated reduced copper or nickel (Sabatier and Senderens, Compt. rend. 1901, 133, 321); and by other methods of catalytic reduction (Hänke and Browne, J. Physikal. Chem. 1923, 27, 52); by heating 1 part of *o*-cresol with 1 part of ammonium chloride and 4 parts of ammonium-zinc chloride for 40 hours at 330°–340° (Merz and Müller, Ber. 1887, 20, 547); together with *p*-toluidine by the action of hydroxylamine on toluene in presence of aluminium or ferric chloride (Graebe, Ber. 1901, 34, 1778). Colourless, thick, refractive liquid, which does not solidify at –20°, b.p. 199.7°/760 mm. (Kahlbaum, Zeitsch. physikal. Chem. 1898, 26, 621) or 198.4°–198.5°/735.4 mm. (Brühl, Ann. 1880, 200, 189); D_4^{25} 1.0112; D_{15}^{25} 1.0031; D_{25}^{25} 0.997; D_{50}^{50} 0.9852 (Perkin, Chem. Soc. Trans. 1896, 69, 1245); D_{30}^{30} 1.003; D_{25}^{25} 0.998 (B. and K.); magnetic rotatory power at 15° 17.18 (Perkin); heat of combustion at constant volume 963.8 Cal.; at constant pressure 964.7 Cal. (Petit, Ann. Chim. 1889, [6] 18, 152; Compt. rend. 1888, 107, 266); refractive index, see Brühl (Zeitsch. physikal. Chem. 1895, 16, 216); surface tension, Dutoit and Friderich (Compt. rend. 1900, 130, 328); cryoscopic behaviour, Ampola and Rimatori, (Gazz. chim. ital. 1897, 27, i. 43, 63). May be separated from *p*-toluidine by means of the acid oxalates (Ihle, J. pr. Chem. 1876, (2) 14, 449; Bindschedler, Ber. 1873, 6, 448; Miniati, Booth and Cohen, J. Soc. Chem. Ind. 1887, 6, 418); by freezing (Rosenstiehl, Bull. Soc. chim. 1871, (2) 17, 7); by means of the nitrate (Schad, Ber. 1873, 6, 1361); by means of the hydrochloride, sulphates or phosphates (Lewy, Zeitsch. anal. Chem. 1884, 23, 269; Ber. 1886, 19, 1717, 2728; D. R. P. 22139 of 1882; cf. Wülling, Ber. 1886, 19, 2132). The crude product contains about 63 p.c. *o*-, 2 p.c. *m*-, and 35 p.c. *p*-toluidine.

According to Friswell (J. Soc. Chem. Ind. 1908, 27, 258) the best method of separation is to freeze in presence of water or ice. *p*-Toluidine forms a hydrate (Walker and Beveridge, Chem. Soc. Trans. 1907, 91, 1797) which can be readily separated from the other isomerides. A full description of the method and apparatus is given by Friswell.

The proof that 2-aminotoluene is identical with 6-aminotoluene is given by Wroblewsky (Ann. 1878, 192, 213).

Estimation of aniline and *o*- and *p*-toluidine, see Reinhardt, Zeitsch. anal. Chem. 1894, 33, 90; Dobriner and Schranz, *ibid.* 1895, 34, 734; Liebmann and Studer, J. Soc. Chem. Ind. 1899, 18, 111; for estimation of small quantities of *p*-toluidine in *o*-toluidine, see Haenemann, Zeitsch. anal. Chem. 1887, 26, 750; estimation of *o*- and *p*-toluidine by specific gravity determination, see Zeitsch. anal. Chem. 1885, 24, 489; by solidification point of the mixed acetyl derivatives (Holleman, Rec. trav. chim. 1900, 27, 458; Proc. K. Akad. Wetensch. Amsterdam, 1904, 7, 395).

For other methods, see Raube, Chem. Zeit. 1891, 15, 116, 179. For the two modifications of *o*-toluidine, see Ostromislensky, Zeitsch. physikal. Chem. 1906, 57, 341).

A colour test to distinguish between aniline

and the three toluidines is described by Murray (Chem. News, 1925, 130, 23).

Salts (see Beilstein and Kahlberg, Ann. 1870, 156, 76; Rosenstiehl, *l.c.*), $B'HCl + H_2O$, scales, m.p. $214.5-215^\circ$ b.p. $240.2^\circ/728$ mm. or $242.2^\circ/760$ mm. (Ullmann, Ber. 1898, 31, 1699); $B'H_2Cl_2.CuCl_2$ (Pomey, Compt. rend. 1887, 104, 365); $B'HBr$, trimetric prisms (Stadel, Ber. 1883, 16, 28); $B'HI$, slender rhombic prisms (Stadel); $B'HNO_3$, leaflets; $B'H_2SO_4$, small crystals; $B'H_2SO_4$ (Wellington and Tollens, Ber. 1885, 18, 3313); $B'H_2SO_4 + H_2O$ (Hitzel, Bull. Soc. chim. 1894, (3) 11, 1054); $B'H_3PO_4$ (Lewy, Ber. 1886, 19, 1718); $B'C_2H_5ClO_2$, m.p. 95° (Reisser, Ber. 1888, 21, 1260); oxalate, small plates; $B'H_2FeC_2N_4$ (Eisenberg, Ann. 1880, 205, 271; Ber. 1879, 12, 2234); $B'H_2SnCl_4$, silky needles, m.p. 164° ; $B'H_2SnCl_4 + H_2O$, short pale pink needles, beginning to decompose at 210° (Druce, Chem. Soc. Trans. 1918, 113, 716); ($B'HC$), $ZnCl_2 + 2H_2O$, tables (Base, Amer. Chem. J. 1898, 20, 653); $B'2HgCl_2$, plates (Swan, *ibid.* 1898, 20, 622); $B'HC.HgCl_2$ (Swan); ($B'HC$), $HgCl_2$ (Swan); $B'HC.HgBr_2$ (Swan); ($B'HC$), $SnCl_2 + \frac{1}{2}H_2O$, colourless prisms (Slagle, Amer. Chem. J. 1898, 20, 640); ($B'HC$), $SnCl_2 + 2H_2O$, (Slagle); ($B'HC$), $SbCl_3$ (Higbee, *ibid.* 1900, 23, 150); ($B'HC$), $BiCl_3$ (Hauser and Vanino, Ber. 1900, 33, 2271); ($B'HB$), $ZnBr_2 + 2H_2O$ (Base); ($B'HB$), $SbBr_3$ (Higbee); $B'H_2PtCl_4$, decomposed by boiling water, unlike the salt of *p*-toluidine (de Coninck, Bull. Soc. chim. 1886, 45, 131); $B'_2ZnCl_2 + 2H_2O$ (Lachovich, Monat. 1888, 9, 513); B'_2HgCl_2 , m.p. 115° (lein, Ber. 1878, 11, 743); B'_2MnCl_2 ; B'_2gBr_2 , leaflets, m.p. 104° (Klein, Ber. 1879, 12, 835); B'_2ZnBr_2 (Leeds, Jahresbericht, 1880, 503); B'_2ZnI_2 ; B'_2CdI_2 ; $B'_2HgC_2N_4$; $H_2FeC_2N_4$; $B'_2H_2Cu_2(SO_4)_2$ (Deniges, Compt. rend. 1870, 112, 870); $B'_2HgH_2(SO_4)_2 + H_2O$; H_2PO_4 and $B'_2H_2PO_4$ could not be prepared; $HSCN(CN)(SCN)_2.2NH_3$, red plates (Christensen, pr. Chem. 1892, (2) 45, 362); *picrate* mononitric crystals, m.p. $212-215^\circ$ (Jerusalem, Chem. Trans. 1909, 95, 1284; Carrasso and Padova, ti R. Accad. Lincei, 1906, (v.) 15, i, 699). $HISbI_3$, red needles (Higbee); ($B'HI$), $(SbI_3)_2$, orange leaflets (H.); B'_2MgCl_2 (Tombeck, mpt. rend. 1896, 124, 963, 1532; Ann. Chim. (7) 21, 397); B'_2ZnBr_2 (Tombeck, Ann. chim. 1900, (7) 21, 466); B'_2CdCl_2 ; B'_2CdBr_2 ; B'_2CdSO_4 ; B'_2AgNO_3 ; $B'_2Ag_2SO_4$; $3B' + 2SiF_6$ (Pomey and Jackson, Amer. Chem. J. 1888, 10, 2). *Chlorate*, white plates exploding at 88 (atta and Choudhury, J. Amer. Chem. Soc. 16, 38, 1079); $B'CdCl_2$, tables (Lachowicz, Monat. 1889, 10, 898); $B'HgCl_2$ (Lachowicz); $B'HgCl_2$ (7), m.p. $113-115^\circ$ (Klein, Ber. 1878, 11, 744); $2B'HgBr_2$, laminated crystals, m.p. -104° (Klein, Ber. 1880, 13, 835); $2B'HgI_2$, decomposes at $40-50^\circ$ (Klein); $4B' + AgNO_3 + AgNO_3$ (Lachowicz, Monat. 1889, 10, 3B' + $2CuSO_4 + H_2O$ (Lachowicz); Br_2 ; $2B'ZnI_2$; $2B'CdI_2$; $2B'HgCl_2$; $(CN)_2$; $2B'MnCl_2$ (Leeds). *Benzene sulfo acid salt*, m.p. 127° (Norton and Weston, Amer. Chem. J. 1888, 10, 135); *toluene p-sulfo acid salt*, long prisms, m.p. 180° and *Oliven*, *ibid.* 144); *amide sul.* $C_6H_4NOHSO_3NH_2$, m.p. 131° (and Ber. 1894, 2162); *toluene*

succinic acid salt, $(C_6H_4N)_2C_4H_4Cl_2O_4 + C_6H_5OH$, crystalline powder (van der Riet, Ann. 1894, 280, 232); *toluene p-sulphonic acid salt*, needles, m.p. 124° (Hälsig, J. pr. Chem. 1897, (2) 56, 217); B'_2Ca (Erdmann and Smitten, Ann. 1908, 361, 52).

o-Toluidine forms precipitates with salts of the rare metals (Jefferson, J. Amer. Chem. Soc. 1902, 25, 540).

o-Toluidine dissolved in diluted sulphuric acid and treated with chromic acid and sulphuric acid yields a blue colour, converted into red-violet on dilution (Rosenstiehl, Bull. Soc. chim. 1868, (2) 10, 200), whilst a solution of *o*-toluidine in diluted sulphuric acid gives an orange coloration with nitric acid (Lorenz, Ann. 1874, 172, 180). When an equal volume of water is added to a solution of the base in ether, and a very dilute solution of bleaching powder is added drop by drop, the aqueous layer is coloured yellow or brown, and the ethereal layer on shaking with sulphuric acid colours this reddish-violet (Rosenstiehl). If a trace of a salt of *o*-toluidine be added to a solution of a salt of 2:5-toluylenediamine, followed by ferric chloride, potassium dichromate, or manganese dioxide, a green colour is formed (distinction from *m*- and *p*-toluidine) (Nietzki, Ber. 1877, 10, 1157).

When passed through a hot tube *o*-toluidine is converted into ditolylamine, with evolution of ammonia and hydrogen (Seyberth, Ber. 1896, 29, 2594), whilst under the influence of an electric discharge it yields a little ammonia and forms a strongly basic polyamine (Berthelot, Compt. rend. 1898, 126, 780). It is oxidised in alkaline solution forming azotoluene, oxalic acid and ammopla, whilst in acid solution it forms quinones. Azoderivatives are formed also with nitric acid (Nietzki, Ber. 1877, 10, 662; Ullmann and Forgan, Ber. 1901, 34, 3805; cf. Bradshaw, Amer. Chem. J. 1906, 35, 326). Its hydrochloride when electrolysed or when treated with potassium dichromate yields dyestuffs (Goppels-roeder, Dingl. poly. J. 1877, 223, 347, 634; Coninck, Compt. rend. 1898, 127, 1221).

o-Toluidine printed on the fibre can be oxidised to a moderately permanent dark violet dye by means of sodium chlorate and potassium ferrocyanide; *m*-toluidine under these conditions yields a blackish-violet colour and *p*-toluidine a chestnut-brown colour (Kirpitschnikoff, Zeitsch. Farb. Text. Ind. 1905, 4, 233).

It gives a violet colouring matter with thallium chloride (Renz, Ber. 1902, 35, 2768). When treated with hydrogen in the presence of reduced nickel it yields methyl cyclo-hexylamine (Sabatier and Senderens, Bull. Soc. chim. 1904, (3) 31, 769).

It reacts with diazo-compounds (Mehner, J. pr. Chem. 1902, 65, 401); with methylene iodide (Senier and Goodwin, Chem. Soc. Trans. 1902, 81, 280); with phenyl urethane (Dixon, *ibid.* 1901, 79, 102); with phosphoryl trithiocyanate (*ibid.* 541); with a number of aldehydes (Kilbner and Peltzer, Ber. 1900, 33, 3480; Fosse, Bull. Soc. chim. 1901, (3) 25, 375; Stard, *ibid.* 1883, (2) 39, 530; Pistot, Ber. 1886, 19, 1663; Sachs and Kempf, Ber. 1902, 35, 2704; Oohn and Blau, Monat. 1904, 25, 365; Walker and Rector, J. pr. Chem. 1905, 65, 285).

o-Toluidine on treatment with strong alkalis

cyanate either at 1°–3° or at the boiling point yields chiefly acetyl-*o*-tolylthiocarbamide, m.p. 184° (Doran and Dixon, Chem. Soc. Trans. 1905, 67, 338). With dichloroacetic acid, *o*-toluidine yields chiefly *o*-methylaminophenyl-*o*-toluidine-acetic acid, prismatic needles, m.p. 239°–240°, as well as some *o*-tolyl-*o*-methylmesatin $C_8H_7ON_2$, golden-yellow leaflets, m.p. 225° (Ostromislensky, Ber. 1907, 40, 4972; cf. Meyer, Ber. 1883, 16, 2261). The magnesium iodide derivative of *o*-toluidine reacts with ethyl chloroacetate to yield iodoaceto-*o*-toluidide, long white needles, m.p. 142° (decomp.) (Bodroux, Compt. rend. 1905, 141, 195), and with α -iodopropionate and α -iodobutyrate to form α -iodopropion-*o*-toluidide, m.p. 148°, and α -iodobutyr-*o*-toluidide, m.p. 135°–139°, respectively (Bodroux and Taboury, *ibid.* 1907, 144, 1437).

The diazoamino-compounds derived from the three toluidines and diphenylamine are described by Vignon and Simonet (Compt. rend. 1905, 140, 788).

Formyl-derivative; by continuous boiling of *o*-toluidine with formic acid (Ladenburg, Ber. 1877, 10, 1129; Tobias, *ibid.* 1882, 15, 2446). Plates, m.p. 62° (Nef, Ann. 1892, 270, 310), b.p. 288°. When boiled for a long time it decomposes into *o*-toluidine, methenylditolylamine, carbon monoxide and carbon dioxide. For solid and liquid modifications, see Orloff (J. Russ. Phys. Chem. Soc. 1905, 37, 439).

Silver salt, amorphous precipitate (Comstock and Clapp, Amer. Chem. J. 1891, 13, 526); **sodium salt** (Wheeler, *ibid.* 1900, 23, 466); **ethyl-*o*-tolylformimino ether**,

from silver *o*-formotoluidide and chloroformic ester, liquid, b.p. 101°/12 mm. (Wheeler and Boltwood, Amer. Chem. J. 1896, 18, 389); **methylether**; from the silver salt and methyl iodide. Liquid, b.p. 211°–213° (C. and C.).

Thioformyl-derivative; by heating the formyl-derivative with phosphorus pentasulphide at 120°. Another method of preparation is given by Nef (Ann. 1892, 270, 313). Yellow needles, m.p. 96° (Senier), or colourless needles, m.p. 100°–101° (Nef). On distillation *in vacuo* it forms methenyldi-*o*-tolylamine. On heating under pressure for 7 hours at 190° it yields a crystalline compound, $C_{10}H_{11}N_2S$, m.p. 160° (Senier, Ber. 1885, 18, 2292; Chem. Soc. Trans. 1885, 47, 762).

Acetyl-derivative; by heating the base with acetic acid (Beilstein and Kuhlberg, Ann. 1870, 156, 77; Alt, *ibid.* 1889, 252, 318), or by shaking with water and acetic anhydride (Hinsberg, Ber. 1890, 23, 2962). See also Lumière and Barbier (Bull. Soc. chim. 1905, (3) 33, 784); Pawlewski (Ber. 1902, 35, 110). Long monoclinic crystals, m.p. 110° (Alt; Sudborough, Chem. Soc. Trans. 1901, 79, 537) or 107°–109° (Bedson and King, Chem. Soc. Trans. 1890, 37, 753), b.p. 296° (Beilstein and Kuhlberg).

With potassium permanganate it yields acetyl-*o*-aminobenzoic acid and with phosphorus pentachloride an unstable iminochloride, $CH_3COCl=NC_6H_4$, which on careful heating yields a base $C_8H_7N=C(CH_3)CH_2CCl=NC_6H_4$, m.p. 53°. When treated hot with bromine it yields the derivative $CH_3C_6H_4Br_2NHCH_2C_6H_4BrO$, whilst bromide in acetic acid solution yields the

6-bromo-derivative. When treated with a mixture of hydrochloric and nitric acids it yields a dichloroaceto-*o*-toluidide, m.p. 155°–156° (Mannino and Donato, Gazz. chim. ital. 1908, 38, ii. 20).

Aceto-*o*-toluidide forms compounds with sodium hydroxide, $C_8H_7ON+NaOH$, with sodium methoxide, $C_8H_7ON+CH_3ONa$, and with sodium ethoxide, $C_8H_7ON+C_2H_5ONa$ (Cohen, Archdeacon and Brittain, Chem. Soc. Trans. 1896, 69, 93; 1898, 73, 161).

With methyl iodide in presence of dry silver oxide, aceto-*o*-toluidide yields a mixture of methyl aceto-*o*-toluidide and *N*-*o*-tolylacetimino-methylether, whilst with ethyl iodide it yields *N*-*o*-tolylacetimino-ethylether (Lander, Chem. Soc. Trans. 1901, 79, 690). Chloroacetyl in the presence of aluminium chloride yields chloroacetyl-*o*-toluidine, m.p. 160° (Kunchell, Ber. 1900, 33, 2644). On heating with diacetylhydrazine, aceto-*o*-toluidide yields 1-*o*-tolyl-2,5-dimethyl-1:3:4-triazole (Pellizzari and Alciatore, Atti R. Accad. Lincei, 1901 [v.] 10, 444).

***N*-Chloro-derivative**, $CH_3C_6H_4NClCOCH_3$, from aceto-*o*-toluidide and potassium hypochlorite at the ordinary temperature. Prisms or plates, m.p. 43°. At 160°, or when a drop of sulphuric acid is added to its solution in acetic acid, 5-chloro-aceto-*o*-toluidide is formed (Chattaway and Orton, Chem. Soc. Trans. 1900, 77, 790).

***N*-Bromo-derivative**; formed by the action of potassium hypobromite on a suspension of the acetyl-derivative in sodium bicarbonate solution at 0°. Yellow, four-sided plates, m.p. 100°.

(On keeping at the ordinary temperature for a few seconds, it is transformed into 5-bromoaceto-*o*-toluidide (Chattaway and Orton).

Chloroacetyl-derivative

by the action of chloroacetyl chloride on a well-cooled solution of *o*-toluidine in benzene (Abenius and Widman, J. pr. Chem. 1888, (2) 38, 299; cf. Bischoff and Walden, Ann. 1894, 279, 62; Grothe, Archiv. der. Pharmacie, 1899, 238, 588). Slender needles, m.p. 111°–112°. For the corresponding bromo-, dichloro-, tri-chloro-, and thioacetyl-derivatives, see Rugheimer and Hoffmann, Ber. 1893, 18, 2987; Cloke, Ann. Chim. 1886, (6) 9, 215; Abenius and Widman, *l.c.*; Wallach, Ber. 1890, 13, 529; 1893, 16, 147).

Propionyl-derivative; from *o*-toluidine and propionic acid (Pictet and Duparc, Ber. 1887, 20, 3421). Needles, m.p. 87°, b.p. 299°/730 mm. Oxidised by potassium permanganate to propionyl-*o*-amino-benzoic acid.

Benzoyl-derivative; long broad needles, m.p. 131° (Gudeman, Ber. 1888, 21, 2553) or 143° (Brückner, Ann. 1880, 205, 130). Phosphorus pentachloride yields $C_8H_7N=CClC_6H_5$ (Just, Ber. 1886, 19, 982).

Oxalyl-derivative; plates, m.p. 131° (Bladis, Bull. Soc. chim. 1884, (2) 41, 130).

Phthalyl-derivative; needles, m.p. 165°, b.p. about 360° (Fröhlich, Ber. 1894, 17, 2679).

Diacetyl-derivative; by heating 1 part of aceto-*o*-toluidide with 1 part of acetyl chloride at 170°–190° (Kay, Ber. 1893, 26, 2885); from the monoacetyl-compound and acetic anhydride at 200°–205° (Bistrzycki and Ullrich, Ber. 1894, 27, 81). Oil (Kay). *crystalline m.m.*

Ber. 1896, 28, 1065; Clayton, Ber. 1895, 28, 1665; Sudborough, Chem. Soc. Trans. 1901, 79, 537).

4-Chloro-o-toluidine; by reduction of 4-chloro-2-nitrotoluene (Goldschmidt and Hönig, Ber. 1886, 19, 2441; Cohn, Monatsh. 1901, 22, 473; cf. Engelbrecht, Ber. 1874, 7, 797); from 2:4-dinitrotoluene (Beilstein and Kuhlberg, Ann. 1871, 158, 337). M.p. 21°-22°, b.p. 237°/722 mm. (G. and H.). B'HCl, needles; (B'HCl), PtCl₄ + 2H₂O, slender yellow needles.

Acetyl-derivative, leaflets, m.p. 139°-140° (E.) or 130°-131° (G. and H.). Oxidised by permanganate in presence of magnesium sulphate to 4-chloro-2-acetylamino-benzoic acid (Cohn).

5-Chloro-o-toluidine; by chlorination of aceto-o-toluidide followed by hydrolysis (Lellmann and Klotz, Ann. 1885, 231, 317); by the action of sulphuryl chloride on aceto-o-toluidide in carbon disulphide solution followed by hydrolysis with hydrochloric acid (Wynne, Chem. Soc. Trans. 1892, 61, 1045). The same (?) chlorotoluidine is obtained together with o-toluidine by reducing o-nitrotoluene with tin and hydrochloric acid (Beilstein and Kuhlberg, Ann. 1870, 156, 81). Thin plates, m.p. 29°-30° (W.; B. and K.; L. and K.), b.p. 241° (B. and K.), 236°-238°/730 mm. (L. and K.), or 246°/746 mm. (W.). B'HCl, small tables; B'HNO₃, leaflets.

Acetyl-derivative; by chlorination of aceto-o-toluidide (L. and K.); by the action of an aqueous solution of bleaching powder on an ice-cold solution of aceto-o-toluidide in diluted acetic acid solution (Claus and Stapelberg, Ann. 1893, 274, 286; cf. Chattaway and Orton, l.c., and Cohen and Dakin, *ibid.* 1902, 81, 1329); or by chlorination using sodium chlorate and hydrochloric acid (Reverdin and Crépeux, Ber. 1900, 33, 2497). Small slender needles, m.p. 129°-140° (W.; C. and O.). **N-Chloro-derivative**; four or six-sided prisms, m.p. 66°. On heating a solution in acetic acid 3:5-dichloroaceto-o-toluidide is formed (Chattaway and Orton, Chem. Soc. Trans. 1900, 77, 790).

6-Chloro-o-toluidine; 6-nitro-o-toluidine is converted into 6-chloro-2-nitrotoluene and the latter is reduced (Reverdin and Crépeux; cf. Wynne and Groves; Nölting; Cohn). Liquid at the ordinary temperature, m.p. 2-8°, and darkens rapidly in the air (Wibaut, Rec. trav. chim. 1913, 32, 244), b.p. 242°-244°. B'HCl, silvery leaflets, decomposing at 250°-252°; H₂SO₄, silvery needles, decomposing at 250°-252°.

Acetyl-derivative; needles, m.p. 156° (Wibaut), 157°-159° (Janson, D. R. P. 107505 of 1898; Cohn, Monatsh. 1901, 22, 473); (Hönig, Ber. 1877, 20, 2417 gave 136°). **Benzoyl-derivative**; m.p. 170°-171° (Wibaut; Cohn) or 173° (N.).

3-Chloro-5-bromo-o-toluidine; by bromination of aceto-o-toluidide, followed by chlorination and hydrolysis. Colourless needles, m.p. 60° (Cohen and Murray, Chem. Soc. Trans. 1915, 101, 847).

Acetyl-derivative; m.p. 171°; **diacetyl-derivative**; m.p. 90-5° (C. and M.).

5-Chloro-3-bromo-o-toluidine; by reducing 5-chloro-3-bromo-2-nitrotoluene with tin and hydrochloric acid; from aceto-o-toluidide by successive chlorination, hydrolysis, and bromine.

Acetyl-derivative; colourless needles, m.p. 187°; **diacetyl-derivative**, m.p. 85° (C. and M.).

5(1)-Iodoaceto-o-toluidide; by treating aceto-o-toluidide with iodine monochloride in glacial acetic acid. It melts at 169-5° and yields a **dichloride**, which decomposes at 109°, and an **iodoso-derivative** (Willgerodt and Heusner, Ber. 1907, 40, 4077).

3:5-Dichloro-o-toluidine; by chlorination of aceto-o-toluidide, followed by hydrolysis (Claus and Stapelberg, Ann. 1893, 274, 291); readily obtained by Chattaway and Orton's method (above) (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1329). Glistening needles, m.p. 53° (C. and S.).

Acetyl-derivative; needles or columns, m.p. 186°. **N-chloro-derivative**, four-sided prisms, m.p. 78° (Chattaway and Orton l.c.).

4:5-Dichloro-o-toluidine; by reducing 3:4-dichloro-6-nitrotoluene with stannous chloride. Plates with a silky lustre, m.p. 100°-101° (Cohen and Dakin).

4:6-Dichloro-o-toluidine (?); by reducing dichloronitrotoluene (Wroblewsky, Ann. 1873, 168, 213). Leaflets, m.p. 88°, b.p. 259°. Does not form salts.

2:4-Dichlorotoluidine (?); by reducing β-dichloronitrotoluene. Plates, m.p. 87° (Seelig, Ann. 1887, 237, 103).

2:3:4-Trichloro-o-toluidine (?); by reduction of 2:3:4-trichloronitrotoluene (?) with stannous chloride and hydrochloric acid. Small needles, m.p. 105° (Seelig, Ann. 1887, 237, 142).

3:4:6-Trichloro-o-toluidine (?); by reduction of trichloronitrotoluene with tin and hydrochloric acid (Schultz, Ann. 1877, 187, 278). Needles, m.p. 91° (Schultz) or 94°-95° (Seelig, Ann. 1887, 237, 141; Ber. 1885, 18, 423). Becomes rose-coloured on keeping.

Acetyl-derivative; m.p. 191°.

Benzoyl-derivative; m.p. 213° (Schultz).

3-Bromo-o-toluidine; by reduction of 3-bromo-2-nitrotoluene (Neville and Winther, Ber. 1880, 13, 1945; Chem. Soc. Trans. 1880, 37, 630; cf. Wynne, *ibid.* 1892, 61, 1036, note). Oil. With bromine water it yields 3:5-dibromo-o-toluidine.

4-Bromo-o-toluidine; by reduction of 4-bromo-2-nitrotoluene (Körner, Zeit. f. Chem. 1889, (2) 5, 636; Hübner and Wallach, Ann. 1870, 154, 298; Hübner and Roos, Ber. 1873, 6, 799; Wroblewsky, Ann. 1873, 168, 77; Neville and Winther, Chem. Soc. Trans. 1880, 37, 442); from dinitrotoluene by conversion into 2-nitro-p-toluidine, replacement of the amino-group by bromine and reduction of the nitro-group (Heinemann, Ann. 1871, 158, 340). Plates, m.p. 32° (H. and R.), b.p. 253°-257° with partial decomposition. B'HCl, six-sided rhombic plates (H. and R.); B'HNO₃, long rhombic tables (W.; H.); B₂H₂SO₄, plates.

5-Bromo-o-toluidine; by successive bromination and hydrolysis of aceto-o-toluidide (Wroblewsky, Ann. 1873, 168, 182); by reduction of 5-bromo-2-nitrotoluene (Graw, Ann. 1875, 177, 249; Ber. 1875, 8, 865). Rhombic plates, m.p. 59-5° (Alt, Ann. 1882, 252, 321) or 56° (Wroblewsky; Niemcewicz, Ber. 1882, 35, 889; Cohen and Dakin, Chem. Soc. Trans. 1915, 105, 811; cf. Neville and Winther, l.c.), b.p. 245°. B'HCl, needles; B₂H₂SO₄, nearly square plates.

TOLUENE.

m.p. 183°; $B_2H_3SO_4 + 2H_2O$ (Alt); *oxalate*, needles, (G.).

Acetyl-derivative; by bromination of aceto-*o*-toluidide (W.; A.; N.); quantitatively by treating 5-iodoaceto-*o*-toluidide with bromine in chloroform solution (Malleis and Meyer, J. Amer. Chem. Soc. 1913, 35, 970); by the action of hydrobromic and nitric acids on aceto-*o*-toluidide (Mannino and Donato, Gazz. chim. ital. 1908, 38, ii. 20). Long needles, m.p. 156°–157° (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 511). For compounds with sodium and potassium hydroxides, see Cohen and Brittain (*ibid.* 1898, 73, 161). *N-Bromo-derivative*; yellow rectangular plates, m.p. 91°. On heating with water at 100° it yields 3:5-dibromo-aceto-*o*-toluidide (Chattaway and Orton, *ibid.* 1900, 77, 794).

6-Bromo-o-toluidine; by reduction of 6-bromo-2-nitrotoluene with tin, stannous chloride, and hydrochloric acid (Friedländer, Bruckner and Deutsch, Ann. 1912, 388, 23). Yellow oil, b.p. 253°–255° (Nölting, Ber. 1904, 37, 1015).

Sulphate; m.p. 256° (N.).

Acetyl-derivative; white needles, m.p. 158° (N.), or 159°–161° (Cohen and Dutt, *l.c.*; Cohen and Miller, Chem. Soc. Trans. 1904, 85, 1627) or 163° (F., B. and D.). It is oxidised by potassium permanganate at 80° in the presence of magnesium sulphate to bromoacetylanthranilic acid, m.p. 224°.

3:5-Dibromo-o-toluidine; by passing bromine vapour into a solution of *o*-toluidine hydrochloride (Wroblewsky, Ann. 1873, 168, 187); by boiling bromoacetodibromo-*o*-toluidide with excess of alcoholic potassium hydroxide (Abenius and Widman, J. pr. Chem. 1888, (2) 38, 288); by dibromination of *o*-toluidine and by the action of bromine on *o*-toluidine 5-sulphonic acid (Neville and Winther, Chem. Soc. Trans. 1880, 37, 429, 629; cf. Wynne, *ibid.* 1892, 61, 1038). Needles, m.p. 45°–46° (N. and W.; Cohen and Dutt), 50° (W.; Möhlau and Öhmichen, J. pr. Chem. 1881, (2) 24, 478), volatile with steam. It forms unstable compounds with strong acids.

Compounds with mercuric chloride, with zinc chloride, and with the chloride and bromide of cadmium are described by Hann and Spencer (J. Washington Acad. Sci. 1925, 15, 163).

($BHCl$), $PtCl_4$, yellow needles (A. and W.), $+1\frac{1}{2}H_2O$ (Claus and Immel, Ann. 1891, 265, 70).

Acetyl-derivative; needles, m.p. 205° (Chattaway and Orton, Ber. 1900, 33, 2399).

N-Bromo-derivative; plates, m.p. 120° (Chattaway and Orton, Chem. Soc. Trans. 1900, 77, 794).

Bromoacetyl-derivative; slender needles, m.p. 207° (A. and W.).

Diacyl-derivative; slender needles, m.p. 88° (A. and W.).

4:5-Dibromo-o-toluidine; by reduction of 4:5-dibromo-2-nitrotoluene. It melts at 96·8°–98° (Neville and Winther, Chem. Soc. Trans. 1880, 37, 439; Cohen and Dutt, *ibid.* 1914, 105, 515; cf. Wroblewsky, Ann. 1873, 168, 184).

5:6-Dibromo-o-toluidine; by bromination of 6-bromoaceto-*o*-toluidide, followed by hydrolysis. It melts at 58°.

Acetyl-derivative; m.p. 165·5°–166·5° (Cohen and Dutt, *l.c.*).

Tribromo-o-toluidine; m.p. 105°–106°, is described by Gerver (Ann. 1873, 169, 379) as

being obtained by the action of 3 mols. of bromine on *o*-toluidine, and he states further that 1 mol. of bromine and a dilute alcoholic solution of *o*-toluidine yields a mixture of di- and tribromotoluidines, m.p. 85°–89°. Neville and Winther (Chem. Soc. Trans. 1880, 37, 438) could not prepare any higher derivative than a dibromotoluidine, however, and state that Gerver's *o*-toluidine possibly contained aniline.

3:5:6-Tribromo-o-toluidine; by reduction of 3:5:6-tribromo-2-nitrotoluene with iron powder and acetic acid; by bromination of 6-bromo-*o*-toluidine (Blanksma, Chem. Weekblad, 1914, 11, 185). Colourless crystals, m.p. 87°.

Acetyl-derivative; colourless crystals, m.p. 218° (B.).

Tribromotoluidine; from *p*-bromotoluene *o*-sulphonic acid by nitration, reduction, and bromination (Schäfer, Ann. 1874, 174, 362; Ber. 1874, 7, 1355). M.p. 72°.

4-Iodo-o-toluidine; by reduction of 4-iodo-2-nitrotoluene (Heinemann, Ann. 1871, 158, 338). Needles, m.p. 48°–49°, b.p. 273° (decomp.). $BHNO_3$, leaflets.

5-Iodo-o-toluidine; reduction of 3-iodo-6-nitrotoluene with ferrous sulphate and ammonia in aqueous solution at 66°–70° (Artmann, Monatsh. 1905, 26, 1091); by the action of iodine chloride on aceto-*o*-toluidide followed by hydrolysis (Fichter and Phillip, J. pr. Chem. 1906, (2) 74, 297); by the action of iodine on *o*-toluidine (Wheeler and Liddle, Amer. Chem. J. 1909, 42, 498); and by trituration of *o*-toluidine hydrochloride with iodine and calcium carbonate, the yield being 98 p.c. (Hann and Berliner, J. Amer. Chem. Soc. 1925, 47, 1709). Long white needles, m.p. 91°–92° (A.), or short, colourless crystals, m.p. 88° (F. and P.), or 87·2° (H. and B.).

$BHCl$, short white needles, m.p. 214°; $BHNO_3$, slender tetragonal scales. The salts are dissociated by water. B_2HgCl_2 , m.p. 134·5°.

Acetyl-derivative; slender matted needles, m.p. 162°–163° (A.), 168° (F. and P.), 169° (W. and L.), or 176° (Malleis and Meyer, J. Amer. Chem. Soc. 1913, 35, 970). Oxidised by potassium permanganate to 5-iodo-*o*-acetylaminobenzoic acid, m.p. 235° (decomp.) (W. and L.).

Benzoyl-derivative; colourless needles, m.p. 184° (W. and L.).

6-Iodo-o-toluidine; obtained by reducing 2-iodo-6-nitrotoluene, is a liquid. $BHCl$, plates (Cohen and Miller, Chem. Soc. Trans. 1904, 85, 1627), m.p. 254° (decomp.) (Nölting, Ber. 1904, 37, 1015).

Acetyl-derivative; white needles, m.p. 166° (N.).

3:6-Di-iodo-o-toluidine; by reduction of 2:5-di-iodo-6-nitrotoluene. Colourless needles, m.p. 86° (Wheeler and Brautlecht, Amer. Chem. J. 1910, 44, 126).

4:5-Di-iodo-o-toluidine; by the action of iodine chloride on *p*-iodo-*o*-toluidine. Stout needles or long prisms (Wheeler and Brautlecht, *ibid.* 1910, 44, 493).

3:5-Dibromo-4-iodo-o-toluidine; by reduction of dibromo-iodonitrotoluene (m.p. 69°) (Wroblewsky, Ann. 1878, 192, 210). Needles, m.p. 84°. On treatment with sodium amalgam it yields *o*-toluidine.

Acetyl-derivative; small needles, m.p. 121° (W.).

5-Nitroso-*o*-toluidine; by heating a mixture of 1 part of 5-nitroso-*o*-cresol, 5 parts of ammonium chloride, and 15 parts of dry ammonium acetate at 100° (Mehne, Ber. 1888, 21, 731). Small green needles with a bluish lustre, m.p. 115°–116° with slight detonation. On heating with sodium hydroxide it yields nitrosocresol and ammonia, and with hydroxylamine it is transformed into toluquinonedioxime.

3-Nitro-*o*-toluidine; together with the 5-nitro-isomeride by nitration of aceto-*o*-toluidide, followed by hydrolysis (Beilstein and Kuhlberg, Ann. 1871, 158, 345; Lellmann and Wurthner, *ibid.* 1885, 228, 240; Reverdin and Crépieux, Ber. 1900, 33, 2498; 1902, 35, 1439; Meisenheimer and Hesse, *ibid.* 1919, 52, 1161; Gabriel and Thieme, *ibid.* 1079; Cohen and Dakin, Chem. Soc. Trans. 1901, 79, 1127). Also by heating oxalo-*o*-toluidine on the water-bath with concentrated sulphuric acid until water-soluble, cooling to 50° and nitrating slowly with a mixture of nitric acid (D 1.52) and sulphuric acid, keeping the temperature below 50°. The product, after keeping for some hours and diluting with water, is heated at 140° until solution is complete, and finally at 160° for 50 minutes. This is then considerably diluted and steam distilled (Hadfield and Kenner, Chem. Soc. Proc. 1914, 30, 253). By treating 2:3-dinitrotoluene with 2.5N methyl alcoholic ammonia under pressure at 150°–160° for 15 hours (Kenner and Parkin, Chem. Soc. Trans. 1920, 117, 856); from 3-nitro-*o*-toluidine 5-sulphonic acid by eliminating the sulphonic group (Gnehm and Blumer, Ann. 1898, 304, 105; Nietzki and Pollini, Ber. 1890, 23, 138); together with the 5-nitro-isomeride by the transformation of *o*-toluene-nitroamine (Bamberger and Stingelin, Ber. 1897, 30, 1259).

Orange-yellow prisms, m.p. 97° (K. and P.; Zincke and Schwarz, Ann. 1899, 307, 44) or 95° (Wibaut, Rec. trav. chim. 1913, 32, 244; R. and C.).

Acetyl-derivative; large shining plates or prisms, m.p. 158° (L. and W.; Körner and Contardi, Atti R. Accad. Lincei, 1915, (v.) 24, i. 888).

4-Nitro-*o*-toluidine; together with the 6-nitro-derivative by nitration of phthalyl-*o*-toluidide, followed by hydrolysis (Städel, Ann. 1884, 225, 385); together with 2-nitro-*p*-toluidine by treating 2:4-dinitrotoluene with warm alcoholic ammonium sulphide (Graeff, Ann. 1885, 229, 343) or alone by reduction with stannous chloride and alcoholic hydrochloric acid (Anschütz, and Heussler, Ber. 1886, 19, 2161); by warming 2:4-tolylenediamine with an aqueous solution of sodium peroxide (O. Fischer and Trost, Ber. 1893, 26, 3085); by a modification of the method of Green and Lawson (Chem. Soc. Trans. 1891, 59, 1013) by adding powdered potassium nitrate to a solution of *o*-toluidine in concentrated sulphuric acid cooled to –5°, a small amount of the 6-nitro-isomeride being formed simultaneously (Cohen and Dakin, *ibid.* 1902, 31, 1333); by heating 4-nitro-5-amino-*m*-toluic acid or its acetyl-derivative with concentrated sulphuric acid (Errera and Maltre, Gazz. chim. ital. 1906, 36, ii. 370); in 75 p.c. yield, together with 2.5 p.c. of 6-nitro-*o*-toluidine, by nitrating *o*-tolu-

idine in concentrated sulphuric acid (Morgan and Challenor, Chem. Soc. Trans. 1921, 119, 1539) with mixed acids (Brady and Williams, *ibid.* 1920, 117, 1138). The latter method is much simpler than that of Nölting and Collin (Ber. 1884, 17, 265). Monoclinic prisms, m.p. 107° (N. and C.), 109° (S.), 104°–105° (A. and H.); cf. Jäger, Z. Krist. 1903, 89, and Willgerodt and Kok, Ber. 1908, 41, 2077.

B'HCl, white needles, m.p. 230° (Willgerodt and Kok); B'HBBr, small lustrous pale red crystals (Staden, J. pr. Chem. 1902, (2) 65, 249); B₂H₄SO₄, plates, decomposed by water.

Nitrous acid yields 4-nitro-*o*-cresol and nitro-indazole, whilst with sodium amalgam it yields azoxytoluidine.

Formyl-derivative, small yellow prisms, m.p. 178°–179° (Geigy & Co., U.S. Pat. 722630; Fr. Pat. 306655; D. R. P. 138839 of 1902).

Acetyl-derivative; yellowish-white needles, m.p. 150°–151° (Nölting and Collin, *l.c.* 269).

5-Nitro-*o*-toluidine; by nitration of toluene *p*-sulphonyl-*o*-toluidide (Reverdin and Crépieux, Bull. Soc. chim. 1902, 27, 742); by nitration of aceto-*o*-toluidide, followed by hydrolysis (see the 3-nitro-derivative); as a by-product of the action of nitric anhydride on *o*-toluidine (Bamberger and Hoff, Ann. 1900, 311, 95); in low yield by heating 2:5-dinitrotoluene with alcoholic ammonia at 150° for 15 hours (Kenner and Parkin, Chem. Soc. Trans. 1920, 117, 859). Small citron-yellow needles, m.p. 127° (K. and P.) or 130° (Wibaut, Rec. trav. chim. 1913, 32, 244; Jäger, *l.c.*; Reverdin and Crépieux, Ber. 1900, 33, 2498).

Acetyl-derivative; short white needles, m.p. 201.6° (Körner and Contardi, Atti R. Accad. Lincei, 1915, (v.) 24, i. 888).

6-Nitro-*o*-toluidine; obtained in 80 p.c. yield by the gradual addition of a 15 p.c. ammonium sulphide solution to 2:6-dinitrotoluene in boiling alcohol, followed by complete extraction of the product with dilute hydrochloric acid (Cohen and Marshall, Chem. Soc. Trans. 1904, 85, 527; Ullmann, Ber. 1884, 17, 1957; Bernthsen, Ber. 1882, 15, 3018; Cunerth, Ann. 1874, 172, 223); in small quantities together with the 4-nitro-isomeride by nitrating *o*-toluidine in presence of an excess of sulphuric acid (Green and Lawson, Chem. Soc. Trans. 1891, 59, 1014). For separation from 2-nitro-*p*-toluidine, see Bernthsen (*l.c.*). Thin rhombic leaflets (Jäger, Z. Kristall. 1903, 38, 89) or long yellow needles, m.p. 91.5° (U.). B'HCl, long flat prisms; B'HBBr, yellowish leaflets or long thin needles, decomposed by water; B'HI, rhombohedra or flat prisms (Tatschaloff, J. pr. Chem. 1902, (2) 65, 239).

Acetyl-derivative; prisms, m.p. 157.5°–158° (U.), m.p. 160° (Cohen and Hodsman, Chem. Soc. Trans. 1907, 91, 975), or colourless needles, m.p. 163°; *benzyl-derivative*, m.p. 167°–167.5° (U.), or 145°–146° (C.).

3:4-Dinitro-*o*-toluidine; as main product, together with 4:5-dinitro-*o*-toluidine, by adding a sulphuric acid solution of 4-nitroaceto-*o*-toluidide to nitric acid (D. 1.5) cooled in ice, followed by hydrolysis by heating for 4–5 hours on the water-bath with dilute sulphuric acid (1 part acid; 2 parts water) (Brady and Williams, Chem. Soc. Trans. 1920, 117, 1138; Morgan and Glover, *ibid.* 1921, 119, 1739). Lustrous, yellowish-brown needles, m.n. 131°–131.5°.

Acetyl-derivative; yellowish-white needles, m.p. 186° (M. and G.).

3 : 5-*Dinitro-o-toluidine*; in small quantity by nitrating toluene *p*-sulphonyl-*o*-toluidide (Reverdin and Crépieux, Bull. Soc. chim. 1902, (3) 27, 742); by heating dinitro-*o*-cresol and its ethers with alcoholic ammonia (Städel, Ann. 1883, 217, 183, 203; Ber. 1881, 14, 900; van Romburgh, Rec. trav. chim. 1884, 3, 398; Barr, Ber. 1888, 21, 1543); by transformation of 5-nitro-*o*-toluene nitroamine (Bamberger and Seitz, Ber. 1897, 30, 1255; Bamberger and Hoff, Ann. 1900, 311, 111); in upwards of 95 p.c. yield by the action of liquid ammonia, methyl or ethyl alcoholic ammonia on 2-chloro-3 : 5-dinitrotoluene (Morgan and Drew, Chem. Soc. Trans. 1920, 117, 790).

Yellow columns or long tables, m.p. 208° or 209°–210° (H.), 211° (B. and S.), 213° (M. and D.).

Acetyl-derivative; slender white needles, m.p. 205·2° (Körner and Contardi, Atti R. Accad. Lincei, 1915, [v.] 24, i. 888. See also Reverdin and Crépieux, Ber. 1902, 35, 1439).

3 : 6-*Dinitro-o-toluidine* (see 5 : 6-dinitro-*o*-toluidine). Brilliant orange-yellow prisms, m.p. 151°.

Acetyl-derivative; pale yellow microscopic prisms, m.p. 209° (Brady and Taylor; cf. Körner and Contardi).

4 : 5-*Dinitro-o-toluidine* (see 3 : 4-dinitro-*o*-toluidine). Yellow needles, m.p. 191°–191·5°.

Acetyl-derivative; colourless needles, m.p. 180° (Morgan and Glover; Brady and Williams).

4 : 6-*Dinitro-o-toluidine*; together with 2 : 6-dinitro-*p*-toluidine by reducing 2 : 4 : 6-trinitrotoluene with ammonium hydrosulphide (Holleman and Boeseken, Rec. trav. chim. 1897, 16, 426) or by reducing in hydrochloric acid solution in presence of cupric chloride at a copper cathode (Brand and Eisenmenger, J. pr. Chem. 1913, (2) 87, 487); together with 2 : 6-dinitrotolyl-*p*-hydroxylamine by reducing 2 : 4 : 6-trinitrotoluene in cold alcoholic ammoniacal solution with hydrogen sulphide (Anschütz and Zimmermann, Ber. 1915, 48, 152). It melts at 155° (H. and B.; A. and Z.) or 135° (B. and E.). On diazotisation it is converted into 2 : 4-dinitrotoluene and 2 : 4-dinitroindazole (B. and E.).

Acetyl-derivative; white needles, m.p. 224° (B. and E.).

5 : 6-*Dinitro-o-toluidine*; formed together with 3 : 6-dinitro-*o*-toluidine by adding 6-nitroaceto-*o*-toluidide to a mixture of sulphuric acid and nitric acid (D 1·5) at 4°–7°, and allowing the temperature to rise to 12°, followed by hydrolysis with concentrated sulphuric acid at 100°. The bases are separated by conversion into the acetyl-derivatives or by crystallisation from glacial acetic acid and sieving the crystals (Brady and Taylor, Chem. Soc. Trans. 1920, 117, 876). Deep yellow needles, m.p. 216° (B. and T.).

Acetyl-derivative; large white crystals, m.p. 180° (B. and T.).

3-*Chloro-5-nitro-o-toluidine*; by chlorination of 5-nitro-*o*-toluidine. It melts at 168° (Wynne and Greeves, Chem. Soc. Proc. 1895, 11, 151).

3-*Chloro-6-nitro-o-toluidine*; apparently formed together with 5-chloro-6-nitro-*o*-toluidine by heating 6-nitrotolyl-*o*-hydroxylamine with concentrated hydrochloric acid (Brand and Zeller, Ber. 1907, 40, 3324).

5-*Chloro-3-nitro-o-toluidine*; in poor yield together with 5-chloro-4-nitro-*o*-toluidine by dissolving 1 part of 5-chloro-2-toluidine nitrate in 25 parts of nitric acid (66 p.c.) and keeping for 6 hours. On pouring into water only the 4-nitro-derivative separates (Claus and Stapelberg, Ann. 1893, 274, 295). Yellow plates, m.p. 118°–119° (C. and S.), or long orange-yellow needles, m.p. 129°–130° (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1330).

Acetyl-derivative; in excellent yield by nitrating 5-chloroaceto-*o*-toluidide in glacial acetic acid at 15°–20° (C. and D.). Glistening needles, m.p. 187° (C. and S.), or prismatic needles, m.p. 197°–198° (C. and D.).

5-*Chloro-4-nitro-o-toluidine*; see 5-chloro-3-nitro-*o*-toluidine (cf. Reverdin and Crépieux, Ber. 1900, 33, 2505). Yellow columns, m.p. 128° (C. and S.), or 124° (Wibaut, Rec. trav. chim. 1913, 32, 244), 129°–130° (C. and D.).

5-*Chloro-6-nitro-o-toluidine*; by heating 6-nitrotolyl-*o*-hydroxylamine (Brand and Zöller, l.c.); by chlorination of 6-nitroaceto-*o*-toluidide in glacial acetic acid, followed by hydrolysis with hydrochloric acid in a sealed tube (Cohen and Hodsman, Chem. Soc. Trans. 1907, 91, 975). Yellow needles, m.p. 95°–96°.

Acetyl-derivative; m.p. 158°–160° (B. and Z.), or 153° (C. and H.); *benzoyl-derivative*; m.p. 212°–213° (C. and H.).

6-*Chloro-3-nitro-o-toluidine*; obtained quantitatively by the action of liquefied ammonia, or saturated alcoholic ammonia, on 2-chloro-5 : 6-dinitrotoluene. Pale amber refractive prisms with pyramidal ends, m.p. 151·5° (Morgan and Drew, Chem. Soc. Trans. 1920, 117, 787).

3(?) : 5-*Dichloro-6-nitro-o-toluidine*; by chlorination of 6-nitroaceto-*o*-toluidide in glacial acetic acid for 5 hours at 100°. It melts at 195°–197° (Cohen and Hodsman, l.c.).

(α)-*Trichloronitrotoluidine*; by the action of alcoholic ammonia on trichlorodinitrotoluene (m.p. 227°). Orange-yellow needles, m.p. 191° (Seelig, Ber. 1885, 18, 423; Ann. 1887, 237, 140).

(β)-*Trichloronitrotoluidine*; in a similar manner to the α -compound from trichlorodinitrotoluene (m.p. 141°). Orange-red needles, m.p. 192° (Seelig).

3-*Bromo-5-nitro-o-toluidine*; by bromination of 5-nitro-*o*-toluidine (Neville and Winther, Ber. 1880, 13, 964; Chem. Soc. Trans. 1880, 37, 431; Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 572). It melts at 180·3°–181·3°.

5-*Bromo-3-nitro-o-toluidine*; by successive bromination, nitration, and hydrolysis of aceto-*o*-toluidide (Wroblewsky, Ann. 1878, 192, 206; Neville and Winther, Ber. 1880, 13, 969; Chem. Soc. Trans. 1880, 37, 436, 448). Orange prisms, m.p. 139° (W.), or 143° (N. and W.).

Acetyl-derivative; by treating 5-bromoaceto-*o*-toluidide with 4 parts of nitric acid (D 1·48) below 25°. Needles, m.p. 205° (Niementowski, Ber. 1892, 25, 869; Claus and Beck, Ann. 1892, 269, 219).

5-*Bromo-4-nitro-o-toluidine*; by nitration of 5-bromo-*o*-toluidine in sulphuric acid with nitric acid (D 1·42) and sulphuric acid below 3°. Yellow crystals, m.p. 118° (Morgan and Clayton, Chem. Soc. Trans. 1905, 87, 949).

6-*Bromo-3-nitro-o-toluidine*; by nitration and hydrolysis of 6-bromoaceto-*o*-toluidide

(Blanksma, Chem. Weekblad, 1912, 9, 968). Orange-yellow crystals, m.p. 144° (B.).

Acetyl-derivative; yellow crystals, m.p. 199° (B.).

3:5-Dibromo-4-nitro-o-toluidine; by bromination of 4-nitro-o-toluidine. Yellow crystals, m.p. 104°.

Acetyl-derivative; colourless crystals, m.p. 201°; *diacetyl-derivative*; m.p. 159° (Blanksma, Chem. Weekblad, 1909, 6, 717; Morgan and Clayton, *l.c.* 951). It shows a remarkable stability to diazotising agents, which leave it practically unaffected.

3:5-Dibromo-6-nitro-o-toluidine; by bromination of 6-nitro-o-toluidine. It melts at 105° (Blanksma, Chem. Weekblad, 1914, 11, 185).

6-Bromo-3:5-dinitro-o-toluidine; by heating 2:6-dibromo-3:5-dinitrotoluene with alcoholic ammonia at 100°. Yellow crystals, m.p. 200°.

Acetyl-derivative; colourless crystals, m.p. above 300° (Blanksma, *ibid.* 1912, 9, 968).

5-Bromo-3:6(1)-dinitro-o-toluidine; *acetyl-derivative*; by treating 1 part of 5-bromo-aceto-o-toluidide with a mixture of 1 part of sodium nitrate and 20 parts of sulphuric acid. Pale yellow hair-like needles, m.p. 244° (decomp.) (Niementowski, Ber. 1892, 25, 870).

3:5-Dibromo-4:6-dinitro-o-toluidine; *acetyl-derivative*; by the action of nitric acid (D 1.52) and sulphuric acid on 3:5-dibromo-4-nitro-aceto-o-toluidide. White crystals, m.p. 280° (Blanksma, Chem. Weekblad, 1909, 6, 717).

3:5:6-Tribromo-4-nitro-o-toluidine; by nitration and hydrolysis of 3:5:6-tribromoaceto-o-toluidide. Light brown crystals, m.p. 203°.

Acetyl-derivative; colourless crystals, m.p. 275° (Blanksma, Chem. Weekblad, 1914, 11, 185).

3-Iodo-5-nitro-o-toluidine; by the action of iodine chloride on 5-nitro-o-toluidine in glacial acetic acid. Long brown prisms, m.p. 173° (Wheeler, Brautlecht and Hoffman, Amer. Chem. J. 1910, 44, 493).

5-Iodo-3-nitro-o-toluidine; by the action of iodine chloride on 3-nitro-o-toluidine in glacial acetic acid. Orange needles, m.p. 135° (Wheeler, &c.).

5-Iodo-4-nitro-o-toluidine; similarly from 4-nitro-o-toluidine. Bright yellow prisms, m.p. 109° (Wheeler, &c.).

5-Iodo-6-nitro-o-toluidine; by warming equal weights of 6-nitro-o-toluidine and iodine for several hours with ether, water, and calcium carbonate. Yellow prisms, m.p. 85° (Wheeler, &c.).

Methyl-o-toluidine; by reduction of nitroso-methyl-o-toluidine with tin and hydrochloric acid (Monnet, Reverdin and Nölting, Ber. 1878, 11, 2279); by heating o-tolylglycine at 200°-210° (Abenius and Widman, J. pr. Chem. 1888, (2) 38, 303); in a yield of 46 p.c. by methylation of o-toluidine hydrobromide or hydroiodide with methyl alcohol at 150° (Reinhardt and Staedel, Ber. 1883, 16, 29) or with dimethyl sulphate (Ullmann, Ann. 1903, 327, 104; Gnehm and Blumer). Colourless oil, b.p. 207°-208°; D_{20}^{20} 0.973; $B^{\circ}H.PtCl_6$ (A. and W.); $B^{\circ}HCl$, prisms (Geigly and Blumer, Ann. 1899, 304, 96); $B^{\circ}O.H_2O$, leaflets (G. and B.); *picrate*, prisms (G. and B.).

For the manufacture of safranine and azine dye from methyl-o-toluidine, see Bayer & Co.,

Eng. Pat. 6176 of 1895; Fr. Pat. 245641; D. R. P. 90256 of 1895; and M. L. B., D. R. P. 80768 of 1894; Weinberg, Ber. 1893, 26, 307; Bernthsen, *ibid.* 992.

Acetyl-derivative; m.p. 55°-56°, b.p. 260° (M., R. and N.), or 250°-251° (R. and S.).

Nitrosoamine; oil. Transformed by alcoholic hydrochloric acid into 5-nitroso-methyl-o-toluidine, green plates, m.p. 151°. With boiling aqueous sodium hydroxide it yields nitroso-o-cresol and methylamine. It is oxidised by potassium permanganate to nitromethyltoluidine, greenish-yellow needles, m.p. 134° (Kock, Ann. 1888, 243, 308).

4-Chloromethyl-o-toluidine; by methylating 4-chloro-o-toluidine (Störmer and Hoffmann, Ber. 1898, 31, 2532). Liquid, b.p. 248.5°-249.5°/760 mm., D_{20}^{20} 1.138.

Nitrosoamine; oil. D_{20}^{20} 1.226 (S. and H.).

5-Chloromethyl-o-toluidine; oil, b.p. 245°-246°/740 mm. (Geigy & Co., D. R. P. 105103 of 1898).

Dichloromethyl-o-toluidine; by heating dichloro-o-tolylglycine above its melting-point Hentschel, J. pr. Chem. 1899, (2) 60, 83). Oil, b.p. 258°-259°; $B^{\circ}H.PtCl_6$, slender yellow needles (H.).

3-Nitromethyl-o-toluidine; together with 5-nitromethyl-o-toluidine by the transformation of the N-methylester of toluene o-nitroamine (Bamberger and Stingelin, Ber. 1897, 30, 1259). Yellowish-red oil. According to Gnehm and Blumer (Ann. 1899, 304, 103) when methyl-o-toluidine is nitrated a mixture of 4-nitromethyl-o-toluidine and a product, m.p. 48°, is obtained. This latter is stated to be possibly the 3-nitro-derivative.

4-Nitromethyl-o-toluidine; by boiling its acetyl-derivative with concentrated hydrochloric acid (Gnehm and Blumer, *l.c.*); by nitration of methyl-o-toluidine; by methylation of 4-nitro-o-toluidine. Red leaflets or yellow prisms, m.p. 107.5°.

$B^{\circ}HCl$, leaflets decomposed by water; *picrate*, compact red prisms; *nitrosoamine*, pale yellow needles, m.p. 95°.

Acetyl-derivative; m.p. 119°.

5-Nitromethyl-o-toluidine; by oxidation of a dilute solution of 5-nitroso-methyl-o-toluidine with potassium permanganate (Kock, Ann. 1888, 243, 309); together with 5-nitrodimethyl-o-toluidine by methylating 5-nitro-o-toluidine. The products are separated by acetylation and distillation with steam (Bernthsen, Ber. 1892, 25, 3131); together with the 3-nitro-isomeride by the method of Bamberger and Stingelin (*l.c.*). Yellow tables, m.p. 137° (B.). It does not form a sulphate with sulphuric acid.

Nitrosoamine; oil which crystallises on keeping, m.p. 65° (B.).

Acetyl-derivative; rhombohedra-like crystals, m.p. 97° (B.).

6-Chloro-3-nitromethyl-o-toluidine; by the action of methylamine on 2-chloro-5:6-dinitrotoluene in alcoholic solution; by heating 6-chloro-3-nitro-o-toluidine with 1 part of methyl sulphate and 2 parts of toluene for 2 hours at 11 (Morgan and Jones, Chem. Soc. Trans. 1901, 119, 190). Orange-coloured acicular prisms, m.p. 84°-87°.

Nitrosoamine, pale yellow prismatic needles, m.p. 86°-87° (M. and J.).

3(1)-Nitro-4-chloromethyl-o-toluidine; by the

action of concentrated hydrochloric acid on its nitrosoamine (Störmer and Hoffmann, Ber. 1896, 31, 2533). Bright yellow needles, m.p. 185°-186°; nitrosoamine; yellowish-white plates, m.p. 80.5°-81.5° (S. and H.).

4-Nitrobromomethyl-o-toluidine; by bromination of 4-nitromethyl-o-toluidine in glacial acetic acid with cooling. Yellowish-brown needles, m.p. 133° (Gnehm and Blumer, Ann. 1899, 304, 103).

3:5-Dinitromethyl-o-toluidine; by the transformation of the N-methyl ester of 5-nitro-o-toluene nitroamine (Bamberger and Seitz, Ber. 1897, 30, 1255). M.p. 128°.

Nitrosoamine; yellowish rhombohedra, m.p. 94°-95° (S. and H.).

3:5-Dinitrotolyl-o-methylnitroamine; by boiling dimethyl-o-toluidine with nitric acid (D 1.48-1.5). Pale yellow crystals, m.p. 119°-120°. Decomposed by heating with 5 p.c. potassium hydroxide into methylamine and 3:5-dinitro-o-cresol, and on reduction with tin and hydrochloric acid it yields the corresponding monomethyl triamine (Romburgh, Rec. trav. chim. 1884, 3, 396).

Dimethyl-o-toluidine; by heating o-toluidine with methyl iodide (Clarke, Amer. Chem. J. 1905, 33, 496); by distilling trimethyl-o-toluidine hydrate (Thomsen, Ber. 1877, 10, 1586; Monnet, Reverdin and Nölting, Ber. 1878, 11, 2279); in 93 p.c. yield by methylating o-toluidine hydrobromide or hydriodide with a little more than 2 equivalents of methyl alcohol for 8 hours at 150° (Reinhardt and Stadel, Ber. 1883, 16, 29). Liquid, b.p. 184.8°; D_4^{20} 0.9286 (Kahlbaum, Zeitsch. physikal. Chem. 1898, 26, 623), or b.p. 185.5°; D_4^{25} 0.9417, D_{15}^{25} 0.9333, D_{25}^{25} 0.9268 (Perkin, Chem. Soc. Trans. 1896, 69, 1211); magnetic rotatory power at 15.3° 18.61 (P.); refractive power, see Brühl (Zeitsch. physikal. Chem. 1895, 16, 218). It does not condense with formaldehyde in presence of hydrochloric acid (Cohn, Chem. Zeit. 1900, 24, 564). $B'_2H_2PtCl_6$, white needles;

yellow unstable crystals (Wurster and Roser, Ber. 1879, 12, 1826); oxide, $CH_3C_6H_4N(CH_3)_2O$, is formed together with other products by prolonged action of hydrogen peroxide on dimethyl-o-toluidine. The oxide forms a picrate, long greenish-yellow needles, m.p. 145.5°-146.5° (Bamberger and Tschirner, Ber. 1890, 32, 354).

Bromodimethyl-o-toluidine; by brominating dimethyl-o-toluidine in acetic acid; by heating bromo-o-toluidine with methyl alcohol and hydrochloric acid at 180°-200° (Michler and Sampaio, Ber. 1881, 14, 2172). Liquid, b.p. 244°-245°, volatile with steam.

4-Nitrodimethyl-o-toluidine; nitration of dimethyl-o-toluidine with mixed acids at 0° (Gnehm and Blumer, Ann. 1899, 304, 107; Rohde, Zeitsch. f. Elektrochem. 1901, 7, 329); by methylation of 4-nitro-o-toluidine (G. and B.; Staden, J. pr. Chem. 1902, (2) 65, 249). Golden leaflets or rods, m.p. 14° (S.), formerly described as a yellow oil, b.p. 280° (decomp.). $B'HI$, yellow leaflets, m.p. 192°.

5-Nitrodimethyl-o-toluidine; together with 5-nitromethyl-o-toluidine by methylating 5-nitro-o-toluidine (Bernthsen, Ber. 1892, 25, 3133; cf. Haibach, J. pr. Chem. 1902, (2) 65,

242). Dark red flat rhombic pyramids, m.p. 48°-50° (H.), or small tables or needles, m.p. 47.5° (B.).

6-Nitrodimethyl-o-toluidine; by heating 6-nitro-o-toluidine hydrobromide with methyl alcohol for 6-10 hours at 100°-110°. Transparent golden crystals, m.p. 25°-25.5°, b.p. 191°-192°/9.5-10 mm. (von Tschaloff, J. pr. Chem. 1902, (2) 65, 239). $B'HI$, greyish-brown leaflets (T.).

Ethyl-o-toluidine; in 54 p.c. yield by heating o-toluidine hydrobromide or hydriodide with 5 p.c. excess of ethyl alcohol at 150° for 8 hours (Reinhardt and Stadel, Ber. 1883, 16, 31); by electrolytic reduction of aceto-o-toluidine in sulphuric acid solution (Baillie and Tafel, Ber. 1899, 32, 73; Vorländer, *ibid.* 1901, 34, 1462). Liquid, b.p. 213°-214° (R. and S.), or 204°-206° (Norton, Amer. Chem. J. 1885, 7, 118), or 214°-216°/737 mm. (B. and T.); D_{15}^{25} 0.9534 (N.).

Acetyl-derivative; b.p. 254°-256° (R. and S.); nitrosoamine; oil, volatile with steam (N.).

5-Chloroethyl-o-toluidine; oil, b.p. 252°-253°/760 mm. (Geigy & Co., D. R. P. 105103 of 1898).

5-Nitrosoethyl-o-toluidine; by keeping a mixture of ethyltolyl-o-nitrosoamine and absolute alcoholic hydrochloric acid (O. Fischer and Hepp, Ber. 1886, 19, 2994); by the action of sodium nitrite upon a solution of ethyl-o-toluidine in hydrochloric acid (O. Fischer, Ann. 1895, 286, 163; Weinberg, Ber. 1892, 25, 1610). Green leaflets with a blue shimmer, m.p. 140°.

4-Nitroethyl-o-toluidine; by nitration of thyl-o-toluidine with mixed acids at a low temperature (MacCullum, Chem. Soc. Trans. 1895, 67, 247). Light red needles, m.p. 81°-82°.

Nitrosoamine; m.p. 56°. When treated with zinc chloride or sulphuric acid the ethyl-amino-compound is regenerated (M.).

Acetyl-derivative; tables, m.p. 90° (M.).

5-Nitroethyl-o-toluidine; together with a little of the diethyl-derivative by heating 5-nitro-o-toluidine with ethyl iodide, alcohol and sodium hydroxide. The two bases are separated by crystallisation from a little hot alcohol and acetylation. Large dark yellow plates, m.p. 96° (Bernthsen, Ber. 1892, 25, 3137).

Acetyl-derivative; tables or prisms, m.p. 96°-97° (B.).

4-Nitrobromoethyl-o-toluidine; by brominating 4-nitroethyl-o-toluidine in acetic acid. Needles, m.p. 114°; $B'HI$, m.p. 194°-195° (decomp.) (MacCullum, *l.c.*).

Diethyl-o-toluidine; in 70 p.c. yield by ethylating ethyl-o-toluidine with ethyl iodide at 100° (Norton, Amer. Chem. J. 1885, 7, 119), or in 90 p.c. yield by ethylating o-toluidine hydrobromide or hydriodide with ethyl alcohol at 150° for 8 hours (Reinhardt and Stadel, Ber. 1883, 16, 29). Oil, b.p. 208°-209°/755 mm. (R. and S.), or 210°/738 mm. (van Romburgh, Rec. trav. chim. 1884, 3, 402). $B'HI + H_2O$, prisms, m.p. 72°-73° (N.).

When warmed with fuming nitric acid it yields a dinitrotolyl-o-ethylnitroamine, crystals, m.p. 71°-72° (v. R.), and when treated in acid solution with iodine and potassium iodide, it yields a hydrogen iodide periodide, $C_{11}H_{11}NHII$, steel-blue crystalline precipitate or dark brown

prisms, m.p. 109° (Samtleben, Ber. 1896, 31, 1145).

5-Nitroethyl-o-toluidine; see 5-nitroethyl-o-toluidine. Oil, readily soluble in dilute sulphuric acid (Bernthsen, Ber. 1892, 25, 3137).

Phenyl-o-toluidine; together with diphenylamine and ditolylamine, by heating o-toluidine with aniline hydrochloride at 280° (Girard and Willm, Bull. Soc. chim. 1876, (1) 25, 248) or by heating a mixture of 1 part of bromobenzene with 3 parts of o-toluidine and 8 parts of soda lime for 8 hours at 390° (Merz and Paschko-wesky, J. pr. Chem. 1893, (2) 48, 461). M.p. 41°, b.p. 305°/727.5 mm. (Graebe, Ann. 1887, 238, 363). It forms a violet-blue coloration with nitric acid.

6-Chloro-3-nitrophenyl-o-toluidine; by heating 2-chloro-5:6-dinitrotoluene with alcoholic aniline for several weeks; in 75 p.c. yield by heating 2-chloro-5-nitro-o-toluidine for 10 hours under a reflux with bromobenzene in presence of nitrobenzene, potassium carbonate, and cuprous iodide. Rhomboidal plates, m.p. 108°-109°.

Nitrosoamine, yellow prisms, m.p. 91° (Morgan and Jones, Chem. Soc. Trans. 1921, 119, 190).

2:4-Dinitrophenyl-o-toluidine; from chloro-2:4-dinitrobenzene and o-toluidine. M.p. 101°-102° (Leymann, Ber. 1882, 15, 1236), or 123° (M. L. B., Eng. Pat. 17639 of 1895; Fr. Pat. 250460; D. B. P. 85388 of 1895), or 120° (Reitzenstein, J. pr. Chem. 1903, (2) 68, 251).

3:5-Dinitrophenyl-o-toluidine; from 2-chloro-3:5-dinitrotoluene and aniline. Red leaflets, m.p. 169° (Nietzki and Rehe, Ber. 1892, 25, 3007).

Di-o-tolylamine (see phenyl-o-toluidine, Girard and Willm); by heating o-cresol, ammonium-zinc chloride, and ammonium chloride at 330°-340° (Merz and Müller, Ber. 1887, 20, 547). Liquid, b.p. 312°/727.5 mm. (Graebe).

Anhydroformaldehyde-o-toluidine; from formaldehyde and o-toluidine. Oil (Wellington and Tollens, Ber. 1885, 18, 3307), or lustrous plates, m.p. about 100° (Eberhardt and Welter, Ber. 1894, 27, 1808).

Methylene-di-o-tolyl-diimide; by heating a mixture of o-toluidine, formaldehyde, potassium hydroxide, and alcohol at 100° (Eberhardt and Welter, l.c.); or by the action of formaldehyde on an aqueous solution of o-toluidine (Eibner, Ann. 1898, 302, 349).

Prismatic needles, m.p. 52° (E. and W.). On heating with aniline hydrochloride it yields diaminoditolylmethane, and by boiling with alcohol it yields anhydroformaldehyde-o-toluidine (E. and W.).

The condensation of formaldehyde with o-toluidine in presence of concentrated sulphuric and acetic acids (cf. J. Russ. Phys. Chem. Soc. 1904, 36, 1126) yields as sole product 6-amino-5-methylbenzo-cyclo-butadiene (Nastukoff and Kroneberg, *ibid.* 1912, 44, 1200; cf. Kroneberg, *ibid.* 1914, 48, 306).

It is also stated that when 4 mols. of o-toluidine and 1 mol. of methylene chloride are heated for 7 hours at 110°-115°, two methylene-di-o-toluidines are formed.

The liquid compound is a thick oil, b.p. above 350° (decamp.); B_2H_6 , $PtCl_4$, is amorphous.

The solid compound forms small trimetric crystals, m.p. 128°, yielding a crystalline di-

hydrochloride, dihydrobromide, sulphate, and dioxalate (Grünhagen, Ann. 1890, 256, 303).

Tolyl-o-hydroxylamine; by reducing o-nitrotoluene with zinc dust and 66 p.c. alcohol in the presence of calcium chloride and sufficient ether to keep the temperature at about 65° (Bretschneider, J. pr. Chem. 1897, (2) 55, 293); by electrolytic reduction of o-nitrotoluene in dilute acetic acid (Haber, Zeitsch. Elektrochem. 1898, 5, 77); by oxidising o-toluidine with a persulphate in presence of ether and in contact with ice (Bamberger and Tschirner, Ber. 1899, 32, 1677). It solidifies to a resin in a mixture of solid carbon dioxide and ether and is readily oxidised to o-nitrosotoluene. On mixing with thionyl-aniline in benzene solution it yields o-toluidine phenyl sulphonamate, m.p. 206°, and azo-o-toluene (Michaelis and Petou, Ber. 1898, 31, 984). The action of methyl alcohol, ethyl alcohol and sulphuric acid, dilute sulphuric acid, dilute and concentrated hydrochloric acid on o-, m-, and p-tolylhydroxylamine under various conditions is described by Bamberger (Ann. 1921, 424, 233, 297).

6-Nitrotolyl-o-hydroxylamine; obtained in 50-60 p.c. yield when 2:6-dinitrotoluene is reduced electrolytically in presence of sodium acetate, acetic acid and alcohol (Brand and Zöller, Ber. 1907, 40, 3324). It exists in three modifications, two stable and one unstable, which are interconvertible by inoculation of their solutions in benzene. The stable yellow form has m.p. 117°-117.5°, the stable colourless form becomes yellow at 105° and melts at 117°-117.5° (Brand, Ber. 1911, 44, 2045).

With aqueous sodium hydroxide it yields mainly 2:2'-dinitro-6:6'-azoxytoluene, and when heated dinitrosotoluene is formed. When oxidised with ferric chloride and sodium acetate in aqueous solution 2-nitro-6-nitrosotoluene, colourless needles, m.p. 117°, is obtained, whilst with concentrated sulphuric acid it yields 2-nitro-6-amino-3-hydroxytoluene, and when heated with concentrated hydrochloric acid 3-chloro-2-nitro-6-aminotoluene, together with a small amount of the isomeric 5-chloro-2-nitro-6-aminotoluene, is produced (Brand and Zöller, l.c.).

4:6-Dinitrotolyl-o-hydroxylamine; together with 2:6-dinitrotolyl-p-hydroxylamine by reducing 2:4:6-trinitrotoluene in almost neutral solution at a silver cathode. Light yellow crystals, m.p. 109° (Brand and Eisenmenger, J. pr. Chem. 1913, (2) 87, 487; Ber. 1916, 49, 673).

m-Toluidine; by reduction of m-nitrotoluene (Beilstein and Kuhlberg, Ann. 1870, 155, 9; 1870, 156, 66); from p-toluidine by successive acetylation, nitration, hydrolysis, elimination of the amino-group, and reduction (Lorenz, Ber. 1874, 7, 448); by heating m-cresol with ammonium-zinc bromide and ammonium bromide at 330°-340° (Merz and Müller, Ber. 1887, 20, 548); by reducing m-nitrobenzylidene chloride with zinc in presence of alcohol and hydrochloric acid below 12° (Krich, Ber. 1892, 15, 2011; Widman, *ibid.* 1890, 13, 677; Herz, *ibid.* 1895, 18, 3396; Steiner and Vienne, Bull. Soc. chim. 1895, 35, 429; Widman, *ibid.* 1891, (2) 36, from m-nitrotoluenes by passing its vapour mixed with hydrogen over heated reduced copper or nickel (Bamberger and

Bamberger, *Chem. Zentr.* 1901, 122, 277).

Colourless oil, b.p. 203.3° (Kahlbaum, *Zeitsch. physikal. Chem.* 1898, 26, 621, 648), 202°-205° (M. and M.; Lorenz, *Ann.* 1874, 172, 190), 199°-202° (Buckha and Schachtebeck, *Ber.* 1889, 22, 840), 199°-199.5° (Schraube and Romig, *ibid.* 1893, 26, 579); D_{40}^{20} 0.98912 (Kahlbaum), D_{40}^{20} 1.0041, D_{15}^{25} 0.9961, D_{25}^{25} 0.990 (Perkin, *Chem. Soc. Trans.* 1896, 69, 1245; cf. Neubeck, *Zeitsch. physikal. Chem.* 1887, 1, 658); magnetic rotatory power at 15° 16.21 (P.); refractive power, see Brühl (*Zeitsch. physikal. Chem.* 1895, 16, 216); molecular heat of combustion at constant volume, 964.6 Cal.; at constant pressure, 965.6 Cal. (Petit, *Ann. Chim.* 1889, [6] 18, 154).

Its solution in diluted sulphuric acid is coloured yellow-brown by chromic acid and sulphuric acid, and dark red by nitric acid. When *m*-toluidine is dissolved in ether and an equal volume of water is added, followed by a few drops of calcium hypochlorite solution, the aqueous layer is coloured brownish-yellow, and the ethereal layer reddish (Lorenz, *Ann.* 1874, 172, 180).

It resembles the *o*-compound in many of its properties, but may be distinguished from the latter by its acetyl-derivative, m.p. 65.5° (aceto-*o*-toluidide melts at 110°). It may be detected and also estimated by conversion into the dimethyl-derivative, which, unlike the corresponding *o*- and *p*-compounds, readily yields a nitroso-derivative as a yellow crystalline precipitate when treated with nitrous acid (Wurster and Riedel, *Ber.* 1879, 12, 1796).

When hydrogenated in the presence of reduced nickel it yields *m*-methyl cyclohexylamine, together with the corresponding secondary and tertiary bases (Sabatier and Senderens, *Bull. Soc. chim.* 1904, (3) 31, 709). It reacts with diphenylthiocarbamide in presence of lead hydroxide to yield diphenyl-*m*-tolyl-guanidine (Alway and Viele, *Amer. Chem. J.* 1902, 28, 294); with benzylidene-acetyl-acetone to yield β -toluidinebenzyl-acetyl-acetone (Ruhemann and Watson, *Chem. Soc. Trans.* 1904, 85, 1170); with methylene di-iodide to yield di-*m*-tolyl-methylenediamine (Senier and Goodwin, *ibid.* 1902, 81, 280); with chloroacetylurethane to yield β -*m*-tolylhydantoin (Frerichs and Breustedt, *J. pr. Chem.* 1902, (2) 66, 231), and with benzaldehyde cyanhydrin to yield *m*-tolylamino-benzyl cyanide (Sachs and Goldmann, *Ber.* 1902, 35, 3319). Coupling with diazo-compounds has been studied by Mehner (*J. pr. Chem.* 1902, (2) 66, 401). The action of dichloroacetic acid on *m*-toluidine has been studied by Heller (*Ann.* 1908, 358, 349).

It is only employed to a limited extent technically in the production of dyestuffs (M. L. B., *Eng. Pat.* 5119 of 1897; *Fr. Pat.* 264579; *D. R. P.* 93499 of 1896; *Eng. Pat.* 14937 of 1908; *U.S. Pat.* 913940; *D. R. P.* 219210 of 1907; Monnet, Reverdin and Nölting, *Ber.* 1879, 12, 445; Rosenstiehl and Gerber, *Compt. rend.* 1882, 94, 1319; 95, 238).

For a new sensitive indicator from *m*-toluidine see Träger and Hille (*J. pr. Chem.* 1903, (2) 68, 297).

Salts (see Lorenz); $B'HCl$, leaflets, m.p. 228°, b.p. 247.8°/728 mm. or 249.8°/760 mm. (Ullmann, *Ber.* 1898, 31, 1699); $B'HNO_2$, large

rhombic tables; $B'H_2SO_4$, needles; $B'C_2H_5O_2$, unstable leaflets; $B'_2(C_2H_5O)_2$; $B'_2C_2H_5O_2$ (Eisenberg, *Ann.* 1880, 205, 270); $B'_2H_2PtCl_6$, yellow slender needles (Widman); $B'HBI_2$ (Kraut, *Ann.* 1881, 210, 323); $B'_2H_2ZnCl_4$, needles (Base, *Amer. Chem. J.* 1898, 20, 654); $B'_2H_2ZnCl_4$, needles (B.); $B'HCl_2HgCl_4$, tables (Swan, *Amer. Chem. J.* 1898, 20, 624); $B'HCl-HgCl_4$, tables (Swan); ($B'HCl$), $HgCl_4$, leaflets (Swan); $B'HSnCl_4 + \frac{1}{2}H_2O$, silver leaflets (Slagle, *Amer. Chem. J.* 1898, 20, 642); $B'_2H_2SnCl_4 + H_2O$, monoclinic tables (Slagle); $B'_2H_2SbCl_5 + H_2O$ (Higbee, *Amer. Chem. J.* 1900, 23, 150); $B'_2H_2SbCl_5$, rhombic tables (H.); $B'_2H_2ZnBr_4 + 4H_2O$, prisms (B.); $B'_2H_2ZnBr_4$, needles and prisms (B.); $B'_2H_2SbBr_4 + H_2O$ (H.); $B'_2H_2SbI_4$ (H.); $B'_2H_2SnCl_4$, pearly white plates, m.p. 76° (Druce, *Chem. News*, 1919, 119, 272); $B'_2H_2SnCl_4$, pale pink, nacreous plates, m.p. 284° (D.); *picrate*, striated monoclinic crystals, decomposing when heated above 180° (Jerusalem, *Chem. Soc. Trans.* 1909, 95, 1284).

Formyl-derivative; liquid at -18°, b.p. 278°/724 mm. (Niementowski, *Ber.* 1887, 20, 1892). Decomposes on long boiling, forming methane ditolylamidine, $CH(NC_2H_5)_2NHC_2H_5$, needles or plates, m.p. 123°.

Acetyl-derivative; long needles, m.p. 65.5°, b.p. 203° (Beilstein and Kuhlberg; Morgan and Micklethwait, *Chem. Soc. Trans.* 1913, 103, 1400); **benzoyl-derivative**; m.p. 125° (Just, *Ber.* 1886, 19, 983).

Chloroacetyl-derivative; m.p. 141°. On fusion with potassium hydroxide it is converted into 5:5'-dimethylindigotin (Kuhara and Chikashigé, *Amer. Chem. J.* 1902, 27, 1).

Dichloroacetyl-derivative; plates which sublime, m.p. 98°-100° (Rugheimer and Hoffmann, *Ber.* 1885, 18, 2988).

2-Chloro-*m*-toluidine; by reducing 2-chloro-3-nitrotoluene (Wynne and Greeves, *Chem. Soc. Proc.* 1895, 11, 151; *Chem. Soc. Trans.* 1895, 67, 1548; cf. Cohen and Dakin, *ibid.* 1901, 79, 1128); by the action of hydrochloric acid on *m*-tolylhydroxylamine (Bamberger, *Ber.* 1902, 35, 3697). M.p. 6.6° (Wibaut, *Rec. trav. chim.* 1913, 32, 244), b.p. 228°-229° (W. and G.), and is volatile with steam.

Acetyl-derivative; needles, m.p. 132°-133° (W. and G.; W.), or 133°-134° (Bamberger, Ter-Sarkissjanz and de Werra, *Ber.* 1905, 35, 3697, 3711), or 126°-128° (Cohen and Dakin, *l.c.* 1321); **benzoyl-derivative**; needles, m.p. 125° (W.).

4-Chloro-*m*-toluidine; by the action of hydrochloric acid on *m*-tolylhydroxylamine (Bamberger); reduction of 4-chloro-3-nitrotoluene (Goldschmidt and Hönig, *Ber.* 1886, 19, 2443; Gattermann and Kaiser, *Ber.* 1885, 18, 2601; cf. Engelbrecht, *ibid.* 1874, 7, 797; Claus, *J. pr. Chem.* 1892, (2) 48, 29). Thin very volatile colourless leaflets, m.p. 29°-30° or 32°, b.p. 230°/758 mm. (G. and K.; C.).

$B'HCl$, needles, partially dissociated in water (G. and K.).

Acetyl-derivative; long silky needles, m.p. 96°-97° (G. and K.; G. and H.; E.), or 124° (C.).

5-Chloro-*m*-toluidine; by reduction of 5-chloro-3-nitrotoluene (Hönl, *Ber.* 1887, 20, 2419). Liquid, b.p. 242°/730 mm., volatile with steam.

BHCl, small needles; **BHNO₃**, m.p. 198° (decomp.) (H.).

Acetyl-derivative; needles, m.p. 146° (H.) or 151° (W. and G.).

6-Chloro-m-toluidine; by the action of hydrochloric acid on *m*-tolylhydroxylamine (Bamberger); by the method of Chattaway and Orton (Chem. Soc. Trans. 1901, 79, 461); by reducing 6-chloro-3-nitrotoluene (Henry and Radziszewski, Ber. 1869, 2, 308, 599; Wroblewsky, Ann. 1873, 168, 206; Goldschmidt and Hönig, Ber. 1886, 19, 2443; 1887, 20, 199; Morgan and Challenor, Chem. Soc. Trans. 1921, 119, 1544); by reducing *m*-nitrotoluene with zinc and hydrochloric acid (Kock, Ber. 1887, 20, 1567). Tables, m.p. 83.5°–84.1° (Bamberger, Ter-Sarkissjanz and de Werra; Reverdin and Crépieux, Ber. 1900, 33, 2503; Chattaway and Orton).

BHCl, long slender needles; **BHNO₃**, long broad needles, m.p. 164°; **B₂H₄SO₄**.

Acetyl-derivative; colourless plates, m.p. 89° (G. and H.), 91.2°–91.7° (B., T-S. and de W.), 92° (M. and C.).

2:5-Dichloro-m-toluidine; by reduction of 2:5-dichloro-3-nitrotoluene (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1330). It melts at 69°–70°.

2:6-Dichloro-m-toluidine; by chlorination of 2-chloro-aceto-*m*-toluidide followed by hydrolysis with hydrochloric acid at 130° (Cohen and Dakin), or by reduction of 2:6-dichloro-3-nitrotoluene, followed by distillation with steam (C. and D., l.c. 1346). Colourless needles, m.p. 59°–60°.

Acetyl-derivative; long needles, m.p. 120°–122° (C. and D.); *benzenesulphonyl-derivative*, m.p. 114° (Raper, Cohen and Thomson, *ibid.* 1901, 85, 371).

4:5-Dichloro-m-toluidine; by reducing 3-nitro-4:5-dichlorotoluene; *acetyl-derivative*, needles, m.p. 158°–159° (Cohen and Dakin, l.c. 1338).

4:6-Dichloro-m-toluidine; by chlorination of aceto-*m*-toluidide in glacial acetic acid with sodium chlorate and hydrochloric acid, followed by hydrolysis (Reverdin and Crépieux, l.c.); by reduction of 2:4-dichloro-5-nitrotoluene (Cohen and Dakin, l.c.). Crystals, m.p. 85°, volatile with steam (*cf.* Seelig, Ann. 1887, 237, 163).

Acetyl-derivative; as above (R. and C.); by the action of bleaching powder on aceto-*m*-toluidide in glacial acetic acid (C. and D., l.c. 1332). Colourless needles, m.p. 156°–157° (R. and C.; C. and D.).

5:6-Dichloro-m-toluidine; by reducing 2:3-dichloro-5-nitrotoluene. Needles, m.p. 88°, b.p. 292° (Wynne and Greeves, l.c.).

Acetyl-derivative, m.p. 187° (W. and S.).

2:4:6-Trichloro-m-toluidine; by chlorination of aceto-*m*-toluidide in acetic acid and hydrochloric acids with sodium chlorate at 15°–25°, followed by hydrolysis of the acetyl-derivative with 50 p.c. sulphuric acid (Cohen and Dakin, l.c. 1336; Reverdin and Crépieux). Glistening white needles, volatile with steam, m.p. 77°–78° (C. and D.).

Acetyl-derivative; m.p. 181° (R. and C.).

2:5:6-Trichloro-m-toluidine; by nitration and reduction of 2:3:6-trichlorotoluene. It melts at 85°–87° (Cohen and Dakin, Chem. Soc. Trans. 1901, 85, 1281).

4-Bromo-m-toluidine; by reduction of 4-bromo-3-nitrotoluene (Nevile and Winther, Chem. Soc. Trans. 1880, 37, 442; Ber. 1880, 13, 972; Claus, J. pr. Chem. 1892, (2) 46, 25; Wroblewsky, Ann. 1873, 168, 77; Hübner and Roos, Ber. 1873, 6, 800). Prisms, m.p. 30.6°–32° (N. and W.), 35° (C.); 67° (W.), 75° (H. and R.). The higher melting-point compounds are impure.

Acetyl-derivative; m.p. 113.7°–114.6° (N. and W.), 164° (C.).

5-Bromo-m-toluidine; by reducing 5-bromo-3-nitrotoluene (Wroblewsky, Ann. 1878, 192, 203). It crystallises with difficulty, m.p. 35.6°–36°, b.p. 255°–260°; D₁₅ 1.442 (W.); Nevile and Winther, Ber. 1880, 13, 964; Chem. Soc. Trans. 1880, 37, 429). **BHCl**, tables; **BHNO₃**, long needles; **B₂H₄SO₄**, tables.

Acetyl-derivative; m.p. 167°–168° (N. and W.).

6-Bromo-m-toluidine; by brominating aceto-*m*-toluidide, followed by hydrolysis of the product with alcoholic potash (Wroblewsky, Ann. 1873, 168, 172); by reducing 6-bromo-3-nitrotoluene (Nevile and Winther, l.c.). Crystals, m.p. 78.4°–78.8°, b.p. 240° (N. and W.). **BHNO₃**, prisms.

It is probable that the product, described as a liquid and obtained by Hübner and Roos (Ber. 1873, 6, 801) by the reduction of nitrated *o*-bromotoluene is identical with this amine. **BHCl**, small rhombic tables; **BHNO₃**, small rhombic tables; **B₂H₄SO₄**, very slightly soluble in water.

2:5-Dibromo-m-toluidine; by reduction of 2:5-dibromo-3-nitrotoluene. M.p. 72.4°–73.1° (Nevile and Winther, l.c.).

Acetyl-derivative; m.p. 144°–145° (N. and W.).

2:6-Dibromo-m-toluidine; this compound is stated by Wroblewsky to be formed by the action of 2 mols. of bromine on aceto-*m*-toluidide, followed by hydrolysis, and is described as melting at 92.5°. Nevile and Winther (Chem. Soc. Trans. 1880, 37, 439) found that under these conditions a mixture of a monobromotoluidine, m.p. 76°–77°, 4:6-dibromo-*m*-toluidine, 2:6-dibromo-*m*-toluidine, m.p. 33°–35°, and 2:4:6-tribromo-*m*-toluidine is formed.

4:5-Dibromo-m-toluidine; by reducing the corresponding dibromonitrotoluene (Nevile and Winther, l.c.; Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 510). Long needles or flat prisms, m.p. 58°–59° (N. and W.).

Acetyl-derivative; m.p. 163.5°–164° (C. and D.).

4:6-Dibromo-m-toluidine; together with 2:6-dibromo-*m*-toluidine by brominating aceto-*m*-toluidide, separation being effected by crystallisation from alcohol in which the 2:6-*is* more soluble; by brominating 4-bromo-aceto-*m*-toluidide, followed by hydrolysis (Nevile and Winther, l.c.); by bromination of 6-bromoaceto-*m*-toluidide (Cohen and Dutt, l.c. 515); by reduction of 4:6-dibromo-3-nitrotoluene with tin and hydrochloric acid (Davies, Chem. Soc. Trans. 1901, 81, 872). Dull greyish radiating prisms, m.p. 74.5°–75° (D.).

Acetyl-derivative; white prisms or needles, m.p. 168°–168.6° (N. and W.), 168°–169° (C. and D.).

5:6-Dibromo-m-toluidine; by bromination and hydrolysis of 4-bromoaceto-

toluidide; by reduction of 5:6-dibromo-3-nitrotoluene (Neville and Winther, l.c.). It melts at 86.4° (N. and W.) or 83°-85° (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 512).

Acetyl-derivative; m.p. 204°-205° (N. and W.).

2:4:6-Tribromo-*m*-toluidine; by the action of bromine vapour on *m*-toluidine hydrochloride; by bromination of aceto-*m*-toluidide, followed by hydrolysis (Wroblewski, Ann. 1873, 168, 195; Neville and Winther, Chem. Soc. Trans. 1880, 37, 440, 448).

Monoacetyl-derivative; colourless crystals m.p. 205°.

Diacetyl-derivative; colourless crystals, m.p. 103° (Blanksma, Chem. Weekblad, 1909, 6, 717).

2:5:6-Tribromo-*m*-toluidine; by brominating 2:5-dibromoaceto-*m*-toluidide, followed by hydrolysis (Neville and Winther). It melts at 93°-94°.

Acetyl-derivative; m.p. 179°-181° (N. and W.).

4:5:6-Tribromo-*m*-toluidine; by successive bromination and hydrolysis of 4:5-dibromoaceto-*m*-toluidide (N. and W.). It melts at 96°-96.8°.

Acetyl-derivative; m.p. 171°-173° (N. and W.).

Tribromo-*toluidine*; from *o*-bromotoluene *m*-sulphonic acid, by nitration, reduction and bromination (Schäfer, Ann. 1874, 174, 362; Ber. 1874, 7, 1355). M.p. 82°.

Tetra-bromo-*m*-toluidine; by brominating 5-bromo-*m*-toluidine (Neville and Winther, Ber. 1880, 13, 975; Chem. Soc. Trans. 1880, 37, 449); or 4:5-dibromo-*m*-toluidine (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 510). White needles, m.p. 223°-224° (N. and W.).

6-Chloro-2:4-dibromo-*m*-toluidine; by brominating an aqueous solution of 6-chloro-*m*-toluidine 4-sulphonic acid (Davies, Chem. Soc. Trans. 1921, 119, 866). Long colourless needles, m.p. 99.5°, which on keeping become bright red. Insoluble in dilute hydrochloric acid and only slightly soluble in hot fuming hydrochloric acid.

2-Iodo-*m*-toluidine; by reducing 2-iodo-3-nitrotoluene with ferrous sulphate and ammonia (Wheeler and Liddle, Amer. Chem. J. 1909, 42, 441). Long flat prisms, m.p. 41°-42°.

Acetyl-derivative; m.p. 135°. On oxidation with potassium permanganate it yields 2-iodo-3-acetylaminobenzoic acid, m.p. 119° (Wh. and L.).

4-Iodo-*m*-toluidine; similarly from 4-iodo-3-nitrotoluene. It melts at 38°-38.5° (Wheeler and co-workers, *ibid.* 1910, 44, 126, 493), and not at 48° as stated by Willgerodt and Simonis (Ber. 1906, 39, 269). B'HCl, pale yellow needles; B'HNO₃, red needles; B'H₂SO₄ (Wi. and S.). *Acetyl-derivative*; m.p. 151° (W.), 145°-146° (Wi. and S.). On treatment with iodine chloride it yields 4:6-di-iodoaceto-*m*-toluidide.

Formyl-derivative; slender colourless needles, m.p. 129° (Wi. and S.).

5-Iodo-*m*-toluidine; by reducing 5-iodo-3-nitrotoluene (W.). Long colourless needles, m.p. 78°-78.5°.

Acetyl-derivative; m.p. 183° (W.).

An *iodo-*toluidine**; needles or leaflets, m.p. 188°-189° described by Hübner and Glassner (Ber. 1875, 8, 562), and is obtained from nitrated

p-iodotoluene. It forms a *hydrochloride*, needles; a *nitrate*, plates; and a *sulphate*, needles.

6-Iodo-*m*-toluidine; by reducing 6-iodo-3-nitrotoluene (Artmann, Monatsh. 1905, 26, 1091; Holleman, Rec. trav. chim. 1912, 31, 267). Colourless leaflets which decompose slowly on exposure to air, m.p. 98°-99° (A.), or m.p. 37°-39° (Wheeler, &c.), or m.p. 42° (H.). B'HCl, short needles; B'HNO₃, aggregates of slender needles (A.).

Acetyl-derivative; white needles, m.p. 132° (A.).

2:5-Di-iodo-*m*-toluidine; by reduction of 2:5-di-iodo-3-nitrotoluene (Wheeler, &c.). Pale brown prisms, m.p. 82°.

Acetyl-derivative; long colourless needles, m.p. 198°-199° (W.).

2:6-Di-iodo-*m*-toluidine; by the action of iodine chloride on 2-iodoaceto-*m*-toluidide, followed by hydrolysis (Wheeler, &c.). Colourless prisms, m.p. 88°.

Acetyl-derivative; colourless prisms, m.p. 171° (W.).

4:5-Di-iodo-*m*-toluidine; by reducing 4:5-di-iodo-3-nitrotoluene (Wheeler, &c., l.c.). Colourless slender needles, m.p. 66°-67°.

Acetyl-derivative; m.p. 183°-184° (W.).

4:6-Di-iodo-*m*-toluidine; by the action of iodine on 4-iodo-*m*-toluidine (Wheeler, &c.). Stout colourless needles, m.p. 73°-74°.

Acetyl-derivative; long colourless needles, m.p. 213° (W.).

5:6-Di-iodo-*m*-toluidine; by the action of ferrous sulphate and ammonia on 2:3-di-iodo-5-nitrotoluene (W.). Colourless crystals, volatile with steam, m.p. 106°.

Acetyl-derivative; m.p. 208° (W.).

2:4:6-Tri-iodo-*m*-toluidine; pale brown hair-like needles, m.p. 135°.

Acetyl-derivative; m.p. 265° (W.).

2:4:6-Tri-iodo-*m*-toluidine; together with 2:4:5:6-tetraiodo-*m*-toluidine by warming mixture of 2:5-di-iodo-*m*-toluidine with iodine, water, ether and calcium carbonate for 18 hours. Colourless needles, m.p. 119°-120° (W.).

4:5:6-Tri-iodo-*m*-toluidine; by warming a mixture of 5:6-di-iodo-*m*-toluidine, iodine, water, ether and calcium carbonate for several hours. Small needles, m.p. 122°.

Acetyl-derivative; colourless needles, m.p. 265° (decomp.) (W.).

2:4:5:6-Tetraiodo-*m*-toluidine; together with other products by iodination of 2:5- or 5:6-di-iodo-*m*-toluidine under similar conditions (W.). Small needles, m.p. 205° (W.).

6-Chloro-4-iodo-*m*-toluidine; by successive chlorination and hydrolysis of 4-iodoaceto-*m*-toluidide (Willgerodt and Simonis, Ber. 1906, 39, 269). Thin colourless plates, m.p. 65°; *oxalate*; large plates, m.p. 165°.

Acetyl-derivative; aggregates of small colourless needles, m.p. 196.5° (Wi. and S.).

6-Nitroso-*m*-toluidine; by heating 1 part of nitroso-*m*-cresol with 15 parts of dry ammonium acetate and 5 parts of ammonium chloride for 1 hour at 100° (Mehne, Ber. 1888, 21, 730). Steel-blue needles, m.p. 178°.

2-Nitro-*m*-toluidine; see also Lampricht, Ber. 1885, 18, 1402; Stadel and Kolb, Ann. 890, 259, 216; Nöling and Stoecklin, Ber. 891, 24, 564; together with small quantities

of 2-nitro-*o*-toluidine and 2,3-toluylenediamine by reduction of 2:3-dinitrotoluene suspended in alcoholic hydrochloric acid with stannous chloride and absolute alcohol at 7° and keeping the mixture for 12 hours. It forms deep red prisms, m.p. 107°–108° (Burton and Kenner, Chem. Soc. Trans. 1921, 119, 1052), and was formerly erroneously regarded as a dinitroazo-toluene (Kenner and Parkin, *ibid.* 1920, 117, 857). When 2:3-dinitrotoluene is reduced with hydrogen sulphide in alcoholic ammoniacal solution, Kenner and Parkin (*l.c.*) obtained a dinitroditolyl sulphide (most probably the 2:2':6:6'-compound) and a substance, m.p. 54°. 2-Nitro-*m*-toluidine is obtained also by heating 3-chloro-2-nitrotoluene with concentrated ammonia solution (D 0.880) at 200° for 8 hours.

Acetyl-derivative; transparent prisms, m.p. 126° (B. and K.) or 136° (L.).

4-Nitro-*m*-toluidine; from 4-nitro-*m*-tolyl-ethyl ether and ammonia (Städel and Kolb, Ann. 1890, 259, 224; Green and Rowe, Chem. Soc. Trans. 1913, 103, 898; Morgan and Scharff, Chem. Soc. Trans. 1914, 105, 121); by hydrolysis of the acetyl-derivative, obtained together with 6-nitroaceto-*m*-toluidide by nitrating aceto-*m*-toluidide with fuming nitric acid in glacial acetic acid (Cohen and Dakin, Chem. Soc. Trans. 1903, 83, 333); from 4-nitro-2:5-toluylenediamine by the diazo-reaction (Morgan and Micklethwait, *ibid.* 1913, 103, 1399; Morgan and Scharff, *l.c.*); by heating 3:4-dinitrotoluene with 2.5/N-methyl alcoholic ammonia at 150° for 6 hours (Kenner and Parkin, *ibid.* 1920, 117, 858). Golden-yellow plates, or orange-yellow spicules, m.p. 109° (S. and K.), 110°–110.5° (C. and D.), or 112° (M. and M.).

Acetyl-derivative; yellow needles, m.p. 88°–89° (M. and M.) or 86°–87° (C. and D.); *benzoyl-derivative*; long yellow needles, melting indefinitely at 83° (M. and M.); *benzenesulphonyl-derivative*; prisms, m.p. 137°–138° (M. and S.).

5-Nitro-*m*-toluidine; in 80 p.c. yield by reducing 3:5-dinitrotoluene with alcoholic ammonium sulphide (Städel, Ann. 1883, 217, 199; Neville and Winther, Ber. 1882, 15, 2985; Brady, Day and Rolt, Chem. Soc. Trans. 1922, 121, 529). Yellow or brownish-red needles, m.p. 98°–98.4° (N. and W.; Haibach). B'HBr, thin leaflets (Haibach, J. pr. Chem. 1902, (2) 65, 242).

Acetyl-derivative; white microcrystalline powder, m.p. 187° (B., D. and R.). If a solution of the acetyl-derivative in concentrated sulphuric acid is added to nitric acid, or if the solid compound be added to a mixture of nitric and sulphuric acids, 5:6-dinitroaceto-*m*-toluidide is the main product, but if the acetyl-compound is added directly to fuming nitric acid 4:5-dinitroaceto-*m*-toluidide preponderates (B., D. and R.).

6-Nitro-*m*-toluidine; by successive nitration and hydrolysis of aceto-*m*-toluidide (Beilstein and Kuhlberg, Ann. 1871, 158, 348), or together with the 4-nitro-isomeride when the nitration is effected in glacial acetic acid solution (Cohen and Dakin, Chem. Soc. Trans. 1903, 83, 333; Cook and Brady, *ibid.* 1920, 117, 752); by heating 6-nitro-3-amino-*p*-toluic acid with hydrochloric acid at 150° (Filati and Cross, Gazz. chim. ital. 1882, 12, 204); by heating 6-nitro-3-amino-

ethyl ether with concentrated ammonia (D 0.9) at 140°–150° for 8 hours (Städel and Kolb, Ann. 1890, 259, 214); as chief product, together with the 4-nitro-isomeride, by nitrating *m*-toluidine dissolved in glacial acetic acid and sulphuric acid with nitric acid (63 p.c.) and sulphuric acid at 0°, the isomerides being separated by distilling with a current of steam (Nölting and Stoecklin, Ber. 1893, 26, 564; cf. Morgan and Micklethwait, Chem. Soc. Trans. 1913, 103, 1397; Kenner and Parkin, *ibid.* 1920, 117, 858). Long, slender, saffron-yellow needles, m.p. 138° (N. and S.), 138°–140° (M. and M.), 133°–134° (C. and D.), or 135°–138° (Cohen and Hodsman, *ibid.* 1907, 91, 976).

Acetyl-derivative; small rhombic cubes, m.p. 101°–102° (B. and K.), or massive red prisms, m.p. 103°–104° (C. and D.), or m.p. 109° (M. and M.). It is separated from 4-nitroaceto-*m*-toluidide by mechanical means, followed by crystallisation from alcohol (C. and D.), or by pouring the reaction product into water when the 6-nitro-isomeride separates, whilst the filtrate on keeping deposits 4-nitroaceto-*m*-toluidide (C. and B.).

2:4-Dinitro-*m*-toluidine; *acetyl-derivative*; colourless needles, m.p. 211°–212° (C. and B.).

2:6-Dinitro-*m*-toluidine; in 10–15 p.c. yield by the action of hydroxylamine hydrochloride on 2:6-dinitrotoluene in methyl alcoholic potassium hydroxide solution at 30°, and addition of much water to the resulting solution (Meisenheimer and Patzig, Ber. 1906, 39, 2533); by the action of 10 p.c. alcoholic ammonia on 3-bromo-2:6-dinitrotoluene (Körner and Contardi, Atti R. Accad. Lincei, 1916, [v.] 25, ii. 339). Pale yellow prisms or needles, m.p. 133.8° (K. and C.) or 132.5° (M. and P.).

Acetyl-derivative; colourless plates or large prisms, m.p. 166° (K. and C.; C. and B.).

4:5-Dinitro-*m*-toluidine; see 5-nitro-*m*-toluidine. Large brownish-yellow needles, m.p. 131°.

Acetyl-derivative; fine white needles, m.p. 177° (B., D. and R.).

4:6-Dinitro-*m*-toluidine; by keeping a mixture of 3:4:6-trinitrotoluene and alcoholic ammonia for 1 day (Hepp, Ann. 1883, 215, 368); by heating *m*-bromo-4:6-dinitrotoluene with alcoholic ammonia (Bentley and Warren, Amer. Chem. J. 1890, 12, 2); by heating 4:6-dinitro-*m*-cresyl ethyl-ether with concentrated aqueous ammonia at 100° (Städel and Kolb, Ann. 1890, 259, 220); as the main product, together with a small quantity of 2:6-dinitro-*m*-toluidine, and very little, if any, 2:4-dinitro-*m*-toluidine, by gradual addition of aceto-*m*-toluidide to 10 times its weight of nitric acid (D 1.5) with thorough agitation, keeping the temperature below 25°, followed by hydrolysis. Occasionally 2:4:6-trinitro-*m*-toluidine is formed also (Cook and Brady, Chem. Soc. Trans. 1920, 117, 760); together with the 2:6-dinitro-isomeride by gradual addition of 6-nitroaceto-*m*-toluidide to an excess of nitric acid (D 1.5) below 25°, followed by hydrolysis (C. and B.). Small golden-yellow crystals, m.p. 192°–193° (H.) or 195° (S. and K.).

Acetyl-derivative; pale yellow needles, m.p. 103° (C. and B.).

3:5-Dinitro-*m*-toluidine; see 5-nitro-*m*-toluidine. Orange-yellow plates, m.p. 145°.

Acetyl-derivative; faintly yellow sandy powder, m.p. 172° (Brady, Day and Rolt).

2:4:6-Trinitro-*m*-toluidine; by the action of concentrated alcoholic ammonia on the ethyl-ether of 2:4:6-trinitro-*m*-cresol (Nölting and Salis, Ber. 1882, 15, 1864; Ann. Chim. 1885, (6) 4, 128; Städel and Kolb, Ann. 1890, 259, 222), or on *m*-bromo-trinitrotoluene (Bentley and Warren, Amer. Chem. J. 1890, 12, 5), or on 3-chloro-2:4:6-trinitrotoluene (Reverdin, Dresel and Deletra, Bull. Soc. chim. 1904, (3) 31, 631). Small crystals, m.p. 136° (S. and K.) or 126° (N. and S.).

Acetyl-derivative, microscopic white silky needles, m.p. 249° (decomp.) (Cook and Brady, Chem. Soc. Trans. 1920, 117, 752).

2-Chloro-4-nitro-*m*-toluidine; by keeping a solution of 2-chloro-3:4-dinitrotoluene in about 60 parts of absolute alcohol saturated with ammonia for 14 days (Morgan and Glover, Chem. Soc. Trans. 1921, 119, 1704). Golden-yellow needles, m.p. 105°. It yields a deep red coloration with alcoholic sodium hydroxide.

6-Chloro-4-nitro-*m*-toluidine; obtained together with 6-chloro-2-nitro-*m*-toluidine by successive nitration and hydrolysis of 6-chloro-aceto-*m*-toluidide (B. A. S. F., D. R. P. 226772 of 1908; Morgan and Challenor, Chem. Soc. Trans. 1921, 117, 1544), or together with 27 p.c. 6-chloro-3-nitro-*p*-toluidine, by the action of alcoholic ammonia on 2-chloro-4:5-dinitrotoluene. The latter mixture melts at 144°, and is not separated by repeated crystallisation from alcohol, petroleum or glacial acetic acid (Morgan and Drew, *ibid.* 1920, 117, 789; Morgan and Challenor, *l.c.*). Yellowish-brown prisms, m.p. 158°–159°.

2:4:5-Trichloro-6-nitro-*m*-toluidine; the *acetyl-derivative*, which does not melt below 200°, is obtained together with a *dichloro-6-nitroaceto-*m*-toluidide*, colourless needles, m.p. 181°–183°, by treating 6-nitroaceto-*m*-toluidide with aqueous sodium chlorate in presence of glacial acetic and concentrated hydrochloric acids (Cohen and Dakin, Chem. Soc. Trans. 1903, 83, 333).

4:5:6-Trichloro-2-nitro-*m*-toluidine; by treating 4:5:6-trichlorodinitrotoluene with alcoholic ammonia at 80°–100°. It melts at 192° (Seelig, Ber. 1885, 18, 420).

6-Bromo-2-nitro-*m*-toluidine; see 6-bromo-4-nitro-*m*-toluidine. It melts at 102°–103° (Neville and Winther, Ber. 1880, 13, 972; Chem. Soc. Trans. 1880, 37, 444; Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 513).

6-Bromo-4-nitro-*m*-toluidine; as main product together with the 2-nitro-isomeride by nitrating 4-bromoaceto-*m*-toluidide with sulphuric and nitric acids (N. and W.), or in presence of glacial acetic acid (C. and D.), followed by hydrolysis. Dark yellow or brown needles, m.p. 179°–181°.

Acetyl-derivative; m.p. 125°–125.5° (C. and D.).

5-Bromo-6-nitro-*m*-toluidine; by successive nitration and hydrolysis of 5-bromoaceto-*m*-toluidide (Neville and Winther, Ber. 1880, 13, 1945; Chem. Soc. Trans. 1880, 37, 630). It melts at 87°–88°.

2:6-Dibromo-4-nitro-*m*-toluidine; by bromination of 6-bromo-4-nitro-*m*-toluidine (N. and W.). Yellow needles, m.p. 130°–133° (C. and D.) or 124°–130° (N. and W.).

2:4:6-Tribromo-5-nitroaceto-*m*-toluidide; by nitrating 2:4:6-tribromoaceto-*m*-toluidide with nitric acid (D 152), followed by hydrolysis with concentrated sulphuric acid at 110° (Blankama, Chem. Weekblad, 1909, 6, 717). Pale yellow needles, m.p. 184°.

Acetyl-derivative; colourless needles, m.p. 261°; *diacetyl-derivative*; colourless crystals, m.p. 188° (B.).

Methyl-*m*-toluidine; by the action of dimethyl sulphate (Ullmann, Ann. 1903, 327, 104) or methyl iodide on *m*-toluidine. The product is freed from *m*-toluidine by treating the ethereal solution with dilute sulphuric acid and from the dimethyl-derivative by subsequent treatment with acetic anhydride (Monnet, Reverdin and Nölting, Ber. 1878, 11, 2279). Liquid, b.p. 206°–207°.

Acetyl-derivative; m.p. 60°, b.p. about 250°.

4-Nitromethyl-*m*-toluidine; by the action of methylamine on the methyl-ether of 4-nitro-*m*-cresol. Brownish-yellow flat prisms, m.p. 83° (O. Fischer and Rigaud, Ber. 1902, 35, 1258).

6-Nitromethyl-*m*-toluidine; by the action of concentrated nitric acid on the nitrosoamine (Störmer and Hoffmann, Ber. 1898, 31, 2535). Yellowish-brown plates with a blue sheen, m.p. 92°–93°.

Nitrosoamine; yellowish plates, m.p. 73°–74°.

6-Chloro-4-nitromethyl-*m*-toluidine; by the action of dry methylamine on an absolute alcoholic solution of 6-chloro-4:5-dinitrotoluene; by heating 6-chloro-4-nitro-*m*-toluidine with methyl sulphate in toluene at 100° for 4 hours (Morgan and Jones, Chem. Soc. Trans. 1921, 119, 190). Long red acicular prisms, m.p. 126°–127°.

Nitrosoamine; yellow plates, m.p. 70°.

2:4:6-Trinitromethyl-*m*-toluidine; by the action of methylamine on the methyl-ether of 2:4:6-trinitro-*m*-cresol. It melts at 138° (Blanksma, Rec. trav. chim. 1902, 21, 327).

Dimethyl-*m*-toluidine; by the action of methyl iodide on *m*-toluidine or by distilling toluene trimethylammonium hydroxide (Monnet, Reverdin and Nölting). B.p. 215° (Wurster and Riedel, Ber. 1879, 12, 1797), 208° (Reinhardt and Städel, *ibid.* 1883, 16, 31). $B'_2H_4Fe(CN)_6 + 2H_2O$, white needles; $B'_2H_4Fe(CN)_6 + 1\frac{1}{2}H_2O$ (Wurster and Roser, *ibid.* 1879, 12, 1826).

Nitroso-derivative; green leaflets or long needles, m.p. 92°. Does not give Liebermann's nitroso-reaction. With aniline, *o*-toluidine, &c., it yields steel-blue double compounds. $B'HCl$, yellow or greenish-yellow needles; $B'_2H_4Fe(CN)_6 + H_2O$; $B'_2H_4Fe(CN)_6 + H_2O$ (Wurster and Roser).

Nitrodimethyl-*m*-toluidine; by oxidising the above nitroso-compound with potassium permanganate (Wurster and Riedel). Long yellow needles, m.p. 84°.

5-Nitrodimethyl-*m*-toluidine; blood-red, glistening rhombic tables or double pyramids, m.p. 52° (Jäger, Z. Kristall. 1903, 38, 89), or 48°–50° (Haibach, J. pr. Chem. 1902, (2) 65, 342).

Dinitrodimethyl-*m*-toluidine; by nitrating an acetic acid solution of dimethyl-*m*-toluidine (Wurster and Riedel). Yellow needles, m.p. 107°. When the nitration is carried out with nitric acid alone or in presence of sulphuric acid this compound is accompanied by an isomeride, small yellow crystals, m.p. 168°, which is less

soluble in alcohol than the former (Wurster and Riedel).

Bromodimethyl-m-toluidine; by brominating dimethyl-m-toluidine hydrochloride (Wurster and Riedel, Ber. 1878, 12, 1800). White leaflets, m.p. 98°, b.p. 276°. $B_2H_4Fe(CN)_6 + 4H_2O$; $B_2H_4Fe(CN)_6 + 4\frac{1}{2}H_2O$ (Wurster and Roser, l.c., 1825).

4-Nitroethyl-m-toluidine; by treating the ethyl-ether of 4-nitro-m-cresol with ethylamine at 165°–170°. It melts at 60° (Fischer and Rigaud, Ber. 1901, 34, 4202).

2:4:6-Trinitroethyl-m-toluidine; in a similar manner from 2:4:6-trinitro-m-cresol. It melts at 98°, and the nitroamine at 79° (Blanksma).

Diethyl-m-toluidine; b.p. 227°–228° (Reinhardt and Stadel, Ber. 1883, 16, 31).

Phenyl-m-toluidine; by strongly heating a mixture of 5-phenylamino-m-cresol with zinc dust (Zega and Buch, J. pr. Chem. 1886, (2) 33, 542). Reddish oil, b.p. 300°–305°. Its solution in sulphuric acid is coloured an intense green by nitric acid.

4-Nitrophenyl-m-toluidine; by heating 5-phenylamino-4-nitrotoluene 2-sulphonic acid with sulphuric acid (25 p.c.) at 145° for 4 hours (Schraube and Romig, Ber. 1893, 26, 581). Yellowish-red plates from alcohol or six-sided tables from ligroin, m.p. 110°.

Diphenyl-m-toluidine; by the interaction of m-chlorotoluene and potassium diphenylamine (Haussermann, Ber. 1901, 34, 38). It melts at 69°–70°.

6-Chloro-4-nitrophenyl-m-toluidine; by boiling 2-chloro-4:5-dinitrotoluene with aniline in alcoholic solution for 36 hours; in a yield of 50 p.c. from 6-chloro-4-nitro-m-toluidine by heating under a reflux with bromobenzene, potassium carbonate and cuprous iodide (Morgan and Jones, Chem. Soc. Trans. 1921, 119, 190). Rectangular pyramids, m.p. 95°–96°.

Nitrosoamine; yellow prisms, m.p. 95°–96°.

2-Chloro-4-nitrophenyl-m-toluidine; in a similar manner to the 6:4-isomide from 2-chloro-3:4-dinitrotoluene and 2-chloro-4-nitro-toluidine, respectively (M. and J.). Orange-red needles, m.p. 95°.

Di-m-tolylamine; by heating m-toluidine with its hydrochloride at 210°–240° (Cosack, Ber. 1880, 13, 1091); by heating m-cresol with ammonia, zinc chloride and ammonium chloride at 330°–340° (Merz and Müller, Ber. 1887, 20, 99). Liquid, b.p. 319°–320°, volatile with steam.

Acetyl-derivative; tables, m.p. 43° (C.).

Tolyl-m-hydroxylamine; plates, m.p. 68° (Bamberger, Ber. 1895, 28, 248). On oxidation yields m-azoxytoluene and m-nitrosotoluene.

Nitroso-derivative, $(CH_3)_2C_6H_3N(NO)OH$, as glistening needles, m.p. 54°–54.5° (B.). **Tolyl-m-hydroxylamine** when treated in the same way with formaldehyde or when acted upon by trimethane yields **methylene-N,N-di-tolyl-hydroxylamine**, $CH_3N(OH)C_6H_4CH_3$, plates, m.p. 118° (Bamberger and Tschirner, Ber. 1900, 33, 951, 959), and when added in a dry-divided condition to concentrated hydrochloric acid saturated at –8° to –10° with hydrogen chloride and the mixture allowed to remain in an ice chest for 7 days, the product consists of m-azoxytoluene, 3-amino-6-cresol, 4-chloro-m-toluidine, 2-chloro-m-toluidine, and

4-chloro-m-toluidine (Bamberger, Tar-Sarkis-janz and de Werra, Ber. 1902, 35, 3697; cf. Bamberger and de Werra, *ibid.* 3711). It reacts with thionyl aniline yielding m-toluidine phenylsulphonamide and benzene-azo-m-toluene (Michaelis and Petou, Ber. 1898, 31, 984).

p-Toluidine; see o-toluidine; by reduction of p-nitrotoluene (Muspratt and Hofmann, Ann. 1845, 54, 1; 1848, 66, 144; Noad, *ibid.* 1847, 63, 305; Miller, Zeit. f. Chem. 1864, 161; Sell, Chem. Soc. Trans. 1863, 16, 186); together with ditolyl oxide by heating p-cresol with ammoniacal zinc chloride at 300° (Buch, Ber. 1884, 17, 2637; Merz and Müller, *ibid.* 1887, 20, 545); by reduction of p-nitrobenzyl chloride with zinc dust (Rudolf, Jahresbericht, 1885, 2082; D. R. P. 34234 of 1885); by treating p-aminobenzyl alcohol with a solution of stannous chloride at 100° for $\frac{1}{2}$ hour (Thiele and Dimroth, Ann. 1899, 305, 121); by reduction of polymerised anhydro-p-aminobenzyl alcohol with zinc dust and hydrochloric acid (Kalle & Co., Eng. Pat. 1963 of 1895; Fr. Pat. 246918; D. R. P. 83544 of 1894); by the action of heat on the salts of methylaniline (Hofmann, Ber. 1872, 5, 720).

The conversion of methylaniline into p-toluidine hydrochloride has been studied by Beckmann and Correns (Ber. 1922, 55, 852), who showed that the main factor governing the change is the temperature, the addition of such salts as zinc chloride or aluminium chloride having little effect. p-Toluidine is also formed by the action of hydroxylamine on toluene in presence of aluminium or ferric chloride (Graebe, Ber. 1901, 34, 1778), and by heating hydrazo-p-toluene with alcohol at 120°–130° (Biehringer and Busch, Ber. 1903, 36, 339).

Commercial p-nitrotoluene usually contains some nitrobenzene and o-nitrotoluene, consequently the crude reduction product contains aniline and o-toluidine. The crude product may be first purified by distillation, freezing the fraction, b.p. 195°–205°, followed by crystallising the solid product from ligroin.

p-Toluidine crystallises from aqueous alcohol in leaflets, m.p. 45° (Städeler, J. pr. Chem. 1864, 425), or 42–77° (Mills, Phil. Mag. 1882, (5) 14, 27), 42–8° (Perkin, Chem. Soc. Trans. 1896, 69, 1245), b.p. 198° (Muspratt and Hofmann), or 200–4° (Hulett, Zeitsch. physikal. Chem. 1898, 28, 651, 657; Kahlbaum, *ibid.* 1898, 29, 621; cf. Neubeck, *ibid.* 1887, 1, 659), or 200–3° (P.); D_{50}^{20} 0.973, D_{70}^{20} 0.967 (P.), 1.046 (Räddorf, Ber. 1879, 12, 252); magnetic rotatory power at 50° 15.87 (P.); dissociation constant, $K = 20.6 \times 10^{-10}$ (Löwenherz, Zeitsch. physikal. Chem. 1898, 25, 394); refractive power, see Brühl (*ibid.* 1895, 16, 216), Eykman (Rec. trav. chim. 1893, 12, 278); cryoscopic behaviour, see Auwers (*ibid.* 1897, 23, 451), Ampela and Rinatoni (Gazz. chim. ital. 1897, 27, i. 43); heat of combustion at constant pressure, 958.6 Cal., heat of combustion at constant volume, 957.96 Cal. (Petit, Compt. rend. 1888, 107, 226; Ann. Chim. 1889, (6) 18, 152).

p-Toluidine may be separated from aniline by means of the oxalate (Brimmeyer, Zeit. f. Chem. 1865, (2) 1, 513), or by acetylation (Weith and Merz, Ber. 1893, 2, 433), or by means of formaldehyde (D. R. P. 87615 of 1895). A

and Tschirner, *ibid.* 1899, 32, 1677; Otto, Ann. Chim. 1898, (7) 13, 142). When heated with aqueous regia *p*-toluidine yields chlorotoluene; with hydrogen iodide toluene is produced; and when heated with a meta-derivative of nitrobenzene in the presence of hydrochloric acid, dyestuffs of the chrysaniline series are formed (D. R. P. 65985 of 1892; 78377, 79263, 79585, 79877, 81048 of 1894).

p-Toluidine heated with sulphur gives rise to the primuline bases (Green, Ber. 1889, 22, 968; Jacobson, *ibid.* 330; Gattermann, *ibid.* 422; Gattermann and Pfitzinger, *ibid.* 1063; Hunter, J. Soc. Chem. Ind. 1923, 42, 302 T). Heated with ethyl alcohol and zinc chloride *p*-toluidine forms 4-amino-1-methyl-3-ethylbenzene (Willgerodt and Brandt, J. pr. Chem. 1904, (2) 69, 433).

p-Toluidine condenses with bromo- and sulphonated methylaminoanthraquinones, &c., forming bluish-green dyes (Fr. Bayer & Co., D. R. P. 159129 of 1901; Wacker, Ber. 1902, 35, 2593; Friedländer and Schick, Zeitsch. Farb. Text. Ind. 1904, 3, 218; see also M. L. B., Eng. Pat. 8905 of 1903; U.S. Pat. 748375; D. R. P. 149780; Bayer & Co., D. R. P. 148767, 153517 of 1903; M. L. B., D. R. P. 174131 of 1905).

p-Toluidine also condenses with diazo-compounds (Mehner, J. pr. Chem. 1902, (2) 65, 401); with phenylurethane (Dixon, Chem. Soc. Trans. 1901, 79, 102); with methylene iodide (Senior and Goodwin, *ibid.* 1902, 81, 280); with acetylene tetrabromide (Sabanéoff and Rakovsky, J. Russ. Phys. Chem. Soc. 1902, 34, 408); with phenyl isocyanate (Walther and Stenz, Bull. Soc. chim. 1901, (3) 26, 395); with epichlorhydrin (Cohn and Friedländer, Ber. 1904, 37, 3034); and with trinitrotoluene, *p*-toluidine forms an additive compound, dark red crystals, m.p. 68° (Jackson and Clarke, Chem. Soc. Proc. 1906, 22, 84). *p*-Toluidine reacts with phenylazoisimide at 140° to form a substance, $C_{12}H_{11}N_3$, colourless needles, m.p. 116°, converted into a brown viscous mass on benzylation, from which benzo-*p*-toluidide is obtained by treatment with alcoholic hydrochloric acid (Wolff and Kolasius, Ann. 1912, 394, 59).

As in the case of *o*-toluidine, the *p*-isomeride when diazotised in sulphuric acid solution, then saturated with sulphur dioxide, treated with copper, filtered, washed with ammonia and the filtered filtrate treated with ferric chloride, the ferric toluene sulphinat, $Fe(C_6H_4(CH_3)SO_3)_3$, is formed (Thomas, Chem. Soc. Trans. 1909, 95, 13).

p-Toluidine condenses with aromatic aldehydes in the presence of its hydrochloride forming acridines (Ullmann, Ber. 1903, 35, 107). The other condensation products of *p*-toluidine with aldehydes, see Eibner and Amann (Ann. 1903, 329, 211); Friedländer (Ber. 1892, 25, 149); Eibner and Parucker (*ibid.* 1900, 33, 62); Hantzsch and Schwab (*ibid.* 1901, 34, 2, 841); Cohn and Friedländer (*ibid.* 1902, 35, 1265); Cohn and Blau (Monatsh. 1904, 25, 5), &c. On hydrogenation in presence of fused nickel, *p*-toluidine yields *p*-methyl-phenylamine, together with the corresponding secondary and tertiary bases (Sabatier and Senderens, Bull. Soc. chim. 1904, (3) 31, 709). When treated with ethyl alcohol in presence of

zinc chloride it yields aminomethylethylbenzene (Willgerodt and Brandt, J. pr. Chem. 1904, (2) 69, 433). With dichloroacetic acid it yields *p*-tolylamino-*p*-methyl-oxindole (Keller, Ann. 1904, 332, 247).

On exhaustive chlorination in acetic acid with moist chlorine *p*-toluidine yields heptachloromethylcyclohexanone. When *p*-toluidine is chlorinated in 97 p.c. sulphuric acid it is converted mainly into 3-chloro- and partly into 2-chloro-derivatives. The same products, together with 3:5-dichloro-*p*-toluidine, are obtained if 40 p.c. sulphuric acid is used. 3-Chloro-, 3:5-dichloro-, and higher chlorinated products are obtained by chlorinating aceto-*p*-toluidide (Hafner, Ber. 1889, 22, 2535; Wroblewsky, Ann. 1873, 168, 196; Lellmann and Klotz, *ibid.* 1885, 231, 308; Zincke, Ber. 1895, 28, 3121). Chlorinated products are obtained also when *p*-toluidine is electrolysed in an excess of hydrochloric acid (Elbs and Brunschweiler, J. pr. Chem. 1895, (2) 52, 559).

Formyl-derivative; together with the oxalyl-derivative by heating *p*-toluidine oxalate (Hübner, Ann. 1881, 209, 372); by boiling *p*-toluidine with formic acid (Tobias, Ber. 1892, 15, 2446). Very long needles, m.p. 52° (T.) or 53° (Bamberger and Wulz, *ibid.* 1891, 24, 2080). $NaC_6H_4NO + H_2O$ (T.); AgC_6H_4NO , needles (Cornstock and Clapp, Amer. Chem. J. 1891, 13, 527); $Hg(C_6H_4ON)_2$, needles (Wheeler and MacFarland, *ibid.* 1896, 18, 545); $HgClC_6H_4ON$, needles, (W. and M.); $(C_6H_4ON)_2HBrCuBr_2$, colourless prisms (Cornstock, *ibid.* 1898, 20, 79). For crystalline and liquid modifications of formyl-*p*-toluidide, see Orloff (J. Russ. Phys. Chem. Soc. 1905, 37, 439).

Acetyl-derivative; when *p*-toluidine is boiled for $\frac{1}{2}$ hour with an excess of acetic anhydride a mixture of 32 p.c. of the monoacetyl-derivative and 60 p.c. of the diacetyl-derivative is formed (Sudborough, Chem. Soc. Trans. 1901, 79, 537).

Dimorphous, crystallising in monoclinic forms (Pantebianco, Gazz. chim. ital. 1879, 9, 362; Riche and Berard, Ann. 1864, 129, 77), m.p. 147° (Hübner and Wallach, Ann. 1870, 154, 303; Kelbe, Chem. Soc. Abstr. 1883, 44, 915), 148°-149° (S.), or 153° (Feitler, Zeitsch. physikal. Chem. 1889, 4, 76), b.p. 307° (Beilstein and Kuhlberg, Ann. 1870, 156, 74). On oxidation with potassium permanganate it yields acetyl-*p*-aminobenzoic acid, and on treatment with phosphorus pentachloride the iminochloride $CH_3CCl=N(C_6H_4 \cdot CH_3)$ is formed (Wallach, Ann. 1882, 214, 203). The *nitrosoamine* is obtained by the action of nitrous acid on an acetic acid solution of aceto-*p*-toluidide (O. Fischer, Ber. 1877, 10, 959), or by treating a strongly alkaline solution of toluene-*p*-diazonium chloride at -5° with acetic anhydride (Pechmann and Frobenius, Ber. 1894, 27, 653). It forms needles, m.p. 80° (decomp.), and regenerates aceto-*p*-toluidide on reduction.

Aceto-*p*-toluidide forms compounds with sodium methoxide and ethoxide (Cohen and Archdeacon, Chem. Soc. Trans. 1896, 69, 93), and yields an *N*-chloro-derivative, four-sided prisms, m.p. 81°-82°, and an *N*-bromo-derivative, yellow four-sided prisms, m.p. 94°-95° (Chettaway and Orton, Chem. Soc. Trans. 1909, 77, 791).

For the halogen derivatives of aceto-*p*-

toluidide containing the halogen in the acetyl group, see Tommasi (Bull. Soc. chim. 1873, (2) 19, 400); Eckenroth and Donner (Ber. 1890, 23, 3287); Bischoff and Walden (Ann. 1894, 279, 65); Grothe (Archiv. der Pharmacie. 238, 589); Cech (Ber. 1877, 10, 879); Rugheimer and Hoffmann (*ibid.* 1885, 18, 2980); Judson (*ibid.* 1870, 3, 784); Cloëz (Ann. Chim. 1886, (6) 9, 216); Abenius (J. pr. Chem. 1889, (2) 40, 433); Meyer (Ber. 1875, 8, 1154); Keller (Ann. 1904, 332, 247).

Diacetyl-derivative: colourless crystals, m.p. 48° (Sudborough, Chem. Soc. Trans. 1901, 79, 537; cf. Clayton, Ber. 1898, 28, 1665), b.p. 153.5°–154.5°/11 mm., 177.5°–178.5°/30 mm., 211.5°–212°/100 mm. (Kay, Ber. 1893, 26, 2852). B'HCl, m.p. 120° (Dehn, J. Amer. Chem. Soc. 1912, 34, 1399).

Benzoyl-derivative: from *p*-toluidine and benzoyl chloride (Jaillard, Zeit. f. Chem. 1865, (2) 1, 440; Kelbe, Ber. 1875, 8, 875; Hübner, Ann. 1881, 208, 310; Wallach, Ann. 1882, 214, 217; Gudeman, Ber. 1888, 21, 2553; Müller, Ber. 1889, 22, 2404). Needles, m.p. 158°, b.p. 232°. *p*-Nitro-derivative, yellow needles, m.p. 197° (Gattermann, Ber. 1892, 25, 1082).

Phthalyl-derivative: m.p. 204° (Fröhlich, Ber. 1884, 17, 2679).

2-Chloro-p-toluidine: by reducing 2-chloro-4-nitrotoluene or 2-chloro-4-nitrobenzyl bromide with tin and hydrochloric acid (Witt, Ber. 1892, 25, 86; Lellmann, Ber. 1884, 17, 535); together with other products by reducing 2-chloro-4-nitrotoluene with sodium disulphide (Blanksma, Chem. Weekblad, 1909, 6, 899), or with iron powder in the presence of a small quantity of sulphuric acid (Wibaut, Rec. trav. chim. 1913, 32, 244), or almost quantitatively with iron filings and hydrochloric acid (Davies, Chem. Soc. Trans. 1921, 119, 868); by boiling acetyl-*p*-toluidine-2-diazopiperidine with concentrated hydrochloric acid (Wallach, Ann. 1886, 235, 253). Colourless crystalline solid, m.p. 26° (D.) or 23.1° (W.), b.p. 237°–238.5°, or 242°–244°/760 mm. (D.), or 245° (Wynne and Greeves, Chem. Soc. Proc. 1895, 11, 151). B'HCl, very large needles; B₂H₂SO₄, small leaflets; B₂H₂PtCl₆.

Acetyl-derivative: m.p. (+1H₂O) 86° (W. and G.), 104°–105° (anhydrous) (Blanksma, l.c.; Kunkell and Lillig, J. pr. Chem. 1912, (2) 86, 517; Wibaut, l.c.); *benzoyl-derivative*: needles, m.p. 122° (Wibaut).

3-Chloro-p-toluidine: in poor yield by successive chlorination and hydrolysis of aceto-*p*-toluidide (Wroblewski, Ann. 1873, 168, 196; Lellmann and Klotz, Ann. 1885, 231, 309; Lellmann, Ber. 1894, 24, 4111); as the chief product by passing a rapid stream of chlorine through a boiling solution of aceto-*p*-toluidide in its own weight of acetic acid, followed by hydrolysis, a dichloro-derivative being simultaneously formed (Erdmann, Ber. 1891, 24, 2768); by chlorination of *p*-toluidine hydrochloride in 15 times its weight of 40 p.c. hydrochloric acid (Hafner, Ber. 1889, 22, 2536); together with 3:5-dichloro-*p*-toluidine and higher chlorinated products by the action of sulphuryl chloride on a suspension of aceto-*p*-toluidide in carbon disulphide, followed by hydrolysis (Wynne, Chem. Soc. Trans. 1892, 61, 1953); together with other products by the action of hydrochloric acid on *p*-nitrosotoluene

(Bamberger, Büsdorf and Szolayski, Ber. 1899, 32, 218); by treating aceto-*p*-toluidide in acetic acid with aqueous sodium chlorate followed by hydrolysis (Reverdin and Crépieux, Ber. 1900, 33, 2500); by reduction of 3-chloro-4-nitrotoluene (Reverdin and Crépieux, Ber. 1900, 33, 2505); in a yield of 50 p.c. by chlorination of aceto-*p*-toluidide by means of bleaching powder, followed by hydrolysis with alcohol and sulphuric acid (Chattaway and Orton, Chem. Soc. Trans. 1900, 77, 792). Oil, which solidifies at 0°, m.p. 7°, b.p. 218°–219°/732 mm. (L. and K.; Lellmann, Ber. 1891, 24, 4111), or 223°–224° (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1337); D₂₀ 1.151 (W.). B'HCl; B'HNO₃; B₂H₂SO₄; B₂C₂H₂O₄.

Acetyl-derivative: Anorthic crystals (Poy Chem. Soc. Trans. 1892, 61, 1057), m.p. 118° (L. 115° (L. and K.), 111°–112° (E.), 113°–113.4° (Wynne; C. and D.); *N-chloro-derivative*: short prisms, m.p. 48° (C. and O.); *benzoyl-derivative*: m.p. 137°–139° (C. and D.).

2:3-Dichloro-p-toluidine: by reducing 2:3 dichloro-4-nitrotoluene with tin and hydrochloric acid (Cohen and Dakin). It is volatile with steam and melts at 40°–42°.

Acetyl-derivative: needles, m.p. 128°–129° (C. and D.).

2:5-Dichloro-p-toluidine: by reducing 2:5-dichloro-4-nitrotoluene (Morgan and Drew, Chem. Soc. Trans. 1920, 117, 789; cf. Cohen and Dakin, *ibid.* 1901, 79, 1130; 1902, 81, 1347). It melts at 91°–92°.

2:6-Dichloro-p-toluidine: by reduction of 2:6-dichloro-4-nitrotoluene with iron filings and dilute hydrochloric acid (Davies, *ibid.* 1922, 121, 813). Colourless needles, m.p. 56°–57°. B'HCl, long colourless needles.

Acetyl-derivative: colourless slender needles, m.p. 220° (D.).

3:5-Dichloro-p-toluidine (see 3-chloro-*p*-toluidine); by successive chlorination and hydrolysis of aceto-*p*-toluidide and of 3-chloroaceto-*p*-toluidide (Lellmann and Klotz, Ann. 1885, 231, 322; cf. Cohen and Dakin); by other methods (Bamberger, Büsdorf and Szolayski; Wynne; Chattaway and Orton; Cohen and Dakin). Needles, scarcely volatile with steam, m.p. 60°. Sublimes.

Acetyl-derivative: crystals which sublime in long needles, m.p. 201° (L. and K.) or 199° (C. and D.). It is hydrolysed by heating with concentrated hydrochloric acid at 120°. *N-chloro-derivative*: slender four-sided prisms, m.p. 72° (C. and O.).

2:3:5-Trichloro-p-toluidine; *acetyl-derivative*, formed by the action of sodium chlorate on a solution of 3:5-dichloroaceto-*p*-toluidide in presence of acetic acid and hydrochloric acid (Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1337); by the action of a mixture of hydrochloric and nitric acids on aceto-*p*-toluidide (Mannino and Donato, Gazz. chim. ital. 1908, 38, ii. 20). Colourless needles, m.p. 179°.

2-Bromo-p-toluidine: by reduction of 2-bromo-4-nitrotoluene (Neville and Winther, Ber. 1881, 14, 418; Chem. Soc. Trans. 1881, 39, 86); by boiling acetyl-*p*-toluidine-2-diazopiperidine with concentrated hydrobromic acid (Wallach, Ann. 1886, 235, 255); together with 3-bromo-*p*-toluidine by keeping a mixture of *p*-toluidine sulphate and bromine in the presence of sul-

phuric acid for 10 days (Hafner, Ber. 1889, 22, 2903); together with 2-bromo-4-aminobenzaldehyde by reduction of 2-bromo-4-nitrotoluene with sodium disulphide in presence of alcohol (Blanksma, Chem. Weekblad, 1909, 6, 899). It melts at 25°-26° (N. and W.), and boils at 254°-257° (H.). B'HCl, needles; B'HBr (W.).

Acetyl-derivative; m.p. 113° (B.). On boiling with potassium permanganate solution it yields 2-bromo-4-acetylamino benzoic acid.

3-Bromo-*p*-toluidine; by successive bromination and hydrolysis of aceto-*p*-toluidide (Wroblewski, Ann. 1873, 168, 153; Neville and Winther); together with other products by the action of hydrobromic acid on *p*-nitrosotoluene (Bamberger, Büsdorf and Szolayski, Ber. 1899, 32, 219); by bromination of *p*-toluidine hydrochloride (Klages and Liecke, J. pr. Chem. 1900 (2) 61, 326). Large plates, m.p. 26° (Claus and Steinberg, Ber. 1883, 16, 914), b.p. 240° D¹⁰⁰ 1.510 (W.), 1.498 (Hand, Ann. 1886, 234, 156). B'HCl, softens at 210° and melts at 221° (decomp.). B'HNO₃, plates, m.p. 182° B₂H₂SO₄ + 2H₂O. The bromotoluidine obtained by Pechmann (Ann. 1874, 173, 210) by distilling brominated *p*-aminotoluene *m*-sulphonic acid with potassium hydroxide is probably identical with the above.

Acetyl-derivative; needles, m.p. 117.5° (W.). *N*-bromo-*derivative*; yellow four-sided plate, m.p. 87°. On heating at 110° it yields 3:1 dibromoaceto-*p*-toluidide (Chattaway and Orton, Chem. Soc. Trans. 1900, 77, 795).

Diacetyl-derivative; thick prisms, m.p. 75°-75.5° (Ulffers and Janson, Ber. 1894, 27, 98).

Benzoyl-derivative, m.p. 140° (Ulffers and Janson, Ber. 1891, 24, 4170).

2:5-Dibromo-*p*-toluidine; by reduction of the corresponding nitro-derivative (Wroblewski, Ann. 1873, 168, 185; Neville and Winther, Ber. 1880, 13, 962; Chem. Soc. Trans. 1880, 37, 441). Prisms, m.p. 83° (W.), leaflets, m.p. 84° (N. and W.).

2:6-Dibromo-*p*-toluidine; by reduction of the corresponding nitro-derivative (Neville and Winther). It melts at 88°-89°.

3:5-Dibromo-*p*-toluidine; by the action of hydrobromic acid on *p*-nitrosotoluene (Bamberger, Büsdorf and Szolayski); from *p*-toluidine and bromine (Wroblewski, Ann. 1873, 168, 18; Neville and Winther; Klages and Liecke, J. pr. Chem. 1900, (2) 61, 326); together with 3-bromo-*p*-toluidine 5-sulphonic acid by the action of bromine on *p*-toluidine 3-sulphonic acid (N. and W.); cf. Pechmann, Ann. 1874, 173, 216). Long acroclinic needles, m.p. 73° (Jäger, Z. Kristall. 903, 38, 89), or 73.5°-74.5° (Bamberger, Ber. 1899, 32, 221). Does not combine with acid.

Acetyl-derivative; long needles, m.p. 113° (Claus and Herababy, Ann. 1891, 265, 3777) or rhombs, 199°-200° (Ulffers and Janson, Ber. 1894, 27, 98; cf. Kunckell, *ibid.* 1908, 41, 411); *benzoyl-derivative*; thick tables and prisms, m.p. 101°-101.5° (U. and J.).

3:4-Dibromo-*p*-toluidine; by reducing the corresponding nitro-compound (N. and Wroblewski). M.p. 98° (N. and W.), or 105° (V.).

2:3:5-Tribromo-*p*-toluidine; by brominating 2-bromo-*p*-toluidine hydrochloride (Neville and Winther, Ber. 1881, 14, 4181) or 2-bromo-

2:3:6-Tribromo-*p*-toluidine; by reducing the corresponding nitro-derivative with iron and acetic acid (N. and W.). Needles, m.p. 118°-119° (Cohen and Dutt, Chem. Soc. Trans. 1914, 105, 514).

Pechmann (Ann. 1874, 173, 217) obtained a *tribromotoluidine*, long needles, m.p. 113°, by the action of bromine on *p*-aminotoluene *m*-sulphonic acid.

Tetrabromo-*p*-toluidine; by brominating 2:6-dibromo-*p*-toluidine hydrochloride (N. and W.); together with dibromonitrotoluene by heating *p*-nitrotoluene with bromine and a little iron bromide at 90° (Scheufelen, Ann. 1885, 231, 179). Slender needles, m.p. 226°-227°.

3-Chloro-5-bromo-*p*-toluidine; by brominating 3-chloro-*p*-toluidine in glacial acetic acid and boiling until most of the hydrogen bromide is removed (Orton and Reed, Chem. Soc. Trans. 1907, 91, 1570); from aceto-*p*-toluidide by successive bromination and chlorination with hydrochloric acid and sodium chlorate in glacial acetic acid, followed by hydrolysis (Cohen and Murray, *ibid.* 1915, 107, 847). Colourless needles, m.p. 65° (O. and R.) or 63.5° (C. and M.).

Acetyl-derivative; prisms, m.p. 189° (O. and R.), or 199° (C. and M.); *diacetyl-derivative*; m.p. 82° (C. and M.).

2-Iodo-*p*-toluidine; by reducing 2-iodo-4-nitrotoluene with ferrous sulphate in ammoniacal solution (Willgerodt and Gartner, Ber. 1908, 41, 2813); or together with 2-iodo-4-aminobenzaldehyde by reducing with sodium disulphide (Blanksma, Chem. Weekblad, 1909, 6, 899). Large white needles, m.p. 37°-38°. B'HCl, long dark needles; B₂H₂SO₄, leaflets; B'HNO₃, rhombs; B'C₂H₂O₄, small rhombs.

Acetyl-derivative; white needles, m.p. 130°, *iodochloride*, yellow needles, decomposing at 110° (W. and G.).

3-Iodo-*p*-toluidine; by the interaction of iodine and *p*-toluidine (Wheeler and Liddle, Amer. Chem. J. 1909, 42, 441). Colourless needles, m.p. 40°. B'HCl, m.p. 188° (decomp.) B'C₂H₂O₄, m.p. 119°-120° (decomp.).

Acetyl-derivative; long colourless needles, m.p. 133°; *benzoyl-derivative*; colourless needles, m.p. 161° (W. and L.). The acetyl-derivative when boiled with concentrated hydrochloric acid yields 3:5-di-iodo-*p*-toluidine.

2:5-Di-iodo-*p*-toluidine; by reducing 2:1-di-iodo-4-nitrotoluene with ferrous sulphate in ammonia. Buff-coloured prisms, m.p. 109° (Wheeler, &c., Amer. Chem. J. 1910, 44, 493).

3:5-Di-iodo-*p*-toluidine; by the action of iodine chloride on *p*-toluidine hydrochloride (Michael and Norton, Ber. 1878, 11, 115); by boiling 3-iodoaceto-*p*-toluidide with concentrated hydrochloric acid (Wheeler and Liddle) or by the action of 2 mols. of iodine on *p*-toluidine in presence of water and calcium carbonate (Wheeler and Liddle). Long slender needles, m.p. 124.5° (M. and N.).

Acetyl-derivative; stout colourless prisms, m.p. 226° (W. and L.).

2-Nitro-*p*-toluidine; together with 4-nitro-*p*-toluidine by partial reduction of 2:4-dinitrotoluene with alcoholic ammonium sulphate (Graeff, Ann. 1885, 229, 343; Anschütz and Heuseler, Ber. 1886, 19, 2161; Beilstein and Kuhlberg, Ann. 1876, 155, 14); together with little 3-nitro-*p*-toluidine by treating a solution

of *p*-toluidine in sulphuric acid with nitric acid, but when a large amount of sulphuric acid is used only the 2-nitro-isomeride is obtained (Hübner, Ber. 1877, 10, 1716; Nölting and Collin, *ibid.* 1884, 17, 263; Foth, Ann. 1885, 230, 299). Yellow glistening broad needles, m.p. 81.5° (Haibach, J. pr. Chem. 1902, (2) 65, 246). $BHCl$, m.p. 220° (decomp.); $BHNO_3$, m.p. 186°; $B_2H_4SO_4 + 2H_2O$, stellate needles; $4C_6H_4N_2O_3 + AgNO_3$, greenish-yellow crystals, m.p. 131°–132° (Mixer, Amer. Chem. J. 1880, 1, 241).

Formyl-derivative; white voluminous needle (Geigy & Co., U.S. Pat. 722630; Fr. Pat. 306655; D. R. P. 138839 of 1902).

Acetyl-derivative; needles, m.p. 160° (Cunerth, Ann. 1874, 172, 229) or 144.5° (Wallach, *ibid.* 1886, 234, 354).

Benzoyl-derivative; pale yellow prisms, m.p. 172° (Bell, Chem. News, 1874, 30, 202).

3-Nitro-*p*-toluidine; by successive nitration and hydrolysis of benzoyl-*p*-toluidine, aceto-*p*-toluidide, or toluene *p*-sulphonyl-*p*-toluidide (Beilstein and Kuhlberg, Ann. 1870, 155, 23; Lorenz, *ibid.* 1874, 172, 77; Hübner, *ibid.* 1881, 208, 313; Lellmann, *ibid.* 1883, 221, 7; Cosack, Ber. 1880, 13, 1088; Ehrlich, *ibid.* 1882, 15, 2009; Gattermann, *ibid.* 1885, 18, 1483; Nölting and Collin, *ibid.* 1884, 17, 263; Reverdin and Crépieux, *ibid.* 1902, 35, 1439; Bull. Soc. chim. 1902, (3) 27, 743; Noyes, Amer. Chem. J. 1888, 10, 475); by heating 3-nitro-*p*-cresol with 35 p.c. ammonia for 16 hours at 170°–180° (Barr, Ber. 1888, 21, 1543); by the transformation of *p*-toluene nitroamine (Bamberger and Hoff, Ber. 1897, 30, 1258; Ann. 1900, 311, 93); or together with other products by the action of nitric anhydride on *p*-toluidine (B. and H.). Red monoclinic prisms (Panbianco, Gazz. chim. ital. 1879, 9, 358; Jäger, Z. Kristall, 1903, 38, 89), m.p. 114° (B. and K.; R. and C.), 116°–117° (Schraube and Romig, Ber. 1893, 26, 579), or 117°–118° (Morgan and Micklethwait, Chem. Soc. Trans. 1913, 103, 1401). Volatile with steam. $BHCl$, yellow prisms immediately decomposed by water; $BHNO_3$, six-sided yellow tables or slender needles (Hübner); $BHBr$, large laminae (Haibach, J. pr. Chem. 1902, (2) 65, 249).

Acetyl-derivative; slender yellow needles from water or concentrated alcoholic solution, long colourless needles from dilute alcoholic solution, m.p. 94°–95° (Gattermann). For the relation and properties of the two forms of 3-nitro-aceto-*p*-toluidide, see Schaum, Ann. 1898, 300, 224; Ber. 1898, 31, 129; Schenck, Zeitsch. physikal. Chem. 1900, 33, 450; Auwers, *ibid.* 1897, 23, 460.

Diacetyl-derivative; citron-yellow prisms, m.p. 78° (Ulffers and Janson, Ber. 1894, 27, 101).

Benzoyl-derivative; yellow needles, m.p. 146°–148° (M. and M.) or 143° (Hübner).

The electrolytic reduction of 3-nitro-*p*-toluidine yields a mixture of *p*-diamino-*o*-azoxytoluene and *p*-diamino-*o*-azotoluene (Elbs and Schwarz, J. pr. Chem. 1901, (2) 63, 562).

2:3-Dinitro-*p*-toluidine; by hydrolysis of the acetyl-derivative which is obtained as the sole product by nitrating 2-nitroaceto-*p*-toluidide with nitric acid alone; or together with 2:5-dinitroaceto-*p*-toluidide when the nitration is effected in presence of sulphuric acid by means

of potassium nitrate (Scott and Robinson, Chem. Soc. Trans. 1922, 121, 844). Orange-yellow needles, m.p. 124°. Weak base.

Acetyl-derivative; colourless silky needles, m.p. 174.5°.

2:5-Dinitro-*p*-toluidine (see above). Deep orange-red needles, m.p. 189°. Feeble base.

Acetyl-derivative; aggregates of colourless slender needles, m.p. 132.5° (S. and R.).

2:6-Dinitro-*p*-toluidine; by reduction of 2:4:6-trinitrotoluene with ammonium sulphide (Tiemann, Ber. 1870, 3, 218; Beilstein, *ibid.* 1880, 13, 243; Städel, Ann. 1884, 225, 384; Holleman and Boeseken, Rec. trav. chim. 1897, 16, 425); by reduction of 2:6-dinitro-*p*-tolylhydroxylamine with copper powder and hydrochloric acid; or together with 4:6-dinitro-*o*-toluidine by reducing 2:4:6-trinitrotoluene in hydrochloric acid solution in presence of cupric chloride at a copper cathode (Brand and Eisenmenger, J. pr. Chem. 1913, (2) 87, 487; cf. Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 27; Cohen and McCandlish, *ibid.* 1905, 87, 1265). Yellow hair-like needles, m.p. 166.5°–168° (T. and B.), 171° (H. and B.), 168°–169° (C. and D.); Anschutz and Zimmermann, Ber. 1915, 48, 152). It exists in four distinct crystalline phases (Artini, Atti R. Accad. Lincei, 1917 [v.] 26, i. 392).

Acetyl-derivative; slender white needles, m.p. 223° (Körner and Contardi, *ibid.* 1916, [v.] 25, ii. 339).

3:5-Dinitro-*p*-toluidine; by successive nitration and hydrolysis of the acetyl- or benzoyl-derivative of *p*-toluidine (Beilstein and Kuhlberg, Ann. 1871, 158, 341; Jackson and Ittner, Amer. Chem. J. 1897, 19, 6; Hübner, Ann. 1881, 208, 278; 1884, 222, 73; Brady, Day and Rolt, Chem. Soc. Trans. 1922, 121, 527); from 3:5-dinitro-*p*-cresol alkyl ether and alcoholic ammonia in the cold (Städel, Ann. 1883, 217, 185); by transformation of 3-nitro-*p*-toluene nitroamine (Bamberger and Voss, Ber. 1897, 30, 1257; Bamberger and Hoff, Ann. 1900, 311, 112). Yellow needles, m.p. 166° (B. and K.), 168° Hübner; B. and V.; Niementowski, Ber. 1886, 19, 717).

Acetyl-derivative; long yellow needles, m.p. 90.5° (B. and K.), or 105° (Friederici, Ber. 1878, 1, 1975).

Diacetyl-derivative; thick citron-yellow tables, m.p. 129.5° (Ulffers and Janson, Ber. 1894, 27, 101).

Benzoyl-derivative; needles, m.p. 186° (Hübner).

(β)-Dinitro-*p*-toluidine; by treating 2:3:4-trinitrotoluene with alcoholic ammonia at 100° (Hepp, Ann. 1882, 215, 371). Short golden-yellow needles, m.p. 94°.

3-Chloro-2-nitro-*p*-toluidine; by heating 2-nitrotolyl-*p*-hydroxylamine with hydrochloric acid (Brand and Zoller, Ber. 1907, 40, 3324). Pale yellow needles, m.p. 63° (B. and Z.) or 67°–68° (Burton and Kenner, Chem. Soc. Trans. 1921, 119, 1052).

Acetyl-derivative; m.p. 123°–124° (B. and Z.).

5-Chloro-2-nitro-*p*-toluidine; by treating dry 3-chloro-*p*-toluidine nitrate with 5 parts of sulphuric acid at –12° to –15° (Claus and Davidson, Ann. 1891, 265, 344; cf. Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 1233); as a by-product of the action of hydrochloric acid

on 2-nitrotolyl-*p*-hydroxylamine (Brand and Zoller). Orange-red plates, m.p. 129.5° (Claus and Davidsen), 131° (B. and Z.).

Acetyl-derivative, m.p. 143° (Cl. and D.).

2-Chloro-5-nitro-*p*-toluidine; by successive nitration and hydrolysis of 2-chloroaceto-*p*-toluidide (Claus and Böcher, Ann. 1891, 265, 354; Davies, Chem. Soc. Trans. 1921, 119, 868); by adding 2-chloro-*p*-toluidine nitrate to well-cooled sulphuric acid (Cohen and Dakin, l.c.); together with 6-chloro-4-nitro-*m*-toluidine by the action of alcoholic ammonia on 2-chloro-4:5-dinitrotoluene; or from *o*-toluidine by nitration, replacement of the amino-group by chlorine, reduction, acetylation, nitration and hydrolysis (Morgan and Challenor, Chem. Soc. Trans. 1921, 119, 1538, 1545). Golden-yellow plates, m.p. 165°.

Acetyl-derivative; pale yellow crystals, m.p. 112° (Blanksma, Rec. trav. chim. 1910, 29, 410), 113° (C. and B.).

3-Chloro-5-nitro-*p*-toluidine; by nitration of 3-chloroaceto-*p*-toluidide (Claus and Davidsen) in presence of glacial acetic acid at 20°, followed by hydrolysis with hydrochloric acid (Cohen and Dakin). Orange-red needles, m.p. 72°-73°, slowly volatile with steam (C. and D.) or orange-red plates, m.p. 70.5° (Cl. and D.).

Acetyl-derivative; m.p. 196° (Cl. and D.).

2:6-Dichloro-3-nitro-*p*-toluidine; by the gradual addition of 2:6-dichloroaceto-*p*-toluidide to nitric acid (D 1.49) cooled in ice-water, followed by hydrolysis with alcoholic sodium hydroxide (Davies, Chem. Soc. Trans. 1922, 121, 813). Minute orange needles, m.p. 130°-131°. B'HCl, clusters of colourless needles, immediately hydrolysed by cold water.

Acetyl-derivative; colourless needles, m.p. 180° (D.).

2-Chloro-3:5-dinitro-*p*-toluidine; by the gradual addition of 2-chloroaceto-*p*-toluidide to well-cooled nitric acid (D 1.5), keeping for 6 hours, followed by hydrolysis with cold sulphuric acid (Davies, *ibid.* 1921, 119, 808). Thin golden-yellow needles, m.p. 137°.

Acetyl-derivative; colourless leaflets, m.p. (D.).

2-Bromo-5-nitro-*p*-toluidine; by nitration and hydrolysis of 2-bromoaceto-*p*-toluidide (Blanksma, Chem. Weekblad, 1912, 9, 968). Orange-red needles, m.p. 165°.

Acetyl-derivative; pale yellow needles, m.p. (B.).

3-Bromo-5-nitro-*p*-toluidine; by nitration and hydrolysis of 3-bromoaceto-*p*-toluidide (Problewsky, Ann. 1878, 192, 202); by bromination and nitration (or *vice versa*) of aceto-*p*-toluidide, followed by hydrolysis (Neville and x, Ber. 1890, 13, 968; Chem. Soc. Trans. 37, 429). Orange-red needles, m.p. 64° (Cohen and Dutt, Chem. Soc. Trans. 1914, 510).

Acetyl-derivative; m.p. 210° (C. and D.); large greenish-yellow tables, 79° (Ulffers and Janson, Ber. 1894, 27, 50).

3-Bromo-6-nitro-*p*-toluidine; by dissolving 1 of dry 3-bromo-*p*-toluidine nitrate in 2 of sulphuric acid at -10° and keeping 2-3 days (Claus and Herbay, Ann. 1891, 265, 354). Yellow needles, m.p. 121° (C. and D.). Morgan and Clayton, Chem.

Soc. Trans. 1905, 87, 948), or 118°-119° (Cohen and Dutt, *ibid.* 1914, 105, 515).

3:5-Dibromo-2-nitro-*p*-toluidine; by bromination of 2-nitro-*p*-toluidine (Blanksma, Chem. Weekblad, 1909, 6, 717). Yellow crystals, m.p. 82°.

Acetyl-derivative; by nitrating 3:5-dibromoaceto-*p*-toluidide with fuming nitric acid (Kunckell, Ber. 1908, 41, 4111); by acetylating 3:5-dibromo-2-nitro-*p*-toluidine with acetic anhydride and a drop of sulphuric acid (B.). M.p. 238°.

3-Bromo-2:6-dinitro-*p*-toluidine; together with a little 3:5-dibromo-2:6-dinitro-*p*-toluidine by the action of bromine on 2:6-dinitro-*p*-toluidine in presence of sodium acetate and acetic acid (Körner and Contardi, Atti R. Accad. Lincei, 1916, [v.] 25, ii. 339). Pale yellow prisms or short needles, m.p. 174°.

Acetyl-derivative; almost colourless plates, m.p. 151° (K. and C.).

3:5-Dibromo-2:6-dinitro-*p*-toluidine; by further bromination of the 3-bromo-derivative (K. and C.). Pale yellow prisms, m.p. 177°.

Acetyl-derivative; m.p. 265°-267°, by nitrating 3:5-dibromoaceto-*p*-toluidide with fuming nitric acid in presence of sulphuric acid (Kunckell, Ber. 1908, 41, 4111).

5-Iodo-3-nitro-*p*-toluidine; by warming 3-nitro-*p*-toluidine with iodine chloride in glacial acetic acid (Wheeler and Scholes, Amer. Chem. J. 1910, 44, 126). Golden needles, m.p. 98°.

Acetyl-derivative; by acetylating the above (W. and S.) or by nitration of 5-iodoaceto-*p*-toluidide (Wheeler and Liddle, *ibid.* 1909, 42, 441). Prisms, m.p. 202°-203°.

Methyl-*p*-toluidine; by methylation with dimethyl sulphate (Ullmann, Ann. 1903, 327, 104); together with dimethyl-*p*-toluidine by the action of methyl chloride on boiling *p*-toluidine. The product is extracted with ether and the unchanged *p*-toluidine precipitated by sulphuric acid. The remainder of the product is acetylated, fractionally distilled, and the acetyl-derivative hydrolysed with dilute hydrochloric acid or sodium hydroxide (Thomsen, Ber. 1877, 10, 1582); by the reduction of nitrosomethyl-*p*-toluidine with tin and hydrochloric acid (Nöling, Ber. 1878, 11, 2279); from *p*-toluidine and diazomethane (von Pechmann, *ibid.* 1895, 28, 858). Liquid, b.p. 208° (T.). B'HCl, m.p. 119.5° (Bamberger and Wulz, *ibid.* 1891, 24, 2081); B'H, PtCl.

Acetyl-derivative; large plates, m.p. 83°, b.p. 283°. It yields trinitromethyl-*p*-toluidine on boiling with nitric acid.

Nitrosoamine; large prisms, m.p. 54° (T.), or 52°-53° (B. and W.).

2-Nitromethyl-*p*-toluidine; by nitration of methyl-*p*-toluidine in presence of sulphuric acid below 0° (Pinnow, Ber. 1895, 28, 3040); by methylation of 2-nitro-*p*-toluidine (Jaeger, Bull. Soc. chim. 1899, (3) 21, 19). Yellow crystals, m.p. 45° (J.), or slender red needles or thick prisms, m.p. 57° (P.).

Acetyl-derivative; slender yellow needles, m.p. 128°-128.5° (P.).

Nitrosoamine; slender yellow needles or thick prisms, m.p. 58° (P.).

3-Nitromethyl-*p*-toluidine; from 3-nitro-*p*-toluidine, methyl iodide, and methyl alcohol; by the action

of nitric acid on *p*-tolylmethyl nitroamine in presence of acetic acid (Pinnow, Ber. 1897, 30, 835); by oxidation of 3-nitrodimethyl-*p*-toluidine with chromic acid in acetic acid (Pinnow, *l.c.* 3121; J. pr. Chem. 1900, (2) 62, 514). Red prisms, m.p. 84°–85° (G.).

Acetyl-derivative; small plates, m.p. 64°; *picrate*, yellow crystalline precipitate, m.p. 210°–212° (decomp.) (Niementowski, Ber. 1887, 20, 1876).

(γ) 2:3-Dinitromethyl-*p*-toluidine; see below (Pinnow). Long orange-yellow plates, with a bluish shimmer, m.p. 158°–159.5°. On treatment with nitric acid (D 1.52) it yields trinitrotolyl-*p*-methyl nitroamine; with alcoholic ammonium sulphide, γ -nitroaminomethyl-*p*-toluidine; with tin and hydrochloric acid 2:3-diaminomethyl-*p*-toluidine (Pinnow, J. pr. Chem. 1900, (2) 62, 507).

Acetyl-derivative; bright yellow needles, m.p. 90°–5°; *benzoyl-derivative*; m.p. 110°–5°.

Nitroamine; yellow needles, m.p. 128°–128.5° (Pinnow, Ber. 1897, 30, 840).

(β) 2:5-Dinitromethyl-*p*-toluidine; the nitration of dimethyl-*p*-toluidine in concentrated sulphuric acid and further treatment of the product with nitric acid in the presence of sodium nitrite yields dinitrotolylmethyl nitroamine. The latter on boiling with phenol and sulphuric acid in the presence of amyl alcohol yields a mixture of 2:5- and 2:3-dinitromethyl-*p*-toluidine (Pinnow, Ber. 1895, 28, 3040; 1897, 30, 836, 840; J. pr. Chem. 1900, (2) 62, 507). Also formed by the oxidation of dinitrodimethyl-*p*-toluidine (m.p. 103.5°–104°) with chromic acid and acetic acid (van Romburgh, Rec. trav. chim. 1889, 8, 248). Bright red prisms with a greenish reflex, m.p. 184.5°–185.5°. On reduction with alcoholic ammonium sulphide 2-amino-5-nitromethyl-*p*-toluidine is formed; with tin and hydrochloric acid at low temperatures it yields 2:5-diaminomethyl-*p*-toluidine, and at higher temperatures methyl-diaminocresol (Pinnow, J. pr. Chem. 1900, (2) 62, 507).

Acetyl-derivative; bright yellow needles, m.p. 151° (P.).

Nitroamine; m.p. 123°–124° (P.).

(α) 3:5-Dinitrotolyl-*p*-toluidine; by nitration of methyl-*p*-toluidine (Thomsen, Ber. 1877, 10, 1582; Gattermann, Ber. 1885, 18, 1487); by boiling 3:5-dinitrotolyl-*p*-methyl nitroamine with a little phenol (Van Romburgh, Ber. 1896, 29, 1015); by the transformation of the *N*-methyl ester of 3-nitro-*p*-toluene nitroamine with acids (Bamberger and Voss, Ber. 1897, 30, 1258); by the prolonged action of nitrous acid on methyl-*p*-toluidine (Störmer and Hoffmann, Ber. 1898, 31, 2535); by the transformation of an alcoholic solution of 3:5-dinitro-4-nitromethylamino-toluene in presence of sunlight (Reverdin, Bull. Soc. chim. 1913, [4] 13, 485; J. pr. Chem. 1913, (2) 88, 90). Light red needles, m.p. 129° (G.).

Nitroamine; yellow needles, m.p. 125° (Gattermann), or 128°–128.5° (Van Romburgh; Pinnow, Ber. 1897, 30, 840).

3:5-Dinitrotolyl-*p*-methylnitroamine; by the action of nitric acid (D 1.48) on dimethyl-*p*-toluidine (Van Romburgh, Rec. trav. chim. 1884, 3, 404; Gattermann, Ber. 1885, 18, 1488; cf. Pinnow, Ber. 1897, 30, 842); by boiling methyl-aceto-*p*-toluidide for 1–2 hours with 10 p.c.

nitric acid (Norton and Livermore, Ber. 1887, 20, 2269); by the action of fuming nitric acid on 3:5-dinitrodimethyl-*p*-toluidine (Pinnow and Mateovich, Ber. 1898, 31, 2518); by the gradual addition of 50 c.c. nitric acid (D 1.48) to a solution of 5 c.c. of dimethyl-*p*-toluidine in 5 c.c. of glacial acetic acid (Van Romburgh, Ber. 1896, 29, 1015); by the action of nitrous acid on a solution of 3-nitrodimethyl-*p*-toluidine in 40 p.c. nitric acid (Pinnow, Ber. 1895, 28, 3044); by dissolving methyl-*p*-tolyl-nitrosoamine in a mixture of acetic acid and nitric acid (D 1.4) with cooling (Pinnow). Yellow serrated needles, m.p. 126° (P.), or 138° (Van R.).

2:3:5-Trinitromethyl-*p*-toluidine; by boiling a mixture of 2:3:5-trinitro-*p*-tolylmethyl-nitroamine, phenol, sulphuric acid, and amyl alcohol (Pinnow, Ber. 1897, 30, 838); by nitration of mono- or dinitromethyl-*p*-toluidine (Gattermann, Ber. 1885, 18, 1488). Orange-red needles, m.p. 129.5°–130° (P.), or yellow needles or large prisms, m.p. 137°–138° (G.).

Nitroamine; yellow plates, m.p. 108°–109° (P.). The *nitroamine* is obtained by heating 2-nitro-*p*-tolylmethyl-nitrosoamine with nitric acid (D. 1.52) at 100°. It melts at 156.5°–157° (P.).

*Dimethyl-*p*-toluidine*; together with isomerides and homologues by heating the trimethylammonium iodide, $C_6H_5N(CH_3)_3I$, at 220°–230° (Hofmann, Ber. 1872, 5, 707); from *p*-toluidine, methyl iodide or methyl chloride (Thomsen, Ber. 1877, 10, 1586; Clarke, Amer. Chem. J. 1905, 33, 496); by heating its trimethylammonium iodide with water and lead oxide and distilling the product (Hübner, Tölle and Athenstädt, Ann. 1884, 224, 337); together with dimethyleneditoluidine by the electrolytic reduction of *p*-nitrotoluene in presence of alcohol, hydrochloric acid and 40 p.c. formaldehyde (Löb, Zeit. Elektrochem. 1898, 4, 428). Liquid, b.p. 209.5°/760 mm. (Kahlbaum, Zeitsch. physikal. Chem. 1898, 26, 623, 646), or 211.2° (Perkin, Chem. Soc. Trans. 1896, 69, 1245), D_4^{20} 0.92870 (K.), L_4^{20} 0.9502, D_{15}^{15} 0.9424, D_{25}^{25} 0.9364 (P.); magnetic rotatory power at 15.4° 22.84 (P.). Refractive power, see Brühl (Zeitsch. physikal. Chem. 1895, 16, 218).

*Dimethyl-*p*-toluidine oxide*; by the action of hydrogen peroxide on dimethyl-*p*-toluidine at 60°–70° (Bamberger and Tschirner, Ber. 1899, 32, 353). *Picrate*; sulphur-yellow needles or prisms, m.p. 106°–107°.

2-Nitrodimethyl-*p*-toluidine; by nitration of dimethyl-*p*-toluidine (M. L. B., D. R. P. 69188 of 1891; cf. Morgan and Clayton, Chem. Soc. Trans. 1905, 87, 947); by methylation of 2-nitro-*p*-toluidine (Haibach, J. pr. Chem. 1902, (2) 66, 246). Orange-red prisms, m.p. 35° (H.), or 37° (M. and C.).

3-Nitrodimethyl-*p*-toluidine; by the action of a concentrated aqueous solution of sodium nitrite on a solution of dimethyl-*p*-toluidine in hydrochloric acid (D 1.06) (Pinnow, Ber. 1895, 28, 3041; 1897, 30, 3119). Six-sided columns, m.p. 24.5°–25°. On reduction with tin and hydrochloric acid a mixture of dimethyltoluenediamine, dimethylbenzimidazole and a compound containing chlorine is obtained.

3-Bromo-6-nitrodimethyl-*p*-toluidine; by heating the hydrobromide of 3-bromo-6-nitro-*p*-

toluidine with methyl alcohol for 8 hours at 140° – 180° . The resultant mixture is treated with acetic anhydride to remove any unaltered base or secondary amines (Morgan and Clayton, *l.c.*). Yellow needles, m.p. 38° .

3:5-Dinitrodimethyl-*p*-toluidine; by the action of 30 p.c. nitric acid on a solution of dimethyl-*p*-toluidine dissolved in dilute sulphuric acid (Pinnow and Mateovich, *Ber.* 1898, 31, 2518). Bright red needles or four-sided prisms, m.p. 95° . With fuming nitric acid it yields 3:5-dinitro-tolyl-*p*-methyl nitroamine, m.p. 138° – 139° .

2:5-Dinitrodimethyl-*p*-toluidine; together with other products by the action of sodium nitrite on 2-nitrodimethyl-*p*-toluidine dissolved in hydrochloric acid (Pinnow, *Ber.* 1895, 28, 3041); together with 2-nitrodimethyl-*p*-toluidine by nitrating dimethyl-*p*-toluidine and pouring the product into water so that the temperature rises to 30° – 40° (M. and C.). Glistening red plates, m.p. 103.5° – 104° (P.), dark red needles, or scarlet scales, m.p. 103° (M. and C.).

Ethyl-*p*-toluidine; from *p*-toluidine by heating with hydriodic acid or hydrobromic acid and ethyl alcohol (N. and L.); from *p*-toluidine and ethyl iodide by heating for 2 days at 100° (Morley and Abel, *Ann.* 1854, 93, 313). Liquid, b.p. 217° , $D_{20}^{25} = 0.9391$. $B^{\circ}_x H_x SO_4$; $B^{\circ}_x C_x H_x O_4$; $B^{\circ}_x H_x PtCl_x$, pale yellow crystals.

Acetyl-derivative; liquid, b.p. 258° (Norton and Livermore, *Ber.* 1887, 20, 2271).

2-Nitroethyl-*p*-toluidine; by nitrating a solution of *p*-ethyltoluidine in 20 parts of sulphuric acid (Nölting and Stricker, *Ber.* 1886, 19, 549); by ethylation of 2-nitro-*p*-toluidine (Jaubert, *Bull. Soc. chim.* 1899, (3) 21, 20). Long flat red prisms, m.p. 47° – 48° (N. and S.), or yellow needles, m.p. 50° (J.).

3-Nitroethyl-*p*-toluidine; by ethylating 3-nitro-*p*-toluidine (Gattermann, *Ber.* 1885, 18, 1483); by successive nitration and hydrolysis of ethylaceto-*p*-toluidine in presence of sulphuric acid (Nölting and Abt, *Ber.* 1887, 20, 3000). Large bright red crystals, m.p. 58° – 59° .

3:5-Dinitroethyl-*p*-toluidine; by nitration of 3-nitroethyl-*p*-toluidine at about 30° (Gattermann, *l.c.*, 1485). Long orange-yellow needles, m.p. 126° – 126.5° .

Nitrosamine; large yellow rhombic crystals, m.p. 77° – 78° (G.).

3:5-Dinitrotolyl-*p*-ethyl nitroamine; by adding diethyl-*p*-toluidine to nitric acid ($D_{1.48}^{1.5}$) and boiling the solution until it becomes yellow (Van Romburgh, *Rec. trav. chim.* 1884, 3, 409; Gattermann); by boiling ethylaceto-*p*-toluidine with 10 p.c. nitric acid (Norton and Livermore, *Ber.* 1887, 20, 2271). Long straw-yellow needles, m.p. 116° . On boiling with 4 p.c. sodium hydroxide it yields dinitro-*p*-cresol, m.p. 83° .

Diethyl-*p*-toluidine; by heating potassium *p*-toluidine *m*-sulphonate with ethyl bromide and absolute alcohol at 150° (Schmidt, *J. pr. Chem.* 1893, (2) 48, 46); from ethyl-*p*-toluidine and ethyl iodide (Morley and Abel, *l.c.*); in 95 p.c. yield by heating *p*-toluidine hydrobromide or hydriodide with 5 p.c. excess of ethyl alcohol for 8 hours at 150° (Reinhardt and Stadel, *Ber.* 1883, 16, 29). Liquid, b.p. 227° – 228° , $D_{20}^{25} = 0.9242$. $B^{\circ}_x HCl$, m.p. 157° (Schmidt); $B^{\circ}_x H_x PtCl_x$, rhombohedra (Söfiling, *Beiblätter zu den Annalen der Physik und Chemie*, 8, 190);

$B^{\circ}_x HBr$, monoclinic crystals; $B^{\circ}_x HNO_3$, monoclinic crystals; $B^{\circ}_x HI$, crystals; $B^{\circ}_x HClH_2Cl_2 + \frac{1}{2}H_2O$, triclinic crystals. The salts are described by Söfiling (*Jahresbericht*, 1884, 463).

Phenyl-*p*-toluidine; by distilling tritolyl-rosaniline acetate (Hofmann, *Ann.* 1864, 132, 291); together with diphenylamine and ditolylamine by heating *p*-toluidine and aniline hydrochloride at 210° – 240° (Girard, de Laire and Chapoteaut, *Ann.* 1866, 140, 347; *Bull. Soc. chim.* 1867, (2) 7, 360); by heating phenol with *p*-toluidine and zinc chloride, or *p*-cresol with aniline and zinc chloride at 260° – 300° , or with antimony trichloride (Buch, *Ber.* 1884, 17, 2634); by heating *p*-toluidine with bromobenzene and soda lime at 360° – 380° , or *p*-bromotoluene, aniline, and soda lime in a similar manner (Merz and Paschkowesky, *J. pr. Chem.* 1893, (2) 48, 455; see also Merz and Weith, *Ber.* 1881, 14, 2345). Crystals, m.p. 87° , b.p. 334.5° (H.), or 317° – 318° /727.5 mm. (Graebe, *Ann.* 1887, 238, 363). Dissolves in nitric acid with a blue colour. $B^{\circ}_x HCl$, leaflets.

Acetyl-derivative; m.p. 51° (Bonna).

Nitrosamine; slender yellow needles, m.p. 82° (Bonna, *Ann.* 1887, 239, 56), or 45° (Reichold, *Ann.* 1889, 255, 163).

***p*-Nitroso-derivative**; blue prisms or tables from alcohol, or green leaflets from benzene, m.p. 163° (Reichold).

For condensation with nitrochlorobenzenes, see Schöpf (Ber. 1890, 23, 1843); Jacobson and Lischke (*Ann.* 1898, 303, 377); Engelhardt and Latschinow (*Zeit. f. Chem.* 1870, (2) 6, 233); Willgerodt (*Ber.* 1876, 9, 980); Hepp (*Ann.* 1882, 215, 369); Jackson and Ittner (*Amer. Chem. J.* 1897, 19, 10, 199, 205; *Ber.* 1895, 28, 3063); Laubenheimer (*Ber.* 1878, 11, 1157); Ritzenstein (*J. pr. Chem.* 1903, 68, 251); Kahrman and Kragler (*Ber.* 1901, 34, 1102).

Di-*p*-tolylamine; by heating *p*-cresol with ammonium-zinc chloride and ammonium chloride at 330° – 340° (Merz and Müller, *Ber.* 1887, 20, 546); by heating a mixture of *p*-bromotoluene, *p*-toluidine, and soda lime at 390° (Merz and Paschkowesky, *J. pr. Chem.* 1893, (2) 48, 463). It melts at 79° , and boils at 328.5° /727.5 mm. or 330.5° /760 mm. (Graebe, *Ann.* 1887, 238, 363).

Nitrosamine; m.p. 100° – 101° (Lehne, *Ber.* 1880, 13, 1544), or 103° (Cosack, *ibid.* 1093). For its nitro-derivatives, see Leilmann (*Ber.* 1882, 15, 831); Jaubert (*ibid.* 1895, 28, 1649); and Lehne (*l.c.*).

Anhydro-formaldehyde-*p*-toluidine; from formaldehyde and *p*-toluidine (Wellington and Tollens, *Ber.* 1885, 18, 3302). It exists in two forms: (a) readily soluble form which crystallises in long needles from ether, m.p. 127° – 128° (Eibner, *Ann.* 1898, 302, 352) or 123° (Eberhardt and Welter, *Ber.* 1894, 27, 1804); (b) sparingly soluble form, m.p. 225° – 227° (E.), 207° – 209° (E. and W.). The lower melting substance is converted on sublimation into the higher melting modification. Both forms have the same molecular weight (Bischoff, *Ber.* 1898, 31, 3253).

For condensation with benzaldehyde and potassium cyanide, see von Miller, Föchl and Sieber (*Ber.* 1898, 31, 2711).

Methylene-di-*p*-tolylid-imide; by heating a mixture of *p*-toluidine, alcoholic potassium hydroxide, and formaldehyde (Eberhardt and

Walter, Ber. 1894, 27, 1808); by the action of formaldehyde on an alcoholic solution of *p*-toluidine (Eibner, Ann. 1898, 302, 350).

Rhombic tables, m.p. 86° (E. and W.) or 89° (E.). On heating with *p*-toluidine or on long boiling with alcohol it yields anhydroformaldehyde-*p*-toluidine, whilst on heating with *p*-toluidine hydrochloride it yields diaminoditolylmethane, silky needles, m.p. 92° . It is also stated that two compounds possessing the constitution $(\text{CH}_3\text{C}_6\text{H}_4\text{NH})_2\text{CH}_2$, are formed by heating 1 mol. of methylene chloride with 4 mols. of *p*-toluidine for 34 hours at 100° . One is a syrup, b.p. above 350° with decomposition and forms the salts, $\text{B}'\text{HCl}$, $\text{B}'_2\text{H}_2\text{PtCl}_6$, and $\text{B}'\text{HAuCl}_4$, all of which are amorphous. The other is an amorphous solid, m.p. about 156° , b.p. above 350° , with decomposition. All the salts of the latter with the exception of the acid oxalate are amorphous and unstable (Grünhagen, Ann. 1890, 256, 286). The same author states that di-methylene-di-*p*-toluidine is sometimes formed during the above reaction.

Tolyl-p-hydroxylamine; by reducing *p*-nitrotoluene with zinc dust in the presence of aqueous alcohol and calcium chloride (Lumière and Seyewitz, Bull. Soc. chim. 1894, (3) 11, 1040; Bamberger, Ber. 1895, 28, 245, 1221); by oxidising *p*-toluidine with a persulphate in presence of ether and in contact with ice (Bamberger and Tschirner, Ber. 1899, 32, 1677; see also Wöhl, Eng. Pat. 11216 of 1894; Fr. Pat. 239173; D. R. P. 84138 of 1893; Kalle & Co., D. R. P. 89978 of 1895). Leaflets, m.p. 92° – 93° (L. and S.), 93.5° – 94° (B.). At 115° it decomposes into *p*-azoxytoluene, and when warmed with dilute sulphuric acid it yields *p*-azoxytoluene, *p*-cresol, amino-cresol, *p*-hydrotoluquinone, and a little *p*-toluidine. Oxidation with chromic acid yields *p*-nitrosotoluene. On treatment with thionyl-aniline in benzene solution it yields *p*-toluidine phenylsulphonate, white plates, m.p. 236° , and (probably) *o*-toluene-azo-*p*-toluene, m.p. 68° – 72° (Michaelis and Petou, Ber. 1898, 31, 988).

Nitroso-p-tolylhydroxylamine; from *p*-nitrotoluene and hydroxylamine in presence of sodium ethylate (Angeli and Angelico, Atti R. Accad. Lincei, 1899, (v.) 8, ii. 28); from *p*-nitrosotoluene and the sodium salt of nitrohydroxylaminic acid (Angeli and Angelico, *ibid.* 1901, (v.) 10, i. 167). Leaflets, m.p. 59° – 59.5° .

2-Nitrotolyl-p-hydroxylamine; by electrolytic reduction of 2:4-dinitrotoluene in nearly neutral solution (Brand and Zöller, Ber. 1907, 40, 3324). Compact yellow crystals, m.p. 90° (B. and Z.) or 106° (Burton and Kenner, Chem. Soc. Trans. 1921, 119, 1052).

2:6-Dinitrotolyl-*p*-hydroxylamine; together with 4:6-dinitro-*o*-toluidine by reduction of 2:4:6-trinitrotoluene in cold alcoholic ammoniacal solution with hydrogen sulphide (Anschütz and Zimmermann, Ber. 1915, 48, 152; cf. Cohen and Dakin, Chem. Soc. Trans. 1902, 81, 27; Cohen and McCandlish, *ibid.* 1905, 87, 1205); together with 4:6-dinitrotolyl-*o*-hydroxylamine by reducing 2:4:6-trinitrotoluene in almost neutral solution at a silver cathode (Brand and Eisenmenger, J. pr. Chem. 1913, (2) 87, 487; Ber. 1916, 49, 673). It melts at 135° – 136° , and is converted by boiling concentrated

hydrochloric acid into 2:6-dinitro-*p*-toluidine and 2:6-dinitro-4-azoxytoluene.

o-Toluidine 3-sulphonic acid; by reduction of 2-nitrotoluene 3-sulphonic acid (von Pechmann, Ann. 1874, 173, 215); from tolyl-*o*-hydroxylamine and sulphurous anhydride (Brotschneider, J. pr. Chem. 1897, (2) 55, 291). Microscopic needles. The aqueous solution forms an intensive reddish-yellow colour when warmed with ferric chloride.

o-Toluidine 4-sulphonic acid; by reducing the corresponding nitro-acid (Bek, Zeit. f. Chem. 1869, (2) 5, 211; Beilstein and Kuhlberg, Ann. 1870, 155, 21) or *o*-nitrotoluene *p*-sulphonyl chloride with tin and hydrochloric acid (Reverdin and Crépieux, Ber. 1901, 34, 2993); sulphonation of *o*-toluidine sulphate with 30 p.c. or 50 p.c. fuming sulphuric acid (Claus and Immel, Ann. 1891, 265, 71; cf. Weckwarth, *ibid.* 1874, 172, 193; Hayduck, *ibid.* 1874, 172, 204; 1874, 174, 343; Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 745). Long needles or four-sided prisms. The aqueous solution forms a dark violet coloration with ferric chloride (Herzfeld, Ber. 1884, 17, 904). With bromine it yields a dibromo-derivative. $\text{NaA}' + \text{H}_2\text{O}$, small lustrous scales (W. and B.); $+3\text{H}_2\text{O}$ (C. and I.); $+4\text{H}_2\text{O}$ (B.); $\text{KA}' + \text{H}_2\text{O}$ (W. and B.); $\text{CaA}'_2 + 6\text{H}_2\text{O}$, small prisms (W. and B.); $\text{BaA}'_2 + 2\text{H}_2\text{O}$, tables (W. and B.); PbA' , anhydrous (H.).

Amide; by reduction of 2-nitrotoluene 4-sulphonamide with ammonium sulphide (Paysan, Ann. 1883, 221, 210; cf. Reverdin and Crépieux, *l.c.*). Large four-sided columns, m.p. 175° . $\text{B}'\text{HCl}$, long silky needles, m.p. 240° .

o-Toluidine 5-sulphonic acid; by heating *o*-toluidine with fuming sulphuric acid at 160° – 180° (Gerver, Ann. 1873, 169, 374), or *o*-toluidine ethylsulphate at 200° (Pagel, Ann. 1875, 176, 292); by reducing 2-nitrotoluene 5-sulphonic acid with ammonium sulphide (Foth, Ann. 1864, 230, 306); by heating *o*-toluidine hydrogen sulphate at 220° – 230° (Neville and Winther, Chem. Soc. Trans. 1880, 37, 628; Wynne, *ibid.* 1892, 61, 1037; cf. Claus and Immel, Ann. 1891, 265, 67); by heating di-*o*-tolylurea at 150° with concentrated sulphuric acid (Cazeneuve and Moreau, Bull. Soc. chim. 1898, (3) 19, 23). Large monoclinic prismatic crystals $+ \text{H}_2\text{O}$ (Zepharovich, Ber. 1888, 21, 1803; cf. Hasse, Ann. 1885, 230, 287) or needles $+ \text{H}_2\text{O}$ (Wynne). $\text{NaA}' + 4\text{H}_2\text{O}$, tables (N. and W.; Wynne); $\text{KA}' + \text{H}_2\text{O}$, tables and prisms (N. and W.); $\text{BaA}'_2 + 7\text{H}_2\text{O}$ (N. and W.; Foth); PbA' , long flat prisms; AgA' , anhydrous prisms.

The aqueous solution when treated with a little lead peroxide is coloured rose-red, then green and finally, on adding more lead peroxide, blackish-violet. On bromination it yields monobromo-*o*-toluidine 5-sulphonic acid and 3:5-dibromo-*o*-toluidine. On nitration the chief product is 3:5-dinitro-2-nitroaminotoluene, yellow explosive crystals, m.p. 92° (Zincke and Malkomeius, Ann. 1905, 339, 202).

Acetyl-derivative, needles (Jungmann, Ber. 1900, 33, 1366).

o-Toluidine 3:5-disulphonic acid; by sulphonating 2-toluidine 5-sulphonic acid at 150° – 170° for $\frac{1}{2}$ hour (Neville and Winther, Chem. Soc. Trans. 1882, 41, 421; Ber. 1882, 15, 2993;

Hasse, Ann. 1885, 230, 243; cf. Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 731). Slender needles $+1\frac{1}{2}\text{H}_2\text{O}$. Decomposed at 240° , forming 2-toluidine 5-sulphonic acid.

Salts (see Hasse). $\text{Na}_2\text{A}''+6\text{H}_2\text{O}$, tables; $\text{K}_2\text{A}''$ (anhydrous) (W. and B.); $\text{K}_2\text{A}''+2\text{H}_2\text{O}$, monoclinic plates (H.); $\text{CaA}''+5\text{H}_2\text{O}$, tables; $\text{BaH}_2\text{A}''+3\frac{1}{2}\text{H}_2\text{O}$, microscopic needles or prisms; $\text{BaA}''+3\text{H}_2\text{O}$, triclinic crystals; $\text{PbA}''+6\frac{1}{2}\text{H}_2\text{O}$, quadratic prisms; $\text{PbA}''+2\text{H}_2\text{O}$, columns.

Chloride, pale yellow prismatic crystals, m.p. 95° (W. and B.), 132° (H.).

o-Toluidine 4:5-disulphonic acid; by sulphonating *o*-toluidine 4-sulphonic acid, finally at 160° (Wynne and Bruce, *loc. cit.*). Needles, $\text{K}_2\text{A}''+2\text{H}_2\text{O}$, thin scales; $\text{K}_2\text{A}''$, short slender anhydrous needles; $\text{BaA}''+1\frac{1}{2}\text{H}_2\text{O}$, small thin scales (W. and B.).

3-Bromo-o-toluidine 5-sulphonic acid; by brominating *o*-toluidine 5-sulphonic acid (Neville and Winther, Ber. 1880, 13, 1942; Chem. Soc. Trans. 1880, 37, 429, 625; Claus and Immel, Ann. 1891, 265, 68; Wynne, Chem. Soc. Trans. 1892, 6, 1037). Lustrous needles or prisms $+ \text{H}_2\text{O}$. On heating with water or hydrochloric acid at 160° a mixture of bromo-*o*-toluidine, m.p. 56° , dibromo-*o*-toluidine, m.p. 46° , and a liquid bromotoluidine is obtained.

KA' , anhydrous thin scales (W.); $\text{NaA}' + 18\text{H}_2\text{O}$, small rectangular prisms, which rapidly lose $17\frac{1}{2}\text{H}_2\text{O}$ on exposure to air; $\text{BaA}' + 3\text{H}_2\text{O}$, long lustrous needles (C. and I.; W.).

Pagel (Ann. 1875, 176, 200) by heating *o*-toluidine with sulphuric acid obtained *o*-toluidine sulphonic acid, the amino-group of which was replaced by bromine, and the bromosulphonic acid nitrated and reduced. The product formed microscopic prisms; $\text{BaA}' + \text{H}_2\text{O}$, thick needles; whilst Gerver (Ann. 1873, 169, 380) by treating an aqueous solution of *o*-toluidine 5-sulphonic acid with bromine obtained a dibromo-*o*-toluidine 5-sulphonic acid together with a tribromo-*o*-toluidine, m.p. 112° . The former compound yielded $\text{BaA}' + 4\text{H}_2\text{O}$, long needles; $\text{PbA}' + 3\text{H}_2\text{O}$, needles or prisms. The validity of the latter author's work is questioned by Neville and Winther.

3:5-Dibromo-o-toluidine 4-sulphonic acid; by brominating *o*-toluidine 4-sulphonic acid (Hayduck, Ann. 1874, 172, 211). Long slender needles $+ \text{H}_2\text{O}$ (see also Kornatzki, Ann. 1883, 221, 191); $\text{BaA}' + 9\text{H}_2\text{O}$, aggregates of small needles (H.).

4-Iodo-o-toluidine 5-sulphonic acid; by heating diazotised 2-nitro-*p*-toluidine 5-sulphonic acid with concentrated hydriodic acid (Foth, Ann. 1885, 230, 308). Slender silky needles $+ \text{H}_2\text{O}$; BaA' , rhombic plates.

3-Nitro-o-toluidine 5-sulphonic acid; by nitrating acetyl-*o*-toluidine 5-sulphonic acid (Nietaki and Pollini, Ber. 1890, 23, 138); by heating aceto-*o*-toluidide with 3 parts of 20 p.c. fuming sulphuric acid at 100° and nitrating the cold product with mixed acids (Gnehm and Blumer, Ann. 1899, 304, 105). Small yellow crystals. On heating with dilute sulphuric acid it yields 3-nitro-*o*-toluidine.

6-Nitro-o-toluidine 4-sulphonic acid; by passing hydrogen sulphide into an ammoniacal solution of 2:3-dinitrotoluene 4-sulphonic acid (Marckwald, Ann. 1893, 274, 353). Slender

needles. KA' , leaflets; CaA' , needles; $\text{BaA}' + 2\frac{1}{2}\text{H}_2\text{O}$, needles; $\text{AgA}' + \frac{1}{2}\text{H}_2\text{O}$, needles.

Methyl-o-toluidine 4-sulphonic acid; by treating methyl-*o*-toluidine with 30 p.c. fuming sulphuric acid with cooling and then heating to 50° (Gnehm and Blumer, Ann. 1899, 304, 109). Leaflets or tables. NaA' , leaflets; $\text{BaA}' + 2\text{H}_2\text{O}$, small irregular crystals.

Acetyl-derivative; by acetylation of the amino-acid or sulphonation of methylacetato-*o*-toluidide. BaA' , flat prisms (G. and B.).

Methyl-o-toluidine (?)sulphonic acid; by sulphonation of methyl-*o*-toluidine with monohydrate at 180° - 210° (G. and B.). Needles. BaA' , readily soluble in water.

Dimethyl-o-toluidine (?)sulphonic acid; by heating dimethyl-*o*-toluidine with 4 parts of sulphuric acid at 180° - 210° (Michler and Sampaio, Ber. 1881, 14, 2168). Large glistening prisms which become opaque on exposure to air. CaA' , nodules; BaA' , leaflets; ZnA' , needles.

m-Toluidine 2-sulphonic acid; together with *m*-toluidine 2:4-disulphonic acid by heating *m*-toluidine with fuming sulphuric acid at 160° - 175° (Lorenz, Ann. 1874, 172, 185). The products are separated by crystallisation from water in which the disulphonic acid is more soluble.

Rhombic tables or leaflets, charring above 275° without melting. $\text{BaA}' + 9\text{H}_2\text{O}$, thin tables or long prisms; $\text{PbA}' + 3\frac{1}{2}\text{H}_2\text{O}$, nodules.

m-Toluidine 4-sulphonic acid; 2-bromotoluene 4-sulphonic acid is nitrated, reduced and then treated with sodium amalgam to remove the bromine (Hayduck, Ann. 1874, 174, 350). Microscopic needles. BaA' , amorphous; PbA' , voluminous flocks.

6-Chloro-m-toluidine 4-sulphonic acid; by reducing sodium 2-chloro-5-nitrotoluene *p*-sulphonate with iron filings and dilute acetic acid. Thin small colourless anhydrous plates which turn red on exposure to air and light (Davies, Chem. Soc. Trans. 1921, 119, 865).

m-Toluidine 2:4-disulphonic acid; by heating *m*-toluidine with fuming sulphuric acid (Lorenz, Ann. 1874, 172, 185). One sulphonic group is removed readily with formation of *m*-toluidine sulphonic acid. $\text{BaA}'' + 12\frac{1}{2}(\text{?})\text{H}_2\text{O}$, needles; $\text{PbA}'' + 2\text{H}_2\text{O}$, crusts.

Aceto-p-toluidide 2-sulphonic acid, small colourless needles, m.p. about 160° (decomp.), is obtained by the action of aqueous sodium sulphite on aceto-*p*-toluidide 2-sulphonylchloride (Johnson and Smiles, Chem. Soc. Trans. 1923, 123, 2384).

p-Toluidine 2-sulphonic acid; together with *p*-toluidine 3-sulphonic acid and *p*-toluidine disulphonic acid by heating *p*-toluidine with fuming sulphuric acid (Sell, Ann. 1903, 126, 155; Malyschew, Zeit. f. Chem. 1869, (3) 5, 212); by reducing 4-nitrotoluene 2-sulphonic acid (Bollstein and Kuhlberg, Ann. 1874, 172, 220; Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 743; cf. Brackett and Hayes, Amer. Chem. J. 1887, 9, 400); from *p*-nitrotoluene (Jannsen, Ann. 1874, 172, 233); by heating di-*p*-toluides with concentrated sulphuric acid at about 150° (Caseneuve and Moreau, Bull. Soc. chim. 1906 (3) 19, 22). Monoclinic crystals $+ \text{H}_2\text{O}$ (Zapfrovich, Ber. 1893, 21, 2189) or rhombic (Himelke, Ann. Acad. Sci. Fennicae, 1911

[A] 10, 1). The cold aqueous solution is coloured yellowish-red on treatment with lead peroxide, and with ferric chloride a bordeaux-red colour is produced on warming (Janowsky and Reimann, Ber. 1888, 21, 1217). It reduces ammoniacal silver solution forming a mirror. On diazotisation and boiling with absolute alcohol toluene *o*-sulphonic acid is formed (Ascher, Ann. 1872, 161, 8; Jenssen) and *p*-ethoxytoluene *o*-sulphonic acid (Remsen and Palmer, Amer. Chem. J. 1886, 8, 245). KA' , leaflets or prisms; BaA' , $+H_2O$, leaflets; PbA' , crystalline powder.

Acetyl-derivative; by sulphonating aceto-*p*-toluidide; *acetylsulphonylchloride*, m.p. 124°; *acetylsulphonanilide*, m.p. 220°–221° (Zincke and Rollhauser), or 230° (Johnson and Smiles, Chem. Soc. Trans. 1923, 123, 2384). The acetyl-sulphonyl chloride when reduced with zinc dust yields 4-acetyl-amino-*o*-tolylmercaptan, m.p. 95°, which, on hydrolysis, yields 4-amino-*o*-tolylmercaptan, m.p. 47° (Hess, Ber. 1881, 14, 488, gives 42°) (Zincke and Rollhauser, Ber. 1912, 45, 1495; see also Johnson and Smiles, l.c.).

Amide; by reducing 4-nitrotoluene 2-sulphonamide with hydrogen sulphide in warm ammoniacal solution (Heffter, Ann. 1883, 221, 208). Silky needles or pearly plates, m.p. 164°. By the action of nitrous acid on a mixture of the amide and concentrated hydrochloric acid, *p*-chlorotoluene *o*-sulphonamide is formed, and with nitrous acid and alcohol toluene *o*-sulphonamide is obtained.

p-Toluidine 3-sulphonic acid; by baking *p*-toluidine sulphate or hydrogen sulphate (Neville and Winther, Ber. 1880, 13, 1947; Chem. Soc. Trans. 1880, 37, 631; Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 739); together with *p*-toluidine 2-sulphonic acid and a disulphonic acid by heating *p*-toluidine with twice its weight of fuming sulphuric acid at 180°. In the latter case, the chief product is *p*-toluidine 3-sulphonic acid, but on further heating a greater proportion of the other products is obtained (von Pechmann, Ann. 1874, 173, 195); by treating tolyl-*p*-hydroxylamine in cold 60 p.c. alcoholic solution with sulphur dioxide (Bretschneider, J. pr. Chem. 1897, (2) 55, 292); by heating di-*p*-tolylurea with concentrated sulphuric acid at 150° (Cazeneuve and Moreau, Bull. Soc. chim. 1898, (3) 19, 22).

The 2- and 3-acids may be separated by means of alcohol, in which only the latter is soluble (Buff, Ber. 1870, 3, 796; cf. von Pechmann), or by means of the lead salts, that of the 3-acid being the less soluble; or by means of aqueous potassium hydroxide (Schneider, Amer. Chem. J. 1886, 8, 274). Yellow needles $+ \frac{1}{2}H_2O$ or H_2O (P.). Its aqueous solution gives a wine-red colour with a little lead peroxide (Janowsky, Ber. 1888, 21, 1804). On bromination it yields 5-bromo-*p*-toluidine 3-sulphonic acid and 2:5-dibromo-*p*-toluidine (N. and W.). The sulphonic group is hydrolysed by water at 180°. $KA' + \frac{1}{2}H_2O$ (Malyschew, Zeit. f. chem. 1869, 212; Schneider); $BaA' + 3H_2O$, six-sided plates (P.); $PbA' + 2H_2O$, long needles (P.); AgA' , shining crystals.

Acetyl-derivative; by sulphonating aceto-*p*-toluidide (Junghahn, Ber. 1900, 33, 1366). Leaflets.

p-Toluidine 2:5-disulphonic acid; by heat-

ing *p*-toluidine 2-sulphonyl chloride with chlorosulphonic acid at 150° or with fuming sulphonic acid at 180° (Richter, Ann. 1885, 230, 331; Wynne and Bruce, Chem. Soc. Trans. 1898, 73, 743). Long silky needles $+ 2\frac{1}{2}H_2O$, hydrolysed at 200° with formation of *p*-toluidine 2-sulphonic acid.

$K_2A'' + 2H_2O$, long needles; BaH_2A'' , $+ \frac{1}{2}H_2O$, nodules, $+ \frac{1}{2}H_2O$, silky needles; BaA' , $+ H_2O$, tables; $PbA'' + \frac{1}{2}H_2O$.

p-Toluidine 3:5-disulphonic acid; by heating *p*-toluidine with fuming sulphuric acid at 200° (von Pechmann, Ann. 1874, 173, 217); by heating *p*-toluidine 3-sulphonic acid with chlorosulphonic acid for 2 hours at 120° and then for 2 hours at 140°–160°, or by heating with fuming sulphuric acid for $1\frac{1}{2}$ hours at 160° (Richter, Ann. 1885, 230, 315). The product obtained by the latter author was originally regarded as *p*-toluidine 2:3-disulphonic acid, but was shown by Wynne and Bruce (Chem. Soc. Trans. 1898, 73, 739) to be the 3:5-disulphonic acid. Microscopic needles $+ 2H_2O$, converted by heating at 200°, or with water at 140°, into *p*-toluidine 3-sulphonic acid. Salts (Richter). $K_2A'' + 2H_2O$, long acicular prisms; $BaH_2A'' + 3H_2O$, nodules; $BaA'' + 3H_2O$, leaflets or tables; $PbA'' + 2H_2O$, slender needles; PbA' , silky needles.

Bromo-p-toluidine 2-sulphonic acid; by adding bromine to a boiling solution of *p*-toluidine 2-sulphonic acid (Jenssen, Ann. 1874, 172, 234). Slender needles. $KA' + H_2O$, prisms; BaA' , $+ 7H_2O$, prisms or needles.

5(?) *Bromo-p*-toluidine 3-sulphonic acid; together with 3:5-dibromo-*p*-toluidine by treating *p*-toluidine 3-sulphonic acid with bromine (von Pechmann, Ann. 1874, 173, 210; Neville and Winther, Chem. Soc. Trans. 1880, 37, 631). Yellowish nodules consisting of grouped needles $+ \frac{3}{2}H_2O$, or fine sulphur-yellow needles $+ \frac{3}{2}H_2O$. KA' , thick prisms; $BaA' + 2H_2O$, small rhombic tables; PbA' , glistening needles; AgA' , long colourless needles (P.).

2-Nitro-*p*-toluidine 5-sulphonic acid; from 2-nitro-*p*-toluidine and fuming sulphuric acid at 135°–150° or chlorosulphonic acid at 160° (Foth, Ann. 1885, 230, 300). Yellow needles, which carbonise without melting. $KA' + H_2O$, small orange-red prisms; $BaA' + 4H_2O$, small yellowish-red prisms $+ H_2O$, red nodules; $PbA' + 3\frac{1}{2}(?)H_2O$, small red needles; ammonium salt, golden-yellow needles; silver salt, white prisms, blackened by light.

Ethyl-p-toluidine 2-sulphonic acid; by sulphonating ethyl-*p*-toluidine (Schmidt, J. pr. Chem. 1893, (2) 48, 62). Yellow prisms $+ H_2O$. $KA' + H_2O$, yellow tables.

Diethyl-p-toluidine 2-sulphonic acid; by sulphonation of diethyl-*p*-toluidine at 180°–200° (Schmidt); by ethylation of potassium-*p*-toluidine 2-sulphonate with ethyl bromide and absolute alcohol at 150° (Schmidt). Prisms $+ H_2O$. $KA' + 2H_2O$, triclinic tables; $CaA' + 3H_2O$; $BaA' + 4H_2O$, triclinic tables.

Diethyl-p-toluidine 3-sulphonic acid; by ethylating potassium *p*-toluidine 3-sulphonate in a similar manner (Schmidt). Monoclinic prisms $+ H_2O$, m.p. 243°. $KA' + \frac{1}{2}H_2O$, tables, m.p. 297°.

Some toluidine sulphonic acids of unknown orientation are described by Pagel (Ann. 1875,

176, 305); Haydock (*ibid.* 1875, 177, 57) Schäfer (*ibid.* 1874, 174, 360).

2:3-Toluylenediamine; by reducing 3-nitro-*o*-toluidine with tin and hydrochloric acid (Lellmann, Ann. 1885, 228, 243) or with hydroiodic acid (Gabriel and Thieme, Ber. 1919, 52, 1079). Crystals, m.p. 61°–62°, b.p. 255° (L.) or m.p. 63°–64° (G. and T.).

6-Chloro-2:3-toluylenediamine; by reducing 6-chloro-2:3-dinitrotoluene with stannous chloride and hydrochloric acid (Cohn, Monatsch. 1901, 22, 477); by reducing 6-chloro-3-nitro-*o*-toluidine with zinc dust and ammonium chloride in dilute alcohol (Morgan and Drew, Chem. Soc. Trans. 1920, 117, 788). Colourless needles, m.p. 46°–47°.

Hydrochloride, nacreous leaflets, decomposing at 263° (M. and D.).

Acetyl-derivative; m.p. 201°–203° (M. and D.).

4:6-Dichloro-2:3-toluylenediamine; by reducing 2:4-dichloro-5:6-dinitrotoluene (See lig. Ann. 1887, 237, 164). Leaflets, m.p. 110°. On boiling with acetic anhydride for 25 hours it yields an *anhydro-base*, m.p. 170°.

4:5:6-Trichloro-2:3-toluylenediamine; by reducing the corresponding dinitro-compound with stannous chloride in hot 5 p.c. alcoholic solution (Seelig, Ber. 1885, 18, 82; Prenntzell Ann. 1897, 298, 182). M.p. 195°–207°.

Anhydro-base; by boiling with acetic anhydride for 40–50 hours. Glistening brown needles, m.p. about 300° (S.).

5-Bromo-2:3-toluylenediamine; by successive bromination, nitration, hydrolysis, and reduction of aceto-*o*-toluidide (Hübner and Schupphaus, Ber. 1884, 17, 776). Small needles m.p. 59°. B'HCl, needles; B'H₂SO₄, plates.

5-Nitro-2:3-toluylenediamine; by reducing 3:5-dinitro-*o*-toluidine with sodium sulphide. Orange-red felted needles.

Diacetyl-derivative; obtained by warming the base with acetic anhydride. Pale yellow needles, m.p. 234°. When the free base is boiled with glacial acetic acid and formic acid it is converted into 5-nitro-2:7-dimethylbenzimidazole, glistening needles, m.p. 186° and 5-nitro-7-methylbenzimidazole, white needles m.p. 199°–200°.

6-Chloro-2-methyl-2:3-toluylenediamine; by reducing 6-chloro-3-nitromethyl-*o*-toluidine with zinc dust and ammonium chloride in aqueous alcoholic solution. Oil. B'HCl, colourless needles. **Diazoimine**, flesh-coloured prismatic needles, m.p. 238°–239° (Morgan and Jones Chem. Soc. Trans. 1921, 119, 191).

2:3-Toluylenediamine 5-sulphonic acid; by reducing 3-nitro-*o*-toluidine 5-sulphonic acid with stannous chloride and hydrochloric acid (Nietzki and Pollini, Ber. 1890, 23, 139). Needles.

2:4-Toluylenediamine, m-toluylenediamine by reducing 2:4-dinitrotoluene (Hofmann Jahresbericht, 1861, 513) or 4-nitro-*o*-toluidine with tin and hydrochloric acid (Nötting and Collin, Ber. 1894, 17, 268); by treating 2:4-dinitrobenzyl chloride with tin and hydrochloric acid (Krasusky, J. Russ. Phys. Chem. Soc. 1895, 27, 237). Long needles, or rhombic prisms, m.p. 99°, b.p. 290°. Its aqueous solution darkens in the air. When treated with sodium peroxide solution at a moderate temperature 4-nitro-*o*-toluidine is obtained, whilst when the mixture is boiled 2:4-dinitrotoluene is

formed (O. Fischer and Trost, Ber. 1893, 26, 3084).

Salts, see Hofmann; Hell and Schoop, Ber. 1879, 12, 723. B'HCl (Bernthsen and Trompeter, Ber. 1878, 11, 1759); B'2HCl, B'H₂PtCl₄; B'2HBr; B'H₂SO₄ + 2H₂O, long monoclinic prisms (Strauss, Ann. 1868, 148, 157; cf. Beilstein and Kuhlberg, Ann. 1871, 158, 251). Reactions with sulphur, see Kalle and Co., D. R. P. 86096 of 1894; Clayton Aniline Co., Eng. Pat. 4792 of 1900; D. R. P. 120504 of 1900; Cassella & Co., Eng. Pat. 11771 of 1902; U.S. Pat. 714542; Fr. Pat. 321122; D. R. P. 139430 of 1902.

With formaldehyde in neutral aqueous or alcoholic solution it yields *anhydroformaldehyde-m-toluylenediamine*, powder, m.p. 150°–180°, whilst in acid solution 3:3'-dimethyl-4:6:4':6'-tetraaminodiphenylmethane, m.p. 203°–204°, is formed (Ullmann and Naef, Ber. 1900, 33, 913; D. R. P. 130943 of 1898).

2-Acetyl-derivative; by reducing 4-nitro-aceto-*o*-toluidide, needles, m.p. 140° (Wallach Ann. 1886, 234, 360).

4-Acetyl-derivative; by prolonged boiling of 2:4-toluylenediamine with acetic acid (Tiemann, Ber. 1870, 3, 221; Schiff and Ostrogoich, Ann. 1896, 293, 371), or by heating 1 part of the diamine with $\frac{1}{2}$ part of acetamide initially at 110° and finally at 160°–170° (S and O.). Long yellow prisms or needles m.p. 161.5° (S. and O.) or 159°–160° (T.).

Diacetyl-derivative (Koch, Ann. 1870, 153, 132; Tiemann, Ber. 1870, 3, 8; Ladenburg *ibid.* 1875, 8, 1211). Long needles, m.p. 221° (T.) or 224° (L.). By boiling with 1 mol. *o*-potassium hydroxide 4-acetamino-2-aminotoluene is obtained (K.).

Formyl-derivative; transparent pyramids m.p. 113°–114°; **diformyl-derivative**; bunches of white needles, m.p. 176°–177° (Geigy & Co. U.S. Pat. 722630; Fr. Pat. 306655; D. R. P. 138839 of 1902).

4-Benzoyl-derivative; by reducing *o*-nitro-4-benzoylaminotoluene with tin and hydrochloric acid (Bell, Ber. 1874, 7, 1506). Prisms m.p. 142°.

Dibenzoyl-derivative; tables, m.p. 224° (Ruhemann, Ber. 1881, 14, 2656).

Benzylidene-derivative; yellow tables, m.p. 90°–91° (Meyer and Gross, Ber. 1898, 31, 2358); **dibenzylidene-derivative**; yellowish crystalline mass, m.p. 122°–128° (Schiff 1866, 146, 98).

5-Chloro-2:4-toluylenediamine; by 5-chloro-2:4-dinitrotoluene with tin and hydrochloric acid (Reverdin and Crépiaux, Ber. 1903, 33, 2507); by successive chlorination and hydrolysis of diacetyl-2:4-toluylenediamine (Morgan, Chem. Soc. Trans. 1900, 77, 1209). Leaflets or rectangular plates, m.p. 120°–121° (M.) or 123° (R. and C.).

Acetyl-derivative; m.p. 170° (R. and C.) **diacetyl-derivative**, small acicular prisms, m.p. above 260° (R. and C.; Morgan, Chem. Soc. Trans. 1902, 81, 95).

Formyl-derivative; colourless silky needles m.p. 166° (Morgan).

Dibenzoyl-derivative; colourless acicular leaflets, m.p. 205° (M.).

6-Chloro-2:4-toluylenediamine; by reducing 2:4-chloro-4:6-dinitrotoluene with stannous

chloride and hydrochloric acid in presence of alcohol, or with zinc dust, ammonium chloride and alcohol (Morgan and Drew, Chem. Soc. Trans. 1920, 117, 788).

5:6-Dichloro-2:4-toluylenediamine; by reduction of 2:3-dichloro-4:6-dinitrotoluene (Seelig, Ann. 1887, 237, 164). Slender needles, m.p. 137°.

5-Bromo-2:4-toluylenediamine; by reducing either 5-bromo-2:4-dinitrotoluene (Grete, Ann. 1875, 177, 231) or 5-bromo-4-nitro-*o*-toluidine (Morgan and Clayton, Chem. Soc. Trans. 1905, 87, 950); by brominating dibenzoyl-2:4-toluylenediamine (Ruhemann, Ber. 1881, 14, 2659; Morgan and Clayton) or diacetyl-2:4-toluylenediamine (Tiemann, Ber. 1870, 3, 220) and hydrolysing the product. Lustrous needles, m.p. 104°-107° (decomp.) (M. and C.), rhombic tables 107° (G.), leaflets 104° (R).

Monoacetyl-derivative, leaflets, m.p. below 100° (Koch, Ann. 1870, 153, 134).

Acetyl-derivative, m.p. 254° (M. and C.).

Dibenzoyl-derivative, m.p. 214° (R).

Dibromo-4-acetyl-2:4-toluylenediamine; by brominating 4-acetyl-2:4-toluylene-diamine (Tiemann, l.c.). Long needles, m.p. 208° with blackening.

3:5:6-Tribromo-2:4-toluylenediamine; by reducing the corresponding dinitro-compound or 3:5:6-tribromo-4-nitro-*o*-toluidine with iron and acetic acid (Blanksma, Chem. Weekblad, 1914, 11, 185). Colourless crystals, m.p. 180°.

Nitroso-2:4-toluylenediamine; m.p. 195° (Täuber and Walder, D. R. P. 123375 of 1900).

6(?) Nitro-2:4-toluylenediamine; by successive nitration and hydrolysis of diacetyl or dibenzoyl-2:4-toluylenediamine (Tiemann, Ber. 1870, 3, 219; Ladenburg, *ibid.* 1875, 8, 1211; Ruhemann, *ibid.* 1881, 14, 2656). Reddish-yellow needles, with a violet sheen, m.p. 154°. Weak base, whose salts are decomposed by water.

Diacetyl-derivative; needles, m.p. 253° (decomp.) (L.). **Dibenzoyl-derivative**; citron-yellow needles, m.p. 245° (R.).

6-Nitro-2:4-toluylenediamine(?); by reducing 2:4:6-trinitrotoluene with alcoholic ammonium sulphide (Tiemann, l.c.). Small red prisms, m.p. 132°; **hydrochloride**, yellow needles.

3:5-Dinitro-2:4-toluylenediamine; together with a mononitro-derivative by nitration of diacetyl-2:4-toluylenediamine in presence of urea nitrate, followed by hydrolysis with dilute sulphuric acid (Nietzki and Rösel, Ber. 1890, 23, 3216); from 2:4-dibromo-3:5-dinitrotoluene and alcoholic ammonia at 150° (Blanksma, Chem. Weekblad, 1912, 9, 968); by heating 3:4:5-trinitro-2-methoxytoluene with ammonia in a sealed tube (Blanksma, Rec. trav. chim. 1910, 29, 410). Dark brown crystals, m.p. 254°.

Acetyl-derivative; does not melt below 300° (B.).

2-Methylamino-4-aminotoluene; by reducing 4-nitro-methyl-*o*-toluidine with tin or zinc dust (Gnehm and Blamer, Ann. 1899, 304, 106). Colourless oil, b.p. 273°.

2-Amino-4-methylaminotoluene; colourless viscid oil, b.p. 276°-276.5° (corr.), coloured brown by exposure to air; **sulphate**, white needles. For its use in the preparation of azines and indulines, see Bayer & Co., Eng. Pat. 16915 of

1892; Fr. Pat. 225086; D. R. P. 92014 of 1892; B. A. S. F., D. R. P. 77228 of 1892.

Nitrosoamine; yellow needles, m.p. 83°; **picrate**, needles, m.p. 103°-105° (Pinnow and Oesterreich, Ber. 1898, 31, 2928).

Nitroamine; by heating 2-nitromethyl-*p*-tolylnitroamine with alcoholic ammonium sulphide at 100°. Dull red prisms, m.p. 83.5° (P. and O.).

5-Nitro-2-amino-4-methylaminotoluene; from 2:5-dinitromethyl-*p*-toluidine and alcoholic ammonium sulphide (Pinnow, J. pr. Chem. 1900, (2) 62, 508). Brown leaflets with a bronze lustre, m.p. 168°.

Acetyl-derivative; yellowish-brown needles, m.p. 205.5°-207° (P.).

3:5-Dinitro-2-amino-4-methylaminotoluene; by heating 2:3:5-trinitromethyl-*p*-toluidine with alcoholic ammonia at 100° (Sommer, J. pr. Chem. 1903, (2) 67, 535); from 3:5-dinitro-2-amino-*p*-tolylnitroamine by heating with twice its weight of phenol for 2 hours at 140°-160° (S.); from the ethyl-ether of 3:5-dinitro-4-methylamino-*o*-cresol by heating with concentrated absolute alcoholic ammonia at 100° (Sommer, l.c. 559). Orange needles with a yellow reflex, m.p. 206°-208°.

Nitrosoamine; by the action of ammonia on the nitrosoamine of 2:3:5-trinitromethyl-*p*-toluidine. Brownish-yellow prisms, m.p. 164° (Sommer, l.c. 562).

2-Dimethylamino-4-aminotoluene; by reducing 4-nitrodimethyl-*o*-toluidine with stannous chloride and hydrochloric acid (Ullmann and Mühlhauser, Ber. 1902, 35, 332; Möhlau, Klimmer and Kahl, Zeit. f. Farb. u. Textilchem., 1902, 1, 313). Yellowish oil, coloured red by air, b.p. 248° (M., K. and K.) or 257°-259°/730 mm. with slight decomposition (U. and M.).

Dihydrochloride; columns, m.p. 208°; **sulphate**; m.p. 209° (M., K. and K.).

Acetyl-derivative; needles, m.p. 103° (M., K. and K.).

2-Amino-4-dimethylaminotoluene; by reducing 2-nitrodimethyl-*p*-toluidine (M. L. B., D. R. P. 69188 of 1891) with tin and hydrochloric acid (Morgan and Clayton, Chem. Soc. Trans. 1905, 87, 948).

Acetyl-derivative; white needles, m.p. 135° (M. and C.).

For the use of this base in the preparation of azines, see M. L. B., D. R. PP. 69188 of 1891; 85231, 85232 of 1892; 87500 of 1895; of safranines, Leonhardt & Co., D. R. P. 86608 of 1892; and of other dyes, Act. Ges. f. Anilfabr., Eng. Pat. 12899 of 1900; Fr. Pat. 301793; D. R. P. 118392 of 1900.

5-Bromo-2-amino-4-monoethylaminotoluene; by brominating 2-acetyl-amino-4-dimethylaminotoluene in glacial acetic acid, followed by hydrolysis (Morgan and Clayton, l.c.); by reducing 3-bromo-6-nitrodimethyl-*p*-toluidine with tin and hydrochloric acid (M. and C.). Pearley leaflets, m.p. 40°.

Acetyl-derivative; crystals, m.p. 163°; **benzoyl-derivative**; m.p. 177°-178°; **2-benzene-sulphonyl-derivative**; m.p. 178°-179° (M. and C.).

3:5-Dinitro-2:4-monomethylaminotoluene; by the action of methylamine on a concentrated boiling alcoholic solution of 2:3:5-trinitro-methyl-*p*-toluidine (Sommer, J. pr. Chem. 1903, (2) 67, 547). It exists in two modifications:

(a) red plates, m.p. 168° – 170° ; (b) yellow needles, m.p. 110° , converted into the red modification at 140° . Both modifications yield with aqueous potassium hydroxide according to the concentration 3:5-dinitro-2:4-dihydroxytoluene and 3:5-dinitro-2-methylamino-*p*-cresol (S.).

4-Nitrosoamine; from the nitrosoamine 2:3:5-trinitromethyl-*p*-toluidine and methylamine. Small yellow needles, m.p. 186° – 187° .

2:4-Dinitrosoamine; from either of the above compounds in acetic acid solution with sodium nitrite. Very stable white leaflets glistening cubes, m.p. 132° (S.).

3:5-Dinitro-2-dimethylamino-4-methylaminotoluene; from 2:3:5-trinitromethyl-*p*-toluidine and dimethylamine in alcoholic solution (Sommer, l.c. 565). Yellow needles, m.p. 115° .

3:5-Dinitro-2:4-di(methylnitroamino)toluene; colourless crystals, m.p. 169° (Blankens Rec. trav. chim. 1910, 29, 410).

Tetramethyl-2:4-toluylenediamine; together with the methylammonium bromide; by heating 2:4-toluylenediamine hydrobromide with methyl alcohol in a sealed tube at 180° (Morga Chem. Soc. Trans. 1902, 81, 653). Yellowish brown oil, b.p. 148° – 150° /24–26 mm., 255° – 256° /757 mm.; D_{20}^{25} 0.9661. $B'H_2PtCl$ yellow prisms; picrate, yellow prisms, m. 162° – 163° .

2-Ethylamino-4-aminotoluene; by reducing 4-nitroethyl-*o*-toluidine with zinc dust and hydrochloric acid (MacCallum, Chem. Soc. Trans. 1895, 67, 247). Liquid, b.p. 274° – 275° .

2-Amino-4-ethylaminotoluene; by reducing the corresponding nitro-compound (Nölting and Stricker, Ber. 1886, 19, 549). Liquid, b.p. 280° – 283° (N. and S.) or 289° – 291° (Jaubert, Bull. So. chim. 1899, (3) 21, 20).

2-Diethylamino-4-aminotoluene; by reducing 4-nitrodiethyl-*o*-toluidine with stannous chloride and hydrochloric acid (Ullmann and Mühlhause Ber. 1902, 35, 335; Möhlau, Klinmer and Kah l.c.). Yellowish oil, b.p. 259° (M., K. and K.), 265° – 266° /730 mm. (U. and M.). Volatile with steam $B'2HCl+H_2O$, m.p. 213° – 215° (decomp.) (M. K. and K.).

2-Amino-4-phenylaminotoluene; by heating 1 part of 2:4-toluylenediamine with $1\frac{1}{2}$ parts of aniline hydrochloride and 3 parts of aniline at 240° – 250° for 10 hours (Bayer & Co., Eng. Pat. 8610 of 1894; Fr. Pat. 240571; D. R. P. 809 of 1894). Prisms, m.p. 76° – 77° . Used for the preparation of azines (Bayer & Co., Eng. Pat. 8610 of 1894; Fr. Pat. 240621; D. R. PP. 819 and 84504 of 1894).

3:5-Dinitro-2-phenylamino-4-methylaminotoluene; from 2:3:5-trinitromethyl-*p*-toluidine and aniline (Sommer, J. pr. Chem. 1903, (2) 6, 137). Thick prisms, m.p. 197° .

4-Nitrosoamine; orange needles, m.p. 122° .

3:5-Dinitrosoamine; sulphur-yellow needles decomposing at 100° (S.).

2:4-Dinitrophenyl-2:4-toluylenediamine; by boiling a mixture of 2:4-toluylenediamine, chloro-2:4-dinitrobenzene and alcohol (Leyman, Ber. 1882, 15, 1237). Red tables, m.p. 184° .

Acetyl-derivative; m.p. 163° – 164° (L.).

3-Ethylamino-4-phenylaminotoluene; by heating 3-amino-4-phenylaminotoluene with ethyl bromide at 150° – 175° for 10 hours (Bayer & Co., Eng. Pat. 8176 of 1893; Fr. Pat. 240571).

D. R. P. 87667 of 1895). Crystals, m.p. 59° – 60° . Used for the preparation of azines (Bayer & Co., Eng. Pat. 9794 of 1895; Fr. Pat. 240621; D. R. P. 87975 of 1895).

2:4-Toluylenediamine 5-sulphonic acid; by warming 2-nitro-*p*-toluidine 5-sulphonic acid with stannous chloride and hydrochloric acid (Foth, Ann. 1885, 230, 309). Small glistening pyramids or rhombohedra. $KA'+H_2O$, glistening prisms; $BaA'+5\frac{1}{2}H_2O$, glistening leaflets or tables; $B'HCl+H_2O$, large rhombic prisms, decomposed by boiling water; $B'HBBr+H_2O$.

This sulphonic acid is possibly identical with that prepared by Wiesinger (Ber. 1874, 7, 464) by sulphonating 2:4-toluylenediamine, although the water content of some of its salts differs from those enumerated above.

2:4-Toluylenediamine 6-sulphonic acid; by reducing 2:4-dinitrotoluene 6-sulphonic acid. Prisms (Oehler, Fr. Pat. 199568; D. R. P. 51862 of 1889).

Anhydroformaldehyde-2:4-toluylenediamine; from 2:4-toluylenediamine and formaldehyde in neutral aqueous or alcoholic solution (Ullmann and Naef, Ber. 1900, 33, 913; D. R. P. 130643 of 1898). Slightly coloured powder, m.p. 150° – 180° . On heating in dilute acid solution it yields acridines (Ges. f. Chem. Ind. Basel, D. R. P. 130617 of 1902).

2:5-Toluylenediamine, *p*-toluylenediamine; by reducing 5-nitro-*o*-toluidine (Beilstein and Kuhlberg, Ann. 1871, 158, 352), *o*-aminoazotoluene (Nietzki, Ber. 1877, 10, 832) or *m*-aminoazotoluene (Nietzki, l.c. 1158) with tin and hydrochloric acid; by reducing 6-nitro-*m*-toluidine (Fileti and Crosa, Gazz. chim. ital. 1888, 18, 306). Colourless prisms, m.p. 64° , b.p. 273° – 274° . By treating a solution of the base containing a little *o*-toluidine with oxidising agents such as potassium dichromate, manganese dioxide, and ferric chloride an intense green coloration is formed (N.).

Dihydrochloride; leaflets; sulphate, powder.

Diacyl-derivative; large prisms, m.p. 221° (Nietzki, Ber. 1877, 10, 1157; *ibid.* 1879, 1, 2237).

4-Chloro-2:5-toluylenediamine; by reducing 4-chloro-2:5-toluquinonedioxime with stannous chloride and hydrochloric acid in presence of alcohol.

Diacyl-derivative; silky snow-white needles (Kehrmann, Silva and Keleti, Ber. 1915, 4, 2028).

Chloro-2:5-toluylenediamine; by saturating an alcoholic, ethereal or glacial acetic solution of *N*-nitroso-*o*-tolylglycine with dry hydrogen chloride (Vörlander and Schröder, Ber. 1901, 34, 1651). White scales rendered violet by air, m.p. 146° . It reduces cold ammoniacal silver nitrate. Ferric chloride-chlorine water, &c., give a green coloration.

Dihydrochloride and sulphate are crystalline. Diacyl-derivative; fine white needles, m. above 300° (V. and S.).

3:4:6-Trichloro-2:5-toluylenediamine; by reducing a glacial acetic acid solution of 2:4-trichlorodinitrotoluene with stannous chloride and aqueous hydrochloric acid (Beilg, Ann. 1897, 237, 143; Ber. 1895, 18, 430). Shaded needles, m.p. 196° .

Tetra-acetyl-derivative; needles, m.p. 220° .

2-Amino-3-dimethylaminotoluene; by heating

ducing nitroso-dimethyl-*m*-toluidine with tin and hydrochloric acid (Wurster and Riedel, Ber. 1879, 12, 1801). Long needles, m.p. 28°.

Acetyl-derivative; m.p. 158° (W. and R.).

5-Amino-2-dimethylaminotoluene; by reducing 5-nitrodimethyl-*o*-toluidine with zinc dust and hydrochloric acid at 0° (Bernthsen, Ber. 1892, 25, 3134). Oil, which solidifies in a freezing mixture and melts at 47°, b.p. 253°–254°. $B \cdot H_2SO_4$, small needles. Ferric chloride yields a bluish-red colour and potassium dichromate a purple-red colour.

Tetramethyl-2:5-toluylenediamine; by heating 5-dimethylamino-*o*-toluidine with methyl alcohol and hydrochloric acid at 180° (Wurster and Riedel, l.c. 1802). Oil, b.p. 260°. Ferric chloride yields an intensive blue colour which disappears on adding hydrochloric acid.

5-Amino-2-ethylaminotoluene; by reducing 5-nitroso-ethyl-*o*-toluidine (Kock, Ann. 1888, 243, 307) with stannous chloride and hydrochloric acid (Weinberg, Ber. 1892, 25, 1611). Viscid liquid, b.p. (in atmosphere of hydrogen) 264° (K.), 272° (W.).

Dihydrochloride, m.p. 124° (decomp.); *sulphate*, large crystals.

5-Amino-2-diethylaminotoluene; by reducing 5-nitrodiethyl-*o*-toluidine (Bernthsen, Ber. 1892, 25, 3138, 3367); by hydrolysis of its acetyl-derivative (Weinberg). M.p. 24° (Weinberg, Ber. 1893, 26, 308), b.p. 266°–267°.

Hydrochloride; glistening leaflets; *sulphate*, $+2H_2O$, prisms.

2-Ethylamino-5-benzoylamintoluene; small needles, m.p. 174° (O. Fischer, Ann. 1895, 286, 166).

4-Nitro-2:5-toluylenediamine; by nitration of diacetyl-2:5-toluylenediamine in glacial acetic acid with a mixture of nitric acid (D 1.47) and glacial acetic acid, followed by hydrolysis (Morgan and Micklethwait, Chem. Soc. Trans. 1913, 103, 1398). Needles, varying in different crystallisations from bright red to dark green with a bronze reflex, m.p. 173°.

Diacetyl-derivative; short pale yellow prisms, m.p. 158° (M. and M.).

2:6-Toluylenediamine; by reducing 6-nitro-*o*-toluidine with tin and hydrochloric acid (Cunerth, Ann. 1874, 172, 227; Ullmann, Ber. 1884, 17, 1959). Prisms, m.p. 103.5°–105°. With ferric chloride it yields a deep blue colour, and with *p*-nitrosodimethylaniline first a green and then a dark blue solution.

Hydrochloride, crystals; *sulphate*, $+1\frac{1}{2}H_2O$, small slender needles.

Diacetyl-derivative; sublimes in white woolly flocks, m.p. 202°–203° (Green and Lawson, Chem. Soc. Trans. 1891, 59, 1017).

3:5-Dinitro-2:6-toluylenediamine; by the action of alcoholic ammonia on 2:6-dibromo-3:5-dinitrotoluene at 150° (Blanksma, Chem. Weekblad, 1912, 9, 968).

Acetyl-derivative; colourless crystals, decomposing above 300° (B.).

3:5-Dinitro-2:6-dimethyltoluylenediamine; by the action of methylamine on 2:6-dibromo-3:5-dinitrotoluene (Blanksma). Orange-red crystals, m.p. 216°.

2:6-Toluylenediamine sulphonic acid; by boiling the corresponding thiosulphonic acid with concentrated hydrochloric acid (Peri, Ber. 1885, 18, 69). Silky needles. $BA_2 + 2H_2O$, microscopic needles.

2:6-Toluylenediamine 4-sulphonic acid; by reducing 2:6-dinitrotoluene 4-sulphonic acid or 6-nitro-2-aminotoluene 4-sulphonic acid with tin and hydrochloric acid (Schwanert, Ann. 1877, 186, 380; Marckwald, Ann. 1893, 274, 351). Rhombic pillars, not melting at 280° (S.). $BaA_2 + 4H_2O$, amorphous; $B \cdot HCl + 2H_2O$, small rhombic pillars; $B \cdot HBr + 2H_2O$; $B \cdot HNO_3 + H_2O$, rhombic needles; $B_2 \cdot H_2SO_4 + H_2O$, rhombic plates (S.).

3:4-Toluylenediamine; reduction of 3-nitro-*p*-toluidine or 3-nitro-*p*-aminobenzyl alcohol with tin and hydrochloric acid (Beilstein and Kuhlberg, Ann. 1871, 158, 351; Meyer and Rohmer, Ber. 1900, 33, 254). Scales, m.p. 88.5°, b.p. 265° (B. and K.). Its aqueous solution darkens in the air. $B \cdot 2HCl$, needles (Hübner, Ann. 1881, 209, 364); *sulphate*, $+1\frac{1}{2}H_2O$, scales.

3-Acetyl-derivative; by reducing 4-nitro-aceto-*m*-toluidide with iron and acetic acid. Nodular aggregates, melting indefinitely at 96°. The corresponding *anhydro-base* melts at 145°–150° (Morgan and Micklethwait, Chem. Soc. Trans. 1913, 103, 1400); *4-acetyl-derivative*; by reduction of 3-nitroaceto-*p*-toluidide, leaflets, m.p. 130°–131° (Bössneck, Ber. 1886, 19, 1757); *picrate*, leaflets (Bankiewicz, Ber. 1889, 22, 1399); *diacetyl-derivative*; long slender needles, m.p. 210° (Bistrzycki and Ulfers, Ber. 1890, 23, 1878). The diacetyl-derivative yields a *nitro-compound*, long needles, m.p. 239°, and a *dinitro-compound*, fine silky needles, m.p. 251°–252° (Bistrzycki and Ulfers, l.c. 1991).

3-Benzoyl-derivative; by reducing 4-nitro-benzoyl-*m*-toluidine with iron and acetic acid. Colourless felted needles or prismatic crystals, m.p. 158° (Morgan and Micklethwait, Chem. Soc. Trans. 1913, 103, 1403); *4-benzoyl-derivative*; crystals, m.p. 193°–194°, together with phenyl-tolimidazole by reducing 3-nitrobenzyl-*p*-toluidine with tin and hydrochloric acid (Hübner, Ann. 1881, 208, 314) or together with the dibenzoyl-derivative by direct benzoylation (Bistrzycki and Cybulski, Ber. 1891, 24, 633); *dibenzoyl-derivative*; by the further treatment of the 4-benzoyl-derivative with benzoyl chloride (Hübner; Bistrzycki and Cybulski) or from *m*-methylbenzimidazole with benzoyl chloride and sodium hydroxide (Bamberger and Berlé, Ann. 1893, 273, 349). It forms glistening needles, m.p. 263°–264° (Hinsberg and Udransky, Ann. 1889, 254, 255), and yields a *nitro-derivative*, prisms or needles, m.p. 246° (Bistrzycki and Ulfers, Ber. 1892, 25, 1994).

2-Chloro-3:4-toluylenediamine; by reducing 2-chloro-4-nitro-*m*-toluidine with zinc dust, dilute alcohol and ammonium chloride (Morgan and Glover, Chem. Soc. Trans. 1921, 119, 1706). Pale brown needles, m.p. 55°–56°.

6-Chloro-3:4-toluylenediamine; obtained quantitatively as the hydrochloride by reducing 6-chloro-4-nitro-*m*-toluidine with zinc dust, ammonium chloride and dilute alcohol, or with alcoholic stannous chloride (Morgan and Drew, Chem. Soc. Trans. 1920, 117, 790; Morgan and Challenor, *ibid.* 1921, 119, 1539). Pale brownish-yellow leaflets, m.p. 143°.

5-Bromo-3:4-toluylenediamine; by reducing 5-bromo-3-nitro-*p*-toluidine with stannous chloride and hydrochloric acid (Bistrzycki, Ber. 1890, 23, 1045). Long flat needles, m.p. 81°–82°.

4-Acetyl-derivative; by reducing 5-bromo-3-nitroaceto-*p*-toluidide at a low temperature with stannous chloride and hydrochloric acid. It forms crystals, m.p. 167°-168° (Hartmann, Ber. 1890 23, 1049); diacetyl-derivative; by direct acetylation, glistening needles, m.p. 222°-223°; dibenzoyl-derivative, needles, m.p. 244°.

4-Methylamino-3-aminotoluene; by reducing 3-nitro-4-methylaminotoluene or its nitrosamine with tin and hydrochloric acid (Gattermann, Ber. 1885, 18, 1487; O. Fischer, Ber. 1893, 26, 194); by reducing methyl-*p*-toluidine azobenzene 4-sulphonic acid with stannous chloride and hydrochloric acid (Bamberger and Wulz, Ber. 1891, 24, 2082). Quadratic tables, m.p. 46°-44°, b.p. 260°/752 mm. (Pinnow, Ber. 1887, 20, 3121). B²HCl, small glistening prisms, decomposing at 180°-185° (B. and W. or 175°-180° (F.)); B²C₂H₅SO₄, deliquescent needles (F.); B²C₂H₅O₄, glistening needles, m.p. 124° (F.); picrate, small yellow crystals, m.p. 164° (F.). Symm-diacetyl-derivative; hexagonal plates, m.p. 183°-184° (Pinnow, J. pr. Chem. 1900, (2) 62, 514).

6-Chloro-4-amino-3-methylaminotoluene; by reducing 6-chloro-4-nitromethyl-*m*-toluidine with zinc dust, alcohol and ammonium chloride (Morgan and Challenor, Chem. Soc. Trans. 1921, 119, 1542). Sublimes in arborescent needles, m.p. 60°.

5-Nitro-4-methylamino-3-aminotoluene; by reducing 3:5-dinitromethyl-*p*-toluidine with hydrogen sulphide in presence of alcohol and ammonia (Pinnow, J. pr. Chem. 1901, (2) 63, 180). Bluish-red plates or short prisms with green sheen, m.p. 131°-132°.

3-Amino-4-dimethylaminotoluene; together with a compound whose picrate melts at 254°-5° by the gradual addition of tin to a solution of 3-nitro-4-dimethylaminotoluene in hydrochloric acid (Pinnow, Ber. 1895, 28, 3042; J. pr. Chem. 1901, (2) 63, 354). Oil, b.p. 234°. Coloured ferric chloride. B²HCl, crystals, m.p. 192°; B²H₂HgCl₂, crystals, m.p. 205°-206°; picrate, yellow-brown prisms, m.p. 150°-151°; acetyl-derivative; plates, m.p. 111°-112° (P.).

5-Nitro-3-acetylamino-4-dimethylaminotoluene; by reducing 3:5-dinitrodimethyl-*p*-toluidine with ammonium sulphide, followed by treatment with acetic anhydride (Pinnow and Matovich, Ber. 1898, 31, 2514). Yellow needles or prisms, m.p. 97°.

6-Nitro-3-acetylamino-4-dimethylaminotoluene; by nitrating 3-acetylamino-4-dimethylaminotoluene with mixed acids below 0° (Pinnow, Ber. 1901, 34, 1181). Bright yellow rhombic tables, m.p. 142°-143°.

Tetramethyl-3:4-toluylenediamine; from 3:4-toluylenediamine and methyl iodide (Niemeiswaki, Ber. 1887, 20, 1888; cf. O. Fischer and Rignard, *ibid.* 1902, 35, 1263). Liquid, b.p. 245°-225°/717 mm. (N.), 259°-260°/740 mm. (F. and R.). Ferric chloride gives a red color. Red crystalline plates. B²HCl, needles (F. and R.).

5-Amino-3-aminotoluene; by reducing methyl-*p*-toluidine with tin and hydrochloric acid (Gattermann, Ber. 1885, 18, 148; O. Fischer, *ibid.* 1893, 26, 199). Large tables, m.p. 54°-55°. Unstable. B²HCl, m.p. 176° (F.); B²C₂H₅O₄, needles, m.p. 151° (F.).

Symm. diacetyl-derivative; obtained together with 2:5-dimethyl-1-ethylbenzimidazole by the action of acetic anhydride on the base (O. Fischer and Rignard, Ber. 1901, 34, 4206). Crystals, m.p. 177°.

3-Ethylamino-4-aminotoluene; by reducing 4-nitro-ethyl-*m*-toluidine with tin and hydrochloric acid (O. Fischer and Rignard). Needles, m.p. 59°, coloured violet in presence of air and moisture. With ferric chloride it yields a deep red oxidation product.

Symm. diethyl-3:4-toluylenediamine; from the diethyl-derivative of dibenzeneulphone-3:4-toluylenediamine and concentrated hydrochloric acid at 160° (Hinsberg, Ann. 1891, 265, 191; cf. O. Fischer and Rignard, Ber. 1902, 35, 1265). Liquid, b.p. 285° (H.). B²HCl, needles. With ferric chloride in presence of hydrochloric acid it forms a reddish-brown colour; a colourless precipitate is formed on the addition of potassium ferrocyanide to the aqueous solution (H.).

6-Chloro-3-phenylamino-4-aminotoluene; by reducing 6-chloro-4-nitrophenyl-*m*-toluidine with zinc dust and ammonium chloride (Morgan and Jones, Chem. Soc. Trans. 1921, 119, 191). Pink needles, m.p. 109°-5°.

Diazoimine; silky pink needles, m.p. 119°-120° (M. and J.).

3 (or 2)-Nitro-2 (or 3)-amino-4-methylaminotoluene; in small yield by reducing 2:3(γ)-dinitromethyl-*p*-toluidine with ammonium sulphide (Pinnow, J. pr. Chem. 1900, (2) 62, 516). Nearly black prisms, m.p. 127°-128°.

3:5-Toluylenediamine; by reducing 3:5-dinitrotoluene (Städell, Ann. 1883, 217, 200) or 2:4-dibromo-3:5-dinitrotoluene (Davis, Chem. Soc. Trans. 1902, 81, 873). Liquid, b.p. 263°-285° (S.); syrupy liquid (D.). B²HCl, white needles, m.p. 255°-260° (decomp.).

Diacetyl-derivative; pike-shaped hemimorphic prisms, m.p. 235°-236°, which become strongly electrical when dry (D.).

2-Chloro-3:5-toluylenediamine; by reducing 2-chloro-3:5-dinitrotoluene with stannous chloride and hydrochloric acid (Nietzki and Rehe, Ber. 1892, 25, 3006). Long needles, m.p. 73° (N. and R.) or 74° (Morgan, Chem. Soc. Trans. 1902, 81, 97).

2:4-Dinitro-3:5-toluylenediamine; by heating an alcoholic solution of 2:4-dinitro-3:5-dibromotoluene with ammonia in a sealed tube at 150° (Blankama, Rec. trav. chim. 1904, 23, 125). Yellow crystals, m.p. 199°.

Trinitro-3:5-toluylenediamine; by the action of alcoholic ammonia on 3:5-dibromo-trinitrotoluene at 100° (Palmer, Ber. 1898, 31, 3501). Small yellow prisms, m.p. 222°.

2:4-Dinitro-3:5-dimethylaminotoluene; from 2:4-dinitro-3:5-dibromotoluene and dimethylamine (Blankama). Bright red crystals, m.p. 140°. On nitration it yields 2:4:6-trinitrodimethylnitroaminotoluene; colourless crystals, m.p. 199°-200° (decomp.) (B.).

2:4-Dinitro-3:5-diphenylaminotoluene; similarly to the preceding dimethyl-compound using aniline (B.). Red crystals, m.p. 163°.

2:4:6-Trinitro-3:5-dimethylaminotoluene; red crystals, m.p. 156°. On treatment with nitric acid (1:52) it yields 2:4:6-trinitrodimethylnitroaminotoluene.

2:4:6-Trinitro-3:5-diphenylaminotoluene; red crystals, m.p. 156°.

4-Chloro-3:5-toluylenediamine 1-sulphonic acid; by reducing 3:5-dinitro-4-chlorobenzyl-sulphonic acid with iron and acetic acid (B. A. S. F., D. R. P. 134988 of 1901). White needles. An aqueous solution on treatment with ferric chloride gives a red colour which gradually changes through violet to blue.

6-Aminodiacyl-3:4-toluylenediamine; by nitration and reduction of diacyl-3:4-toluylenediamine (Maron and Salzberg, Ber. 1911, 44, 2999). M.p. 238°.

Triacyl-derivative; m.p. 273°–274° (M. and S.).

5-Aminodiacyl-2:4-toluylenediamine; by nitration and reduction of diacyl-2:4-toluylenediamine (Maron and Salzberg, l.c.; Kym and Ringer, *ibid.* 1915, 48, 1671). M.p. 252°–253°.

Triacyl-derivative (M. and S.; K. and R.)

2-Acetyl-amino-3:5-toluylenediamine; from 3:5-dinitroaceto-*o*-toluidide and reducing agents, such as iron and acetic acid or mineral acids (Bayer & Co., U.S. Pat. 742845 of 1903; D. R. P. 183843 of 1902). Yellow needles, m.p. 210°–211°.

Triaminotoluene; by reducing trinitrotoluene with iron and dilute hydrochloric acid at 60°–80°. It serves as an intermediate product, as a dye for cotton, silk and wool, and as a photographic developer (Bielouss, Eng. Pats. 137529, 166934 of 1920).

ALDEHYDE DERIVATIVES.

Tolualdehydes are obtained from *o*-, *m*-, and *p*-xylene by passing the vapour mixed with air over a metallic oxide, other than vanadium oxide, of the fifth or sixth periodic group at 300° to a dull red heat, the period of contact being about 0.3 second (The Barrett Co., Eng. Pat. 189107).

***o*-Tolualdehyde, *o*-toluic aldehyde**; by boiling *o*-chloro-*o*-xylene with lead nitrate solution (Lauth and Grimaux, Bull. Soc. chim. 1867, (2) 7, 233; Rayman, *ibid.* 1877, (2) 27, 498); by oxidation of *o*-xylene with chromyl chloride (Bornemann, Ber. 1884, 17, 1467), or with manganese dioxide and sulphuric acid (Fournier, Compt. rend. 1901, 133, 635), or of *o*-tolylcarbinol with potassium dichromate and sulphuric acid (Fournier, *ibid.* 1903, 137, 716). Liquid, b.p. 90°/20 mm., or 197°/atm. (F.). **Anti-oxime**, m.p. 48°–49°, obtained in the usual manner (Dollfus, Ber. 1892, 25, 1922) or together with *p*-tolualdoxime and the nitrile by treating toluene with mercury fulminate and aluminium chloride containing small quantities of the hydrated chloride and aluminium hydroxide. The oximes are primarily obtained in the syn-form, but on separating from the nitrile, alkalis are used and the anti-forms are produced (Scholl and Kačer, Ber. 1903, 36, 322); **semicarbazone**, small white needles, m.p. 196° (Law and Perkin, Trans. Faraday. Soc. 1904, 1) or 200° (Fournier); **phenylbenzylhydrazone**, m.p. 57° (Fournier); **diphenylhydrazone**, white needles, m.p. 103°–104° (Maurenbrecher, Ber. 1906, 39, 3583; Rorive and Tollens, *ibid.* 1907, 40, 3107); **5-dimethylamino-derivative**, from dimethyl-*m*-toluidine and formaldehyde, leaflets, m.p. 67° (Geigy & Co., D. R. P. 105103 of 1898).

***p*-Chloro-*o*-tolualdehyde**; by chlorinating 4-keto-1-methyl-1-dichloromethylidihydrobenzene

with phosphorus pentachloride and heating the crude product with water at 160°–180° (Auwers and Keil, Ber. 1905, 38, 1693). Oil, b.p. 228°, solidifying to colourless crystals; D_{17}^{20} 1.277.

Semicarbazone; colourless needles, m.p. 224° (A. and K.).

***m*-Tolualdehyde**; by boiling *o*-chloro-*m*-xylene with lead nitrate solution (Gundelach, Bull. Soc. chim. 1876, (2) 26, 44; Müller, Ber. 1887, 20, 1213; cf. Lauth and Grimaux, l.c.); by treating *m*-xylene with chromyl chloride (Étard, Ber. 1881, 14, 848; Ann. Chim. 1881, (5) 22, 218; Bornemann, Ber. 1884, 17, 1464); together with 3:3'-dimethyldibenzyl by oxidising *m*-xylene with potassium persulphate (Moritz and Wolfenstein, Ber. 1899, 32, 2533); by oxidising *m*-xylyl alcohol with potassium dichromate and dilute sulphuric acid (Sommer, Ber. 1900, 33, 1078). Liquid, with an almond odour, b.p. 199°; D_0^{20} 1.037; D_{20}^{20} 1.024. It forms an **anilide**, b.p. 313°–314°; **semicarbazone**, needles, m.p. 216° (Sommer); **phenylhydrazone**, prisms, m.p. 91° (B.) or 88° (Rudolph, Ann. 1888, 248, 100); **diphenylhydrazone**, light yellow plates, m.p. 74°–75° (Maurenbrecher; Rorive and Tollens). For condensation products with ammonia and ethyl cyanoacetate, see Guareschi (Atti R. Accad. Sci. Torino, 1901–02, 37, 593).

2-Nitro-*m*-tolualdehyde; together with the 4-nitro-isomeride by nitrating *m*-tolualdehyde (Mayer, Ber. 1914, 47, 406; cf. Gilliard, Monnet and Cartier, Eng. Pat. 25634 of 1898; U.S. Pats. 662074, 662075; D. R. P. 113604 of 1898). The isomerides are separated by fractionation *in vacuo*. The product obtained by Bornemann (Ber. 1884, 17, 1473) and M. L. B. (Eng. Pat. 3216 of 1882; U.S. Pats. 276889, 276890; Fr. Pat. 149935; D. R. P. 21683 of 1882) is a mixture of the isomerides. Crystals, m.p. 64° (G., M. and C.; M.) or 61° (Reissert and Scherk, Ber. 1898, 31, 392); b.p. 135°–145°/2 mm. With acetone it yields the greenish-blue dimethylindigotin. **Ammonia-derivative**, m.p. 93°; **anilide**, m.p. 79°; **oxime**, m.p. 134°–135°; **phenylhydrazone**, m.p. 131°–132°; **hydrobenzamide**, m.p. 93°.

4-Nitro-*m*-tolualdehyde (see above). Yellow needles, m.p. 44°. With acetone it yields the reddish-blue dimethyl-indigotin. **Ammonia-derivative**; m.p. 140°; **anilide**, m.p. 51°–5°; **oxime**, m.p. 104°–105°; **phenylhydrazone**, m.p. 141°–142°; **hydrobenzamide**, m.p. 140° (G., M. and C.).

Dinitro-*m*-tolualdehyde; long silky needles, m.p. 110°–112° (Bornemann).

2-Iodo-*m*-tolualdehyde; m.p. 55°–56° (Mayer, Ber. 1914, 47, 406).

4-Iodo-*m*-tolualdehyde; m.p. 83°–84° (M.).

6-Amino-*m*-tolualdehyde; by heating 4-nitro-*m*-xylene with a solution of sulphur in sodium hydroxide (Geigy & Co., D. R. P. 87255 of 1895; see also Böhringer, D. R. P. 108026 of 1898). Sinters above 90° and melts at 99°–101° (B.) or 92° (G.).

4-Chloro-derivative; yellow crystals, m.p. 153° (Geigy & Co., D. R. P. 105103 of 1898).

6-Methylamino-*m*-tolualdehyde; colourless leaflets or needles, m.p. 114° (Geigy & Co., Fr. Pat. 280514; D. R. P. 103578 of 1898); **4-chloro-derivative**, yellowish needles, m.p. 157° (Geigy & Co., D. R. P. 105103 of 1898); the

p-dimethylaminoanilide, yellowish-green prisms, melts at 162°, and the phenylhydrazone at 124° (Ullmann and Frey, Ber. 1904, 37, 863).

6-Ethylamino-*m*-tolualdehyde, needles or pale yellow prisms, m.p. 70°; 4-chloro-derivative, yellowish needles, m.p. 78°–79° (Geigy & Co.); oxime, m.p. 82°; phenylhydrazone, m.p. 95° (U. and F.; G.).

m-Tolualdehyde *o*-sulphonic acid; by sulphonation of *m*-tolualdehyde at low temperatures. With aromatic amines it yields dyes fast to alkalis (Fr. Pat. 311739 of 1901).

p-Tolualdehyde; by heating a mixture of calcium *p*-toluate and calcium formate (Cannizzaro, Ann. 1862, 124, 254); by oxidising *p*-xylene with chromyl chloride (Bornemann, Ber. 1884, 17, 1467); by the action of hydrocyanic acid and hydrochloric acid on toluene in presence of aluminium chloride (Bayer & Co., Eng. Pat. 19204 of 1897; Fr. Pat. 270334; D. R. P. 99568 of 1897); by passing a mixture of carbon monoxide and hydrogen chloride through toluene in presence of aluminium chloride and cuprous chloride (Gattermann and Kock, Ber. 1897, 30, 1623; Bayer & Co., Eng. Pat. 13709 of 1897; Fr. Pat. 268168; D. R. P. 98706 of 1897; cf. Reformatzki, J. Russ. Phys. Chem. Soc. 1901, 33, 157); by the action of boiling dilute sulphuric acid on *p*-methylbenzylazoisimide (Curtius and Darapsky, Ber. 1902, 35, 3229); together with a little *p*-toluic acid by electrolytic oxidation of a warm solution of *p*-xylene with an excess of current at a lead peroxide anode (Fichter and Grisard, Helv. Chim. Acta. 1921, 4, 928); by heating *p*-tolylglyoxylic acid with aniline and hydrolysing the product (Bouveault, Bull. Soc. chim. 1897, (3) 17, 367); by the action of nickel carbonyl on toluene in presence of aluminium chloride (Dewar and Jones, Chem. Soc. Trans. 1904, 85, 212) and by other methods (Fournier, Compt. rend. 1903, 136, 557; Bodroux, Compt. rend. 1904, 138, 92; Bull. Soc. chim. 1904, (3) 31, 586). Oil with a peppery odour, b.p. 204° (G.); D_{20}^{25} 1.072; n_D^{25} 1.5484 (Hanzlik and Bianchi, Ber. 1899, 32, 1286).

p-Tolualdehyde ammonia; m.p. 43°–44° (Francis, Ber. 1909, 42, 2216); hydro-*p*-toluamide, white needles, m.p. 92° (Gattermann, Ann. 1906, 347, 347); bisulphite-compound, scales; semicarbazone, m.p. 215° (Fournier); diacetate, colourless glistening leaflets, m.p. 69°, forming a leuco-malachite Green with dimethyl-aniline and zinc chloride (Claussner, Ber. 1905, 38, 2860); phenylhydrazone, yellow compound, m.p. 113°, coloured red by exposure to light (Law and Perkin, Trans. Faraday Soc. 1904, 1); phenylbenzylhydrazone, m.p. 140° (Fournier, Compt. rend. 1903, 137, 716); diphenylhydrazone, white needles, m.p. 83°–84° (Maurenbrocher, l.c.; Rorive and Tollens, l.c.); anti-oxime, m.p. 79°–80°; syn-oxime, m.p. 108°–110° (Hantzsch, Zeitsch. physikal. Chem. 1904, 13, 523); dioxime peroxide, white shining plates, decomposing with a slight explosion at 121° (Ponzo, Atti R. Accad. Lincei, 1906, [v.] 15, ii. 42, 118; Techugaeff and Spiro, Ber. 1908, 41, 2219); nitroso-derivative, silvery needles, m.p. 128° (Gattermann, l.c.).

p-Tolualdehyde when exposed to light in presence of iodine for 3 years yields *p*-

toluic acid, a trimeric tolualdehyde, thin colourless prismatic crystals, m.p. 215°, and *p*-tolyl *p*-toluate, pale yellow oil, b.p. 213°–217°/15 mm. (Muscarelli and Russi, Atti R. Accad. Lincei, 1910, [v.] 19, ii. 239). With ethyl iodide and magnesium it yields *p*-tolylethylcarbinol, a dimeride of *p*-tolualdehyde, m.p. 130°, and *p*-xylyl alcohol (Oddo, Gazz. chim. ital. 1911, 41, i. 273).

2-Nitro-*p*-tolualdehyde; by nitration of *p*-tolualdehyde with mixed acids below 0° (Hanzlik and Bianchi, Ber. 1899, 32, 1288). Needles, m.p. 43°–44° (H. and B.) or 48°–49° (Gattermann, Ann. 1906, 347, 347). Diacetate, monoclinic tables, m.p. 98°–98.5° (Hanzlik and Bianchi, l.c., 2286); phenylhydrazone, orange crystals, m.p. 112°; *p*-nitrophenylhydrazone, reddish-brown crystalline powder, m.p. 223°–224° (H. and B.).

3-Nitro-*p*-tolualdoxime; needles, m.p. 128° (M. L. B., Fr. Pat. 290643 of 1899; D. R. P. 107095 of 1898).

CARBOXYLIC ACID DERIVATIVES.

o-Toluic acid; by boiling *o*-xylene with dilute nitric acid (1 vol. D 1.4 to 2 vols. water) (Fittig and Bieber, Ann. 1870, 156, 242); by the action of sodium amalgam on a mixture of ethylchloroformate and *o*-iodotoluene, followed by hydrolysis of the ester formed (Kekulé, Ber. 1874, 7, 1007); in a yield of 97 p.c. by boiling phthalide (phthalic aldehyde) with hydriodic acid (b.p. 127°) and yellow phosphorus in an atmosphere of carbon dioxide (Hessert, Ber. 1878, 11, 238; Racine, Ann. 1887, 239, 72); from toluene *o*-sulphonic acid by heating with potassium cyanide and hydrolysing the product (Fittig and Ramsay, Ann. 1873, 168, 246; Zeit. f. Chem. 1871, (2) 7, 584); by boiling the nitrile (Weith, Ber. 1874, 7, 722); from *o*-toluidine via the nitrile (Cahn, Ann. 1887, 240, 280); by heating naphthalene 1 : 3-disulphonic acid, 1 : 3-dihydroxynaphthalene, α -naphthol or α -naphthylamine 3-sulphonic acid, β -naphthol- or β -naphthylamine 4-sulphonic acid with sodium hydroxide at 150°–300° (Kalle & Co., Eng. Pat. 16559 of 1894; Fr. Pat. 241109; D. R. P. 79028 of 1893; Friedländer and Rüdte, Ber. 1896, 29, 1611). Crystals, readily volatile with steam, m.p. 103.5°–104° (Kellaa, Zeitsch. physikal. Chem. 1897, 24, 221); b.p. 258.5°–259°/751 mm. (Serkow, J. Russ. Phys. Chem. Soc. 1893, 25, 633); D_{20}^{25} 1.0621; molecular refractive power 62 (Eykman, Rec. trav. chim. 1893, 12, 178). Oxidised to phthalic acid with permanganate or dilute nitric acid, whilst it is charred by chromic acid mixture. Bromine vapour above 100° yields phthalide, whilst in the cold bromine forms bromo-*o*-toluic acid, m.p. 167°. It condenses with tertiary aromatic amines to form dyestuffs of the Malachite Green series (Bayer & Co., D. R. P. 101426 of 1897). $\text{NaA} + 2\text{H}_2\text{O}$, glistening leaflets, m.p. 227°–228° (R.); $\text{CaA} + 2\text{H}_2\text{O}$, small needles (F. and B.); $\text{BaA} + 2\text{H}_2\text{O}$, small needles (F. and B.).

Hydroxylamine salt, m.p. 105° (Oesper and Ballard, J. Amer. Chem. Soc. 1925, 47, 3424).

Methyl-ester, b.p. 207°–208° (Kellaa, Zeitsch. physikal. Chem. 1897, 24, 245) or 213°; D_{20}^{25}

1-073 (van Scherpenzeel, Rec. trav. chim. 1901, 20, 149).

Ethyl-ester; b.p. 219.5°/713 mm. (Ador and Rilliet, Ber. 1879, 12, 2301) or 227°; D_4^{25} 1-0479, D_{15}^{15} 1-039, D_{25}^{25} 1-0321; magnetic rotatory power 15-064 at 15.2° (Perkin, Chem. Soc. Trans. 1896, 69, 1238).

Benzyl-ester; oil, b.p. 315°, D_{17}^{17} 1-12 (Hodgkinson, Chem. Soc. Proc. 1891, 7, 167).

Chloride; b.p. 211°/733 mm. (A. and R.), 110°-111°/29 mm. (Klages and Lickroth, Ber. 1899, 32, 1861), 102°/7 mm. (Frankland and Wharton, Chem. Soc. Trans. 1896, 69, 1311; cf. Frankland and Aston, *ibid.* 1899, 75, 494).

Anhydride; m.p. 36°-38° (Racine, Ann. 1887, 239, 74) or 39° (K. & L.), b.p. above 325° (R.) or 220°-221°/11 mm. (K. and L.).

Peroxide; irregular prisms, m.p. 60° (Vanino and Thiele, Ber. 1896, 29, 1727).

Amide; needles, m.p. 138° (Weith, Ber. 1873, 6, 420), 142.8° (Remsen and Reid, Amer. Chem. J. 1899, 21, 290). *Sodium-derivative* (Wheeler, *ibid.* 1900, 23, 466).

Methylamide; colourless needles, m.p. 75°; *dimethylamide*, b.p. 147°, D_{25}^{25} 1-033 (van S.).

Nitrile; by heating potassium toluene *o*-sulphonate or tri-*o*-tolyl phosphate with potassium cyanide (Heim, Ber. 1883, 16, 1776); by heating tolyl isothiocyanate with copper powder (Weith, Ber. 1873, 6, 419); by the action of heat on tolyl isocyanide (Weith, Ber. 1874, 7, 722); by heating *o*-iodotoluene with silver cyanide at 350° (Merz and Weith, Ber. 1877, 10, 751); by boiling the formyl-derivative of *o*-toluidine with zinc dust (Gasirowski and Merz, Ber. 1884, 17, 74; 1885, 18, 1004); from *o*-toluidine by Sandmeyer's reaction (Cahn, Ber. 1886, 19, 756); by the action of mercury fulminate on toluene in presence of aluminium chloride (Scholl, Ber. 1903, 36, 10). Liquid, b.p. 203°-204° (W.), or 205.2°; D_4^{25} 1-0061, D_{15}^{15} 0-9975, D_{25}^{25} 0-9912; magnetic rotatory power 12-98 at 15.7° (Perkin, Chem. Soc. Trans. 1896, 69, 1244). On boiling with alcoholic potassium hydroxide it yields the amine and with concentrated hydrochloric acid at 200° it yields *o*-toluic acid. In a well-cooled solution *o*-toluonitrile is converted at a lead peroxide anode into *o*-cyanobenzoic acid. If the cooling is not efficient the nitrile is hydrolysed to *o*-toluic acid which is oxidised to phthalic acid (Fichter and Grisard, Helv. Chim. Acta, 1921, 4, 928). Fuming sulphuric acid at 60°-70° forms *iminodi-o-toluidamide*, prisms, m.p. 103° (Krafft and Karstens, Ber. 1892, 25, 455). Concentrated hydriodic acid yields $C_7H_7CN_2HI$, lemon-yellow crystals, m.p. 135°-140° (decomp.) (Biltz, Ber. 1892, 25, 2540). $(CH_3)_2C_6H_4(CN)(Cu_2Cl_2)$, white crystals (Rabaut, Bull. Soc. chim. 1898, (3) 19, 787).

Isocyanide; liquid, b.p. 75°/10 mm., 101°/55 mm., 183°-184°/753 mm. (with slight decomp.); D_{24}^{24} 0-968. At 240° it is converted into the nitrile (Nef, Ann. 1892, 270, 309).

3-Chloro-o-toluic acid; by careful addition of sodium nitrite in excess to a hot solution of the amide (Kenner and Witham, Chem. Soc. Trans. 1921, 149, 1458). Long slender needles, m.p. 102°.

Nitrile; from 2-cyano-*m*-toluidine by the

Sandmeyer reaction. Long slender prisms, m.p. 82°-83°, b.p. 143°/38 mm.

Amide; by heating a solution of the nitrile with diluted sulphuric acid at 100°-110° for 1½ hours. Scales, m.p. 167° (K. and W.).

4-Chloro-o-toluic acid; together with 5-chloro-*o*-toluic acid by boiling the corresponding chloroxylylene with nitric acid (D 1-2) (Krüger, Ber. 1885, 18, 1757); together with the 5-acid by passing chlorine through a solution of *o*-toluic acid in glacial acetic acid (Claus and Bayer, Ann. 1893, 274, 308). M.p. 137° (C. and B.), and not 166° as given by Krüger. Its salts are more sparingly soluble than those of the 5-chloro-isomeride. $CaA_2 + 2H_2O$, prisms.

5-Chloro-o-toluic acid; see 4-chloro-*o*-toluic acid. The nitrile is obtained from 5-chloro-*o*-toluidine by the Sandmeyer reaction (Claus and Stapelberg, Ann. 1893, 274, 287). Small needles m.p. 170° (C. and B.), not 130° as given by Krüger. $KA + H_2O$, needles; $CaA_2 + 3H_2O$, needles; $BaA_2 + 4H_2O$, needles.

Ethyl-ester; oil, b.p. 258° (C. and S.).

Nitrile; long needles, m.p. 67° (C. and S.).

Amide; m.p. 183° (C. and S.).

6-Chloro-o-toluic acid; by boiling 3-chloro-*o*-xylene with dilute nitric acid (Krüger, Ber. 1885, 18, 1758). Needles, m.p. 154° (Kr.) or 156° (Claus and Bayer). Oxidation with potassium permanganate yields 3-chlorophthalic acid. $CaA_2 + 2H_2O$, long prisms.

3:5-Dichloro-o-toluic acid; from the nitrile which is prepared from 3:5-dichloro-*o*-toluidine by the Sandmeyer reaction (Claus and Stapelberg, Ann. 1893, 274, 292). Glistening needles, m.p. 181°.

Nitrile; needles, m.p. 92° (C. and S.).

A *dichlorotoluic acid* was obtained by Holleman (Ann. 1867, 144, 269) by oxidising crude dichloroxylylene (m.p. 22°) with chromic acid mixture. $CaA_2 + 9H_2O$.

ω-Dichloro-o-toluic acid; needles, m.p. 155°. Its chloride is obtained by chlorinating *o*-toluoyl chloride. The *amide* melts at 117°.

ω-Trichloro-o-toluic acid; obtained by the action of formic acid at 50° on its chloride, which is formed by chlorinating *o*-toluoyl chloride, crystallises from benzene in needles, m.p. 141°-144° (Davies and Perkin, Chem. Soc. Trans. 1922, 121, 2213).

4-Bromo-o-toluic acid; by keeping *o*-toluic acid in contact with excess of bromine for 24 hours (Jacobsen and Wieras, Ber. 1883, 16, 1956; Racine, Ann. 1887, 239, 74); from 2-nitro-*p*-toluidine by replacing the amino- by bromine and the nitro-group by carb (von Meyer and Geiringer, Ber. 1895, 28, 11). Long needles, volatile with steam, m.p. 167° $CaA_2 + H_2O$; $BaA_2 + 5H_2O$.

Methyl-ester; leaflets, m.p. 44°-46° (R.).

A *bromo-o-toluic acid*, slender needles, m.p. 118°, whose *nitrile* melts at 42°, has been obtained by oxidising bromo-ethylxylylene with dilute nitric acid at 200° (Claus and Plescock, Ber. 1886, 19, 3083; Claus and Kunath, J. pr. Chem. 1889, (2) 39, 489). This acid is not identical with that of Jacobsen (Ber. 1884, 17, 2375), obtained by oxidising bromo-*o*-xylene with dilute nitric acid. Jacobsen's product forms stellate groups of silky needles, m.p. 174°-176°, yielding $BaA_2 + 2H_2O$, small hard prisms, and is probably identical with the following acid.

5-Bromo-o-toluic acid; by saponification of the nitrile (Nourrisson, Ber. 1887, 20, 1016). Sublimes in needles, m.p. 187° (N.) or 175° (Konowaloff, J. Russ. Phys. Chem. Soc. 1904, 36, 537). $\text{BaA}'_2 + 2\text{H}_2\text{O}$ (C. and K.).

Amide; pearly plates subliming in needles, m.p. 181°–182°.

Nitrile; long needles, volatile with steam, m.p. 70° (N.).

3:5-Dibromo-o-toluic acid; by hydrolysis of the amide with concentrated hydrochloric acid at 250° (Claus and Beck, Ann. 1892, 269, 215). Needles, m.p. 157°. $\text{BaA}'_2 + \text{H}_2\text{O}$, crystalline crusts.

Amide; glistening needles or columns, m.p. 198°.

Nitrile; from 3:5-dibromo-o-toluidine by Sandmeyer's reaction. Glistening needles, m.p. 86° (C. and B.).

4:5-Dibromo-o-toluic acid; by heating 5-bromo-o-toluic acid with 1 mol. of bromine in the presence of water at 120° for 3 hours (Claus and Beck, Ann. 1892, 269, 213). Glistening needles, m.p. 210°. $\text{BaA}'_2 + 6\text{H}_2\text{O}$, glistening needles.

When nitrated at 0°, o-toluic acid yields a mixture of 4-nitro-o-toluic acid, m.p. 178°–178.5°, and 6-nitro-o-toluic acid, m.p. 184°–184.5°, the latter being probably identical with Jacobsen and Wierss' β -nitro-acid, m.p. 145°. The methyl-ester, amide, methylamide, and dimethylamide of o-toluic acid yield the corresponding derivatives of the 4- and 6-nitro-acids when nitrated at 0°. When nitrated at ordinary temperatures, o-toluic acid and its 4- and 6-mononitro-derivatives yield 4:6-dinitro-o-toluic acid. The methyl-ester under similar conditions yields methyl-4:6-dinitro-o-toluate, m.p. 73°–73.5°. The amide and methylamide yield the 4:6-dinitro-acid, but the dimethylamide yields the 4-nitro-acid (van Scherpenzeel, Rec. trav. chim. 1901, 20, 149).

3-Nitro-o-toluic acid; from 3-nitro-o-toluidine via the nitrile (Mayer, J. pr. Chem. 1915, (2) 92, 137) or the amide (Gabriel and Thieme, Ber. 1919, 52, 1079). The latter authors could not prepare it by hydrolysis of the nitrile. Colourless needles, or short rods, m.p. 151°–152° (G. and T.), or colourless silky needles, m.p. between 200°–210° (M.). It sublimes, and it is stated to undergo certain physical changes when exposed to air for a few days, e.g. it becomes less soluble in water, and melts at about 180°–185° (M.).

$\text{NaA}' + 3\frac{1}{2}\text{H}_2\text{O}$; $\text{BaA}'_2 + 3\text{H}_2\text{O}$ (G. and T.).

Amide; by the action of sulphuric acid on the nitrile. Needles, m.p. 158° (G. and T.).

Nitrile; from the amine by the Sandmeyer reaction and treatment of the crude product with alcohol or nitric acid. Silvery leaflets, m.p. 109°–110° (G. and T.), or yellow silky needles on subliming, m.p. 89°–91° (M.).

Methyl-ester; by the action of methyl sulphate. M.p. 72°–75° (M.), or from the acid chloride (m.p. 41°) by the action of methyl alcohol, when needles and leaflets, m.p. 50°, are formed (G. and T.). **Ethyl-ester**, oil (G. and T.).

Anhydride; six-sided plates, m.p. 174° (G. and T.).

(a)-4-Nitro-o-toluic acid; together with the nitro-acid by warming o-toluic acid with alic acid (D 1.4) at 100° (Jacobsen and Wierss,

Ber. 1883, 16, 1957); together with the 5-nitro-acid by oxidising 4-nitro-o-xylene with dilute nitric acid (Jacobsen, Ber. 1884, 17, 162). Small needles, slowly volatile with steam, m.p. 179°. $\text{KA}' + \text{H}_2\text{O}$, long needles; $\text{CaA}'_2 + 2\text{H}_2\text{O}$, needles; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, slender needles.

Nitrile; by nitration of o-toluenitrile, needles, m.p. 105°, subliming at 100° (Landsberger, Ber. 1898, 31, 2880).

Amide; by warming the nitrile for $\frac{1}{2}$ hour with six times its weight of concentrated sulphuric acid, fine needles, m.p. 173° (L.); **methylamide**, slender needles, m.p. 160°; **dimethylamide**, m.p. 105°–106° (van Scherpenzeel, Rec. trav. chim. 1901, 20, 149).

Methyl-ester; oblong prisms, m.p. 69°.

Chloride; colourless needles, m.p. 59°–60° (van S.).

(\gamma)-5-Nitro-o-toluic acid; together with the 4-acid by boiling a mixture of 25 grms. of 4-nitro-o-xylene, 250 c.c. of nitric acid (D 1.4) and 500 c.c. of water for 48 hours. The mixture is converted into the barium salts, which are separated mechanically (Jacobsen, Ber. 1884, 17, 162); from 5-nitro-o-toluidine via the nitrile (Mayer, l.c.; Gabriel and Thieme, l.c.). It melts at 152°–153° (G. and T.). $\text{BaA}'_2 + 5\text{H}_2\text{O}$, long transparent flat prisms (J.).

Nitrile; colourless leaflets, m.p. 100° (G. and T.), or long yellow felted needles, which sublime, m.p. 113°–115° (M.).

(\beta)-6-Nitro-o-toluic acid; see the 4-nitro-acid, and van Scherpenzeel, l.c. Long needles, m.p. 145° (J. and W.), or 184°–184.5° (van S.). Slowly volatile with steam. $\text{CaA}'_2 + 2\text{H}_2\text{O}$, crusts; $\text{BaA}'_2 + 2\text{H}_2\text{O}$ (J. and W.).

Methyl-ester; pale yellow needles, m.p. 66° (van S.).

Amide; colourless needles, m.p. 163°; **methylamide**, m.p. 131°–132°; **dimethylamide**, m.p. 69.5°–70° (van S.).

Chloride; m.p. 68°–68.5° (van S.).

Nitrile, m.p. 69.5° (Nölting, Ber. 1904, 37, 1025).

3:4-Dinitro-o-toluic acid; together with 3:4-dinitrophthalic acid by oxidising 3:4-dinitro-o-xylene with dilute nitric acid in a sealed tube (Warner, Chem. Soc. Proc. 1913, 29, 61). Stout colourless needles, m.p. 182°.

Ethyl-ester; colourless rectangular plates, m.p. 63° (W.).

4:6-Dinitro-o-toluic acid; together with 3:5-dinitrophthalic acid by oxidising 3:5-dinitro-o-xylene in a similar manner (Warner); by keeping 4- or 6-nitro-o-toluic acid with a mixture of equal volumes of sulphuric acid and fuming nitric acid for 24 hours (Jacobsen and Wierss). Very long brittle needles, m.p. 206°. With dilute nitric acid at 170° it yields 3:5-dinitrophthalic acid. $\text{BaA}'_2 + 2\text{H}_2\text{O}$ (Racine, Ann. 1887, 239, 77).

Methyl-ester; needles, m.p. 73°–74° (R.).

3:4:6 (or 3:5:6)-Trinitro-o-toluic acid; by oxidising 3:4:6-trinitro-o-xylene with chromic acid (Giua, Gazz. chim. ital. 1922, 52, i. 183). White needles, m.p. 201°–202°. It gives a reddish-brown coloration with alkalis.

\omega-Chloro-5-nitro-o-toluic acid; amide; by warming the nitrile for 2 hours with concentrated sulphuric acid (Gabriel and Landsberger, Ber. 1898, 31, 2734). White felted needles, melting at 228° when heated rapidly. When heated

for some time at 110° it yields 5-nitro-pseudo-phthalimidine, needles, m.p. 158°.

Nitrile; by nitration of *o*-cyanobenzyl chloride (G. and L.).

Yellow crystals, m.p. 94°. When heated with acetic and hydrochloric acids at 140°–150° it yields 5-nitrophthalide.

5-Chloro-3-nitro-o-toluic acid; from 5-chloro-3-nitro-*o*-toluidine via the nitrile (Claus and Stapelberg, Ann. 1893, 274, 297). Glistening needles, m.p. 189°.

Nitrile; golden-yellow glistening prisms, m.p. 140° (C. and S.).

5-Chloro-4-nitro-o-toluic acid; together with 5-chloro-6-nitro-*o*-toluic acid, by treating 5-chloro-*o*-toluic acid with nitric acid (D 1-52) at 110°–120° (C. and S.). On pouring into water, the 6-nitro-acid gradually separates. Large glistening prisms, m.p. 193°. $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$, prisms; $\text{MgA}'_2 + 4\text{H}_2\text{O}$, four-sided pillars. The salts are more sparingly soluble in water than those of the 6-nitro-isomeride.

Nitrile; from 5-chloro-4-nitro-*p*-toluidine. Thick glistening pillars, m.p. 86° (C. and S.).

5-Chloro-6-nitro-o-toluic acid; see above. Glistening pillars, m.p. 186°. $\text{KA}' + \text{H}_2\text{O}$, crusts; $\text{MgA}'_2 + 5\text{H}_2\text{O}$, glistening needles (C. and S.).

3:5-Dichloro-6-nitro-o-toluic acid; by oxidising 3:5-dichloro-6-nitro-*o*-xylene with nitric acid (D 1-15) for 6 hours at 180°–190° (Crossley, Chem. Soc. Trans. 1904, 85, 281). Feathery needles, m.p. 187°–189°.

5-Chloro-4:6-dinitro-o-toluic acid; by prolonged boiling of 5-chloro-*o*-toluic acid, 5-chloro-4-nitro-*o*-toluic acid, or 5-chloro-6-nitro-*o*-toluic acid with mixed acids (C. and S.). Needles, m.p. 212°.

5-Bromo-3-nitro-o-toluic acid; from the amide by heating with concentrated hydrochloric acid at 230°–250° for 8–10 hours (Claus and Beck, Ann. 1892, 269, 212). Fine needles, m.p. 226°.

Amide; by boiling the nitrile with 50 p.c. sulphuric acid. Vitreous needles, m.p. 235°.

Nitrile; from 5-bromo-3-nitro-*o*-toluidine by Sandmeyer's reaction. Glistening yellow needles, m.p. 106°–107°.

5-Bromo-4-nitro-o-toluic acid; together with 5-bromo-6-nitro-*o*-toluic acid, by nitrating 5-bromo-*o*-toluic acid for 6–8 hours at 50°. The greater part of the 5-bromo-4-nitro-*o*-toluic acid separates on cooling (C. and B.). Needles, m.p. 200°, which sublime. $\text{NaA}' + 4\text{H}_2\text{O}$, large pearly plates; $\text{KA}' + \text{H}_2\text{O}$, silky needles; $\text{MgA}'_2 + 7\text{H}_2\text{O}$, vitreous needles; $\text{BaA}'_2 + 4\text{H}_2\text{O}$, long needles.

5-Bromo-6-nitro-o-toluic acid; see above. The two acids may be separated by means of their magnesium salts. Small needles, m.p. 220°, which sublime. The magnesium salt is extremely soluble in water. $\text{BaA}'_2 + \text{H}_2\text{O}$, nodules.

3-Amino-o-toluic acid; obtained as the hydrochloride, together with 3-methyl-benzisoxazole-3-one and *m*-toluidine hydrochloride, by reducing 3-nitro-*o*-toluamide with tin and hydrochloric acid, or as the free acid by reducing 3-nitro-*o*-toluic acid with ferrous sulphate in ammoniacal solution (Gabriel and Thieme, Ber. 1919, 52, 1079). Needles, m.p. 125°–126°. According to Mayer (J. pr. Chem. 1915, (2) 92, 137), reduction of the acid with tin and hydro-

chloric acid yields initially the amino-acid, but this could not be isolated, as it was converted into *m*-toluidine during evaporation.

Nitrile; by reducing 3-nitro-*o*-toluonitrile with hydriodic acid and phosphorus. It melts at 127°–128° (G. and T.).

4-Amino-o-toluic acid; small prisms, m.p. 196° (Jacobsen and Wiersma, Ber. 1883, 16, 1959; Jacobsen, *ibid.* 1884, 17, 164).

Nitrile; by reducing 4-nitrotoluonitrile. It melts at 88°, its hydrochloride at about 220°, and its picrate at 177°–179° (Landsberger, Ber. 1898, 31, 2881).

5-Amino-o-toluic acid; by reducing 5-nitro-*o*-toluic acid with tin and hydrochloric acid (Jacobsen, Ber. 1884, 17, 164); by heating *p*-nitrophthalide with hydriodic acid and phosphorus at 205° (Hönig, Ber. 1885, 18, 3449). Needles which sublime, m.p. 153° (H.) or 165° (decomp.) (J.).

Nitrile; by reducing 5-nitro-*o*-toluonitrile with stannous chloride and hydrochloric acid. Rhombic crystals, m.p. 90° (G. and T.).

6-Amino-o-toluic acid; small vitreous needles, m.p. 191° (Jacobsen; Jacobsen and Wiersma).

Nitrile; silky needles, m.p. 95-5° (Nöling, Ber. 1904, 37, 1025).

m-Toluic acid; by reducing bromo-*m*-toluic acid (Ahrens, Zeit. f. Chem. 1869, (2) 5, 106; Richter, Ber. 1872, 5, 424; Böttger and Ramsay, Ann. 1873, 168, 255); by oxidising *m*-xylene with dilute nitric acid (Tawildarow, Ber. 1873, 4, 410; Brückner, Ber. 1876, 9, 406; Reuter, Ber. 1884, 17, 2028); by hydrolysing the nitrile (Weith and Landolt, Ber. 1875, 8, 720) or the 6-sulphonamide (Jacobsen, Ber. 1881, 14, 2349); by boiling ω -chloroxylene with dilute nitric acid (Senff, Ann. 1883, 220, 247; cf. Ador and Rilliet, Ber. 1879, 12, 2300; van Scherpenzeel, Rec. trav. chim. 1901, 20, 149). Very long needles, volatile with steam, m.p. 110-5° (Jacobsen; Bornemann, Ber. 1887, 20, 1382) or 108°–109° (Kellas, Zeitsch. physikal. Chem. 1897, 24, 221), b.p. 283° (J.); $D_4^{11} 6$ 1-0543; molecular refractive power 62-01 (Eykmann, Rec. trav. chim. 1893, 12, 178). $\text{CaA}'_2 + 3\text{H}_2\text{O}$, flat needles; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, small plates; AgA' ; $(\text{CH}_3\text{C}_6\text{H}_4\text{COO})_2\text{HK}$, long needles; $(\text{CH}_3\text{C}_6\text{H}_4\text{COO})_2\text{H}\cdot\text{NH}_4$, tabular crystals (Farmer, Chem. Soc. Trans. 1903, 83, 1443).

Hydroxylamine salt; m.p. 83° (Oesper and Ballard, J. Amer. Chem. Soc. 1925, 47, 2424).

Methyl-ester; b.p. 214°–215° (Kellas) or b.p. 220-5°–221°/758 mm., $D_4^{15} 1-066$ (van S.).

Ethyl-ester; b.p. 224-5°–226-5°/710 mm. (Ador and Rilliet).

Chloride; b.p. 218°/724 mm. (A. and R.), 120°/38 mm. (Klages and Lückroth, Ber. 1899, 32, 1560), 109°/8 mm. (Frankland and Wharton, Chem. Soc. Trans. 1896, 69, 1311), 109°/15 mm. (Frankland and Aston, *ibid.* 1899, 75, 494), 219°–220°/773 mm. (van S.); m.p. –23° (van S.); $D_4^{20} 1-173$ (K. and L.).

Amide, m.p. 94° (Remsen and Reid, Amer. Chem. J. 1899, 21, 290; van S.); *methylamide*, m.p. 44-5°–45° (van S.); *dimethylamide*, oil, b.p. 148°, $D_4^{15} 1-043$ (van S.).

Nitrile; from *m*-toluidine by the Sandmeyer

reaction (Buchka and Schachtebeck, Ber. 1889, 22, 841). Liquid, b.p. 206°–210° (B. and S.) or 212°–214° (Biltz, Ber. 1892, 25, 2539). See also Weith and Landolt (l.c.).

Meraptan; b.p. 195.4°/760 mm., D_4^{20} 1.06251 (Bourgeois, Rec. trav. chim. 1899, 18, 426).

Anhydride; m.p. 71°, b.p. 230°/17 mm. (Denham, Chem. Soc. Trans. 1909, 95, 1240).

Pseudo-m-toluic acid; m.p. 47° (Perkin and Simonis, *ibid.* 1907, 91, 840).

4-Chloro-m-toluic acid; by oxidising 3-acetyl-*p*-chlorotoluene (Claus, J. pr. Chem. 1892, (2) 46, 27). Needles, m.p. 167°.

5-Chloro-m-toluic acid; together with a chloronitroxylene and other products by boiling dihydro-5-chloroxylene with 30 p.c. nitric acid for 20 hours (Klages and Knoevenagel, Ber. 1895, 28, 2045). Needles, m.p. 178°. With potassium permanganate it yields 5-chloroisophthalic acid and a little 5-hydroxyisophthalic acid.

6-Chloro-m-toluic acid; by replacing the nitro-group by chlorine in 6-nitro-*m*-toluic acid (Beilstein and Kreusler, Ann. 1867, 144, 182; Remsen and Kuhara, Amer. Chem. J. 1881, 3, 431); by oxidising 4-chloro-*m*-xylene with chromic acid mixture (Vollrath, Ann. 1867, 144, 266; Bull. Soc. chim. 1867, (2) 7, 342; Jacobsen, Ber. 1885, 18, 1761). M.p. 203° (V.), 204° (corr.) (R. and K.), 210° (corr.) (J.). $\text{CaA}'_2 + 3\text{H}_2\text{O}$, fine needles; $\text{BaA}'_2 + 3\text{H}_2\text{O}$ (V.).

Ethyl-ester; b.p. 260°–265° (V.).

ω -Chloro-m-toluic acid; by boiling the nitrile with concentrated hydrochloric acid (Reinglass, Ber. 1881, 24, 2418). Fine needles, m.p. 135°.

Amide; m.p. 124°.

Nitrile; by chlorination of *m*-toluonitrile at 150°. Plates or prisms, m.p. 67°, b.p. 258°–260° (R.).

4:6-Dichloro-m-toluic acid; by heating 1 part of 4:6-dichloro-*m*-xylene with 15 parts of dilute nitric acid (D 1:18) (Claus and Burstert, J. pr. Chem. 1890, (2) 41, 557; cf. Hollemann, Ann. 1867, 144, 269). Vitreous needles, m.p. 170°. $\text{BaA}'_2 + 2\text{H}_2\text{O}$, needles or pillars. Hollemann's product melted at 101° and yielded $\text{CaA}'_2 + 9\text{H}_2\text{O}$ and AgA' .

ω -Dichloro-m-toluic acid; m.p. 132°, is formed from its chloride, m.p. 49°.

ω -Trichloro-m-toluic acid: obtained from its chloride, which is formed by chlorinating *m*-toluoyl chloride (Davies and Perkin, Chem. Soc. Trans. 1922, 121, 2214). Sparkling laminae, m.p. 142°.

4-Bromo-m-toluic acid; together with the 3-bromo-isomeride by keeping a mixture of *m*-toluic acid and an excess of bromine (Jacobsen, Ber. 1884, 14, 2351); by heating 4-bromoisoxylene with dilute nitric acid at 130°–135° (Kelbe and Czarnomski, Ann. 1886, 235, 295); from 4-bromo-2-nitro-toluene by heating with alcohol and potassium cyanide at 220°, and hydrolysing the nitrile with alcoholic potassium hydroxide (Richter, Ber. 1872, 5, 425); by oxidising 3-acetyl-4-bromotoluene with permanganate (Claus, J. pr. Chem. 1892, (2) 46, 21). slender needles, m.p. 152°–153° (K. and C.). Alkaline fusion yields 4-hydroxy-*m*-toluic acid, and oxidation yields 4-bromoisophthalic acid.

CaA'_2 , long needles (J.); $\text{BaA}'_2 + 4\text{H}_2\text{O}$, needles (C.).

6-Bromo-m-toluic acid; by oxidising bromo-*m*-xylene with chromic acid mixture (Fittig, Ahrens and Mattheides, Ann. 1868, 147, 32; Jacobsen, Ber. 1881, 14, 2352); together with the 4-acid by brominating *m*-toluic acid (Jacobsen); by oxidising 6-bromoisoxylene with dilute nitric acid (Kelbe, Ber. 1882, 15, 41); from 6-nitro-*m*-toluic acid (Remsen and Kuhara, l.c.). Crystalline powder, m.p. 209° (Jacobsen). Sodium amalgam yields *m*-toluic acid, and alkaline fusion yields 6-hydroxy-*m*-toluic acid. $\text{CaA}'_2 + 3\text{H}_2\text{O}$, needles; $\text{BaA}'_2 + 4\text{H}_2\text{O}$, long needles; AgA' .

Ethyl-ester; solidifies at –5°, b.p. 270°–275° (F., A. and M.).

Bromo-m(?) -toluic acid; together with 6-bromo-*m*-toluic acid by oxidising crude bromoxylene (b.p. 200°–208°) with chromic acid mixture (Ahrens, Zeit. f. Chem. 1869, (2) 5, 106), m.p. 185°–190°. $\text{CaA}'_2 + 8\text{H}_2\text{O}$, small needles, more soluble in water than the salt of 6-bromo-*m*-toluic acid.

Dibromo(?) -toluic acid; by oxidising crude dibromoxylene with chromic acid mixture (F., A. and M.). Microscopic needles, m.p. 185°–186°. $\text{BaA}'_2 + 9\text{H}_2\text{O}$, long needles; AgA' .

ω -Bromo-m-toluic acid; by brominating *m*-toluic acid in bromoform (Zalkind and Semenow, J. Russ. Phys. Chem. Soc. 1914, 46, 512). White crystals, m.p. 151°–152°.

Ethyl-ester; b.p. 160°–161°/10 mm.

4:6-Dibromo-m-toluic acid; by oxidising 4:6-dibromo-*m*-xylene with nitric acid (Eckert and Seidel, J. pr. Chem. 1921, (2) 102, 338). White crystals, m.p. 174°.

Methyl-ester; m.p. 43°, b.p. 203°–206°/758 mm.

Amide; white needles, m.p. 188°.

2-Nitroso-m-toluic acid; grey prisms, m.p. 172°–173° (Freundler, Bull. Soc. chim. 1911, [4] 9, 657).

2-Nitro-m-toluic acid; together with 4-nitro-*m*-toluic acid (Jacobsen, Ber. 1881, 14, 2347; Findekle, *ibid.* 1905, 38, 3553; Jürgens, *ibid.* 1907, 40, 4409; van Scherpenzeel, Rec. trav. chim. 1901, 20, 149; Wheeler and Hoffman, Amer. Chem. J. 1910, 44, 113, 507) and the 6-nitro-acid (Müller, Ber. 1909, 42, 430) when *m*-toluic acid is nitrated. The 2-nitro-acid is formed also by boiling 2-nitro-*m*-xylene with nitric acid (D 1:4) (Nölting and Gachot, Ber. 1906, 39, 73). Monoclinic prisms, m.p. 219° (Jacobsen; Findekle; Müller; Jürgens), 217.5°–218° (Nölting and Gachot).

The 2- and 4-nitrotoluic acids may be separated by means of their barium salts. $\text{BaA}'_2 + 2\text{H}_2\text{O}$. This acid is identical with one of the three acids which Ahrens (Zeit. f. Chem. 1867, (2) 3, 525; 1869, (2) 5, 106) obtained by the action of nitric acid on a mixture of toluic acids.

Amide; m.p. 192° (Jürgens).

Nitrile; needles, m.p. 84° (Gabriel and Thieme, Ber. 1919, 52, 1079; Jürgens; cf. Reissert and Scherk, Ber. 1898, 31, 390).

Methyl-ester; m.p. 74° (Jürgens).

4-Nitro-m-toluic acid; see 2-nitro-*m*-toluic acid. It melts at 182° (Jacobsen) or 134° (F.; M.). The barium salt is sparingly soluble (Jacobsen).

Amide; stout flat needles, m.p. 176°–177° (F.).

Methyl-ester; stout needles, m.p. 78°–79° (M.).

A number of derivatives of both 2- and 4-nitro-*m*-toluic acids have been prepared by van Scherpenzeel (Rec. trav. chim. 1901, 20, 149), but are of doubtful orientation.

5-Nitro-m-toluic acid; by warming an acetic acid solution of 5-nitro-*m*-xylene with potassium permanganate on the water-bath (Thöl, Ber. 1885, 18, 359) or by heating with nitric acid (D 1·16) in a sealed tube for 50 hours at 100° (Müller, *ibid.* 1909, 42, 430). Long silky needles, m.p. 170° (M.) or 167° (T.). $\text{BaA}_2 + 4\text{H}_2\text{O}$, groups of microscopic needles (T.).

Nitrile; m.p. 104°–105° (G. and T.).

Amide; small needles, m.p. 164°–165° (G. and T.).

Methyl-ester; tables, m.p. 84°–85° (M.).

6-Nitro-m-toluic acid; by oxidising crude nitroxylenes (Beilstein and Kreusler, Ann. 1867, 144, 168; Kreusler, Zeit. f. Chem. 1866, (2) 2, 320) or nitroisocymene (Kelbe, Ann. 1883, 221, 161); together with the 2- and 4-nitro-acids by nitrating *m*-toluic acid (Müller, *l.c.*).

Crystalline powder, m.p. 211° (B. and K.), 214° (K.), or pointed needles, m.p. 215°–216° (M.). $\text{NH}_4\text{A}' + 2\text{H}_2\text{O}$; $\text{MgA}'_2 + 7\text{H}_2\text{O}$; $\text{CaA}'_2 + 2\text{H}_2\text{O}$ yellow prisms; $\text{BaA}'_2 + 4\text{H}_2\text{O}$, fine needles.

Nitrile; m.p. 80° (B. and K.; G. and T.).

Amide; leaflets, m.p. 151° (B. and K.), or prisms, m.p. 190° (Wheeler and Hoffman, Amer. Chem. J. 1910, 44, 113, 507).

Methyl-ester; m.p. 81°–82° (M.) or 72° (Herre, Ber. 1895, 28, 597).

2:4-Dinitro-m-toluic acid; m.p. 173°.

Methyl-ester, m.p. 104°–105° (van Scherpenzeel).

Bromonitro-m-toluic acid; by warming bromo-*m*-toluic acid with fuming nitric acid (Fittig, Ahrens and Mattheides, Ann. 1868, 147, 347). Crystals, m.p. 175°–176°. $\text{CaA}'_2 + 3\text{H}_2\text{O}$, nodules; $\text{BaA}'_2 + 3\text{H}_2\text{O}$, long needles.

2-Amino-m-toluic acid; by reduction of the corresponding nitro-compound (Jacobsen; Findekle, Jürgens, *l.c.*). It melts at 172°.

Acetyl-derivative; glistening needles, m.p. 193°–194° (Miller and Meyer, Ber. 1891, 24, 1909).

Nitrile; m.p. 38° (Gabriel and Thieme).

Amide; m.p. 149° (Gabriel and Thieme; Jürgens).

Methyl-ester; oil with an odour of orange peel (Jürgens).

Ethyl-ester; large transparent prisms, m.p. 71°–72°.

Diethyl-ester; long slender needles, m.p. 55°–57° (Wheeler and Hoffman).

4-Amino-m-toluic acid; by reduction of the corresponding nitro-compound (Jacobsen; Findekle, *l.c.*). It melts at 132° (Jacobsen), 175° (Findekle), or 172° (P.). $\text{B}'\text{HCl}$, long needles (Panaotović, J. pr. Chem. 1886, (2) 33, 62).

Nitrile; glistening needles and plates, m.p. 60°–61° (Ehrlich, Ber. 1901, 34, 3366).

Amide; monoclinic prisms, m.p. 178° (P.) or 179° (F.).

Anilide; pearly rhombic tables, m.p. 240° (P.).

Acetyl-derivative; fibrous needles, m.p. 193°–194° (von Miller and Ohler, Ber. 1891, 24, 1910).

Methyl-ester, m.p. 62° (P.).

5-Amino-m-toluic acid; in a yield of 50 p.c. by reducing the corresponding nitro-compound with ferrous sulphate and ammonia (Müller, Ber. 1909, 42, 423). Small needles with a pink tint, m.p. 183° (M.).

Nitrile; needles, m.p. 75° (Gabriel and Thieme, Ber. 1919, 52, 1079).

6-Amino-m-toluic acid; by reducing 6-nitro-*m*-toluic acid with tin and hydrochloric acid (Beilstein and Kreusler, Ann. 1867, 144, 177; Kreusler, Zeit. f. Chem. 1866, (2) 2, 320) or with ferrous sulphate and ammonia (Müller). Long needles, m.p. 168°–169°. $\text{B}'\text{HCl}$; $\text{B}'\text{HNO}_2$; $\text{B}'_2\text{H}_2\text{SO}_4 + 2\text{H}_2\text{O}$, long prisms.

Nitrile; long colourless needles, m.p. 95° (Gabriel and Thieme).

Amide; crystals $+\text{H}_2\text{O}$, which when anhydrous melt at 115° (B. and K.).

Methyl-ester; prisms, m.p. 115° (Herre, Ber. 1895, 28, 598).

Ethyl-ester; colourless needles, m.p. 79° (H.).

ω-Amino-m-toluic acid; by heating *m*-cyanobenzylphthalimide with concentrated hydrochloric acid at 200° (Reinglass, Ber. 1891, 24, 2419). Scales, m.p. 215°–218°. *Platinichloride*, ochre-yellow crystalline precipitate; *aurochloride*; yellow prisms, m.p. 175°–177° (R.).

When *m*-toluic acid is sulphonated a mixture of the 5- and 6-monosulphonic acids is formed, which could not be separated. On alkaline fusion, 5-hydroxy-*m*-toluic acid and 6-hydroxy-*m*-toluic acid respectively are formed (Jacobsen, Ber. 1881, 14, 2355).

p-Toluic acid; by oxidising *p*-xylene (Beilstein and Yessel, Ann. 1866, 137, 302; Kekulé and Dittmar, Ann. 1871, 162, 339; Brückner, Ann. 1880, 205, 113), cymene (Noad, Ann. 1847, 63, 289; Phil. Mag. 1848 (3) 32, 19), or terpenes (Hirzel, Zeit. f. Chem. 1866, (2) 2, 205) with dilute acid; by heating *p*-bromotoluene with ethylchloroformate and sodium amalgam followed by hydrolysis of the product (Wurtz, Compt. rend. 1869, 68, 1293); from *p*-bromotoluene, carbon dioxide and sodium (Kekulé, Ann. 1866, 137, 184); by reducing bromo-*p*-toluic acid with sodium amalgam (Remsen and Morse, Amer. Chem. J. 1880, 1, 138); from the acid chloride, obtained by the action of phosgene on toluene in presence of aluminium chloride (Ador and Crafts, Ber. 1877, 10, 2176); from the amide, obtained by the action of aluminium chloride on a mixture of toluene, carbon disulphide and chloroformamide (Gattermann and Schmidt, Ann. 1888, 244, 51; Ber. 1887, 20, 858); by heating a mixture of toluene and acetic acid at 110° in presence of zinc chloride and phosphorus oxychloride, and treatment of the product with dilute sodium hydroxide (Frey and Horowitz, J. pr. Chem. 1891, (2) 43, 114); together with benzoic acid by fusing tolylbenzoic acid with potassium hydroxide (Friedel and Crafts, Bull. Soc. chim. 1881, (2) 35, 508); by passing gaseous cyanic acid and hydrogen chloride into toluene at 100° in presence of aluminium chloride (Gattermann and Rossolym, Ber. 1890, 23, 1195); by heating dinitro-*p*-tolylmethane at about 130° (Ponzo, Atti R. Acad. Lincei, 1906, [v.] 15, ii, 42, 118).

Needles, m.p. 176°–177° (B. and Y.), 177°–

178° (A. and C.), or 180° (Fischli, Ber. 1879, 12, 615), b.p. 264° (Cannizzaro, Ann. 1862, 124, 254) or 274°-275° (F.), volatile with steam. When oxidised with chromic acid it yields terephthalic acid which is formed also when *p*-toluic acid is oxidised in presence of acetone and sulphuric acid at a lead peroxide anode (Fichter and Grisard, Helv. Chim. Acta, 1921, 4, 928). When treated with potassium persulphate it yields dibenzyl-4:4'-dicarboxylic acid (Fischer and Wolfenstein, Ber. 1904, 37, 3215). $\text{NH}_4\text{A}'$, plates (Lossen, Ann. 1897, 298, 72); KA' (B. and Y.); $\text{MgA}'_2 + 3\text{H}_2\text{O}$ (B. and Y.); $\text{CaA}'_2 + 3\text{H}_2\text{O}$, needles (B. and Y.); $\text{BaA}'_2 (\text{N.}) + 2\text{H}_2\text{O}$, fine needles (Buchka and Irish, Ber. 1887, 20, 1764); $\text{CuA}'_2 (\text{N.})$; $\text{AgA}'_2 (\text{N.})$; KHA'_2 , large laminæ (Farmer, Chem. Soc. Trans. 1903, 83, 1443); $\text{NH}_4\text{HA}'_2$, long needles (Farmer).

Hydroxylamine salt; m.p. 128° (Vesper and Ballard, J. Amer. Chem. Soc. 1925, 47, 2424).

Methyl-ester; m.p. 32°; b.p. 217° (Fischli), or m.p. 34°-35° (Kellas, Zeitsch. physikal. Chem. 1897, 24, 245).

Ethyl-ester; liquid, b.p. 228° (N.) or 235.5° (Perkin, Chem. Soc. Trans. 1896, 69, 1238) (D_4^{20} 1.0393; D_{15}^{15} 1.0306; D_{25}^{25} 1.024 (P.); magnetic rotatory power at 15° 14.74 (P.).

Chloride; liquid, b.p. 107°/8 mm. (Frankland and Wharton, Chem. Soc. Trans. 1896, 69, 1311), 102° (or 108°)/15 mm. (Frankland and Aston, *ibid.* 1899, 75, 494), 224°-226°/720 mm. (Ador and Rilliet, Ber. 1879, 12, 2298), 214°-216° (Cahours, Ann. 1858, 108, 316), D 1.175 (C.).

Amide; m.p. 160.8° (Remsen and Reid, Amer. Chem. J. 1899, 21, 290), fine needles or large tables, m.p. 151° (Fischli), 156° (Gattermann and Schmidt, Ann. 1888, 244, 51; Ber. 1887, 20, 120), 158°-159° (Holleman, Rec. trav. chim. 1887, 6, 78; cf. Spica, Ber. 1878, 9, 82; Vollrath, Zeit. f. Chem. 1866, (2) 2, 489); *methylamide*, m.p. 143° (G. and S.), 144°-145.5° (Wheeler, and Atwater, Amer. Chem. J. 1900, 23, 146; van Scherpenzeel, Rec. trav. chim. 1901, 20, 149); *dimethylamide*, m.p. 41°, b.p. 156°/10 mm. (van S.); *ethylamide*, m.p. 90° (G. and S.).

The methyl-ester, amide, and methylamide when nitrated at 0° yield derivatives of the 2-nitro-acid (van S.).

Anhydride; plates, m.p. 95° (Frankland and Wharton, Chem. Soc. Trans. 1899, 75, 344).

Nitrile; by distilling potassium toluene *p*-sulphonate with potassium cyanide (Merz, Zeit. f. Chem. 1868, (2) 4, 33); by heating tri-*p*-tolyl phosphate with potassium cyanide (Heim, Ber. 1883, 16, 1775); by heating *p*-tolyl isocyanate with copper (Weith, Ber. 1873, 6, 421); from *p*-toluidine by the Sandmeyer reaction (Glock, Ber. 1888, 21, 2650; Herb, Ann. 1890, 258, 9); by the action of mercury fulminate on toluene in presence of aluminium chloride (Scholl, Ber. 1903, 36, 10).

Crystals, m.p. 38° (Pinner and Caro, Ber. 1894, 27, 3275), b.p. 217.8° (Spica and Paternò, Ber. 1875, 8, 441; cf. Vollrath, Zeit. f. Chem. 1866, (2) 2, 489), or m.p. 29.5°, b.p. 215° (Kröber, Ber. 1890, 23, 1030), or b.p. 217.8°, D_{20}^{20} 0.9805, D_{25}^{25} 0.9751; magnetic rotatory power at 31° 12.84 (Perkin, Chem. Soc. Trans. 1896, 69,

1244). When reduced with sodium and alcohol a small quantity of *p*-methylbenzylamine is formed, but the greater part is saponified (Bamberger and Lodter, Ber. 1887, 20, 1710), and on hydrogenation with hydrogen at 250° in presence of reduced nickel it yields *p*-methylbenzylamine and di-*p*-methylbenzylamine (Frebault, Compt. rend. 1905, 140, 1036; cf. Sabatier and Senderens, *l.c.* 482). On oxidation at a lead peroxide anode it readily yields *p*-cyanobenzoic acid (Fichter and Grisard, Helv. Chim. Acta, 1921, 4, 928). For its polymeride, see Glock (*l.c.*) and Piepes-Poratyński (Bull. Acad. Sci. Cracow, 1900. Cf. Chem. Soc. Absts. 1900, 78, 648).

Isocyanide; m.p. 21°, b.p. 99°/32 mm., D_{24}^{24} 0.96 (Nef, Ann. 1892, 270, 320; Smith, Amer. Chem. J. 1894, 16, 374).

Mercaptan; b.p. 195°/760 mm. (Bourgeois, Rec. trav. chim. 1899, 18, 426).

2-Chloro-p-toluic acid; by oxidising 2-chlorocymene with dilute nitric acid (Fleischer and Kekulé, Ber. 1873, 6, 1090; Gerichten, *ibid.* 1877, 10, 1249). Large plates, m.p. 194°-196° (199°-201° corr.) (Gerichten, *ibid.* 1878, 11, 366). $\text{KA}' + \frac{1}{2}\text{H}_2\text{O}$, columns (Claus and Böcker, Ann. 1891, 265, 363); $\text{CaA}'_2 + 3\text{H}_2\text{O}$, nodules; $\text{BaA}'_2 + 4\text{H}_2\text{O}$, needles (G.).

Nitrile; from 2-chloro-*p*-toluidine by the Sandmeyer reaction, small pillars or needles, m.p. 48°-48.5° (Claus and Davidsen, J. pr. Chem. 1889, (2) 39, 498).

Amide; glistening plates (C. and D.).

Ethyl-ester; b.p. 149°-150° (C. and D.).

3-Chloro-p-toluic acid; together with other acids by boiling 1 part of 3-chlorocymene with 15 parts of nitric acid (D 1.24-1.29) (Fleti and Crosa, Gazz. chim. ital. 1886, 16, 290). Needles, m.p. 155°-155.5°.

Salts, see Claus and Davidsen (*l.c.*). $\text{NaA}' + \text{H}_2\text{O}$ crusts; $\text{CaA}'_2 + 2\text{H}_2\text{O}$, prisms; $\text{BaA}'_2 + 5\text{H}_2\text{O}$, prismatic needles; AgA' , silvery plates.

Nitrile; leaflets or flat needles, which sublime, m.p. 61°-62° (C. and D.).

Amide; glistening prismatic needles, m.p. 182° (C. and D.).

ω -Chloro-p-toluic acid; from the nitrile, obtained by passing chlorine into nearly-boiling *p*-toluonitrile, by hydrolysis with 25 parts of boiling hydrochloric acid for 1½ hours (Mellinghoff, Ber. 1889, 22, 3208); from *ω -chloro-p-toluoil chloride* by dissolving in 98 p.c. sulphuric acid and maintaining at 0°-5° until the evolution of hydrogen chloride ceases (B. A. S. F., D. R. P. 239311 of 1910). Silky microscopic needles or pillars, m.p. 199° (M.) or 190°-192° (B. A. S. F.).

Amide; thin plates, m.p. 173° (M.). *Nitrile*, rhombic prisms, m.p. 79.5°, b.p. 263° (Fock, Ber. 1889, 22, 3208).

Ethyl-ester; b.p. 260°-280° (Einhorn and Papastavros, Ann. 1900, 310, 205).

2:5-Dichloro-p-toluic acid; from 5-chloro-2-amino-*p*-toluic acid by the diazo-reaction (Claus and Davidsen, Ann. 1891, 265, 346) or from 3-chloro-6-nitro-*p*-toluic acid (Claus and Böcker, *l.c.* 359). Flat needles, m.p. 187°. $\text{BaA}'_2 + 4\text{H}_2\text{O}$, small needles.

2:6-Dichloro-p-toluic acid; from 6-chloro-2-nitro-*p*-toluic acid or 2:6-diamino-*p*-toluic acid (Claus and Böcker; Claus and Beynen,

Ann. 1891, 266, 239). Leaflets, m.p. 186°-188°. $\text{BaA}'_2 + 4\text{H}_2\text{O}$, small needles.

o-Dichloro-*p*-toluic acid, m.p. 151°-158°, has a chloride, m.p. 45°, and an ethyl ester, m.p. 46° (Davies and Perkin, Chem. Soc. Trans. 1922, 121, 2212).

o-Trichloro-*p*-toluic acid; prepared from its chloride, which is obtained by chlorinating *p*-toluoyl chloride (Davies and Perkin, Chem. Soc. Trans. 1922, 121, 2214). Minute plates, m.p. 197°.

Tetrachloro-*p*-toluic acid; by oxidising tetrachloro-*p*-xylene with nitric acid and potassium permanganate (Rupp, Ber. 1896, 29, 1628). Needles, m.p. 212°.

2-Bromo-*p*-toluic acid; by oxidising 2-bromocymene (Landolph, Ber. 1872, 5, 268), 2-bromo-*p*-xylene (Jannasch and Dieckmann, Ann. 1874, 171, 83), or bromo-*p*-ethyltoluene (Morse and Remsen, Ber. 1888, 11, 225) with chromic acid mixture; by keeping a mixture of *p*-toluic acid and excess of bromine for 12 hours in the cold (Brückner, Ber. 1876, 9, 407); from 2-bromo-*p*-toluidine via the nitrile Claus and Kunath, J. pr. Chem. 1889, (2) 31, 487). Thin needles or laminae, m.p. 203.5°-204°. $\text{CaA}'_2 + 3\text{H}_2\text{O}$, needles; $\text{BaA}'_2 + 4\text{H}_2\text{O}$, hair-like needles.

Nitrile; small needles, m.p. 44° (C. and K.).

3-Bromo-*p*-toluic acid; from 3-bromo-*p*-toluidine via the nitrile (C. and K.). Needles, m.p. 140° (C. and K.) or leaflets, m.p. 196°; by oxidation of bromocymene, obtained by the hydrolysis of β -bromocymene sulphonic acid (Kelbe and Koschnitzky, Ber. 1886, 19, 1731). $\text{NaA}' + 3\text{H}_2\text{O}$, needles; $\text{KA}' + 4\text{H}_2\text{O}$, nodules; $\text{CaA}'_2 + 2\text{H}_2\text{O}$, needles; $\text{BaA}'_2 + 6\text{H}_2\text{O}$, small leaflets.

Chloride; needles, m.p. 120° (C. and K.).

Nitrile; needles, m.p. 47° (C. and K.).

Amide; sublimes in needles, m.p. 137 (C. and K.).

o-Bromo-*p*-toluic acid; by the action of bromine on a bromoform solution of *p*-toluic acid (Zalkind, J. Russ. Phys. Chem. Soc. 1914, 46, 508). Plates with a vitreous lustre, m.p. 223° (Z.).

Nitrile; by bromination of *p*-toluonitrile at 200°. Prisms with a pungent odour, m.p. 115°-116° (Banse, Ber. 1894, 27, 2169).

Methyl-ester; vitreous needles, m.p. 53°-53.5°, b.p. 160°-161°/17 mm. (Z.).

2:3-Dibromo-*p*-toluic acid; from 3-bromo-2-nitro-*p*-toluic acid (Claus and Herbabny, Ann. 1891, 265, 375). Needles, m.p. 194°(?).

2:5-Dibromo-*p*-toluic acid; by oxidising 6-dibromo-*p*-xylene with chromic acid in presence of acetic acid (Schultz, Ber. 1885, 18, 1762); from 5-bromo-2-amino-*p*-toluic acid (Fileti and Crosa, Gazz. chim. ital. 1888, 18, 308). Needles m.p. 195° (S.), 200°-201° (F. and C.).

$\text{NaA}' + 7\frac{1}{2}\text{H}_2\text{O}$, large tables (C. and H.); $\text{CaA}'_2 + 4\text{H}_2\text{O}$, long needles; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, long thin needles.

Ethyl-ester; long needles, m.p. 49°, b.p. about 310° (S.).

Chloride; needles, m.p. 60° (Claus and Herbabny).

2:6-Dibromo-*p*-toluic acid; from 2:6-dibromo-*p*-toluidine via the nitrile (Claus and Seibert, Ann. 1891, 265, 378). Silky needles, m.p. 235°-236°. $\text{NaA}' + \text{H}_2\text{O}$, fine needles; $\text{KA}' + 1\frac{1}{2}\text{H}_2\text{O}$, silvery needles.

Nitrile; large glistening needles, m.p. 49° (C. and H.).

Amide; small needles, m.p. 117° (C. and S.).

Chloride; needles, m.p. 86° (C. and S.).

Ethyl-ester; vitreous needles, m.p. 79°-80° (C. and S.).

3:5-Dibromo-*p*-toluic acid; from 3:5-dibromo-*p*-toluidine via the nitrile (Claus and Herbabny, Ann. 1891, 265, 378). Needles, m.p. 182°.

Nitrile; large silky needles, m.p. 156° (C. and H.).

Amide; leaflets, m.p. 148° (C. and H.).

3-Chloro-6-bromo-*p*-toluic acid; together with 2-chloro-5-bromo-*p*-toluic acid by heating 3-chloro-6-bromocymene with dilute nitric acid (Plancher, Gazz. chim. ital. 1893, 23, ii. 73; cf. Willgerodt and Wolfen, J. pr. Chem. 1889, (2) 39, 409). The mixture is separated by crystallisation from ligroin. Fibrous crystals, m.p. 187°-188° (P.), 186° (W. and W.).

5-Chloro-2-bromo-*p*-toluic acid; from 5-chloro-2-amino-*p*-toluic acid (Claus and David-son, Ann. 1891, 265, 347). Needles, m.p. 192°-193°. $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$, needles.

2-Nitro-*p*-toluic acid; by treating cymene with concentrated nitric acid (Noad, Ann. 1847, 63, 297; cf. Fittig, *ibid.* 1874, 172, 309); by nitrating *p*-toluic acid at 0° (van Scherpenzeel, Rec. trav. chim. 1901, 20, 149; cf. Fittig and Ramsay, Ann. 1873, 168, 251).

Large monoclinic prisms, m.p. 189°-190° (Ahrens, Zeit. f. Chem. 1869, (2) 5, 104). Yields 6-amino-3-hydroxy-*p*-toluic acid on electrolysis its solution in sulphuric acid.

$\text{CaA}'_2 + 3\text{H}_2\text{O}$; $\text{BaA}'_2 + 4\text{H}_2\text{O}$, needles (A.); $\text{CuA}'_2 + 7\text{H}_2\text{O}$, blue needles (Noyes, Amer. Chem. J. 1888, 10, 483); $\text{Cu}_2\text{A}'_4(\text{OH})_2$; $\text{Cu}_2\text{A}'_4(\text{OH})_2$ aq. (Noyes, *ibid.* 472).

Nitrile; by nitrating *p*-toluonitrile (Banse, Ber. 1894, 27, 2162). Long yellow needles, which sublime, m.p. 107° (Noyes).

Amide; long needles, m.p. 165°-166° (Fileti and Cairoli, Gazz. chim. ital. 1892, 22, ii. 392); formed also by nitrating *p*-toluamide at 0° (van S.).

Chloride; b.p. 185°/36 mm. (Soderman and Johnson, J. Amer. Chem. Soc. 1925, 47, 1390).

Methyl-ester; crystals (Noad), formed also when methyl-*p*-toluate is nitrated at 0° or 20° (van S.); ethyl-ester, yellow crystals (Noad).

3-Nitro-*p*-toluic acid; by heating the nitrile with hydrochloric acid (D 1:17) for 8-10 hours (Niemientowski and Rozański, Ber. 1888, 21, 2993; Noyes, Amer. Chem. J. 1888, 10, 476); in small yield by oxidising 3-nitro-*p*-xylene with potassium ferricyanide and potassium hydroxide (Noyes).

Long needles or monoclinic pillars which sublime (Nimentowski, Rozański and Haushofer, Ber. 1888, 21, 1994), m.p. 161° (N. and R.), 164°-165° (corr.) (Noyes). When warmed with mixed acids it yields 2:3- and 2:5-dinitro-*p*-toluic acids.

$\text{NaA}' + 6\text{H}_2\text{O}$, large tables (Claus and Joachim, Ann. 1891, 266, 210); $\text{KA}' + 6\text{H}_2\text{O}$, large tables (C. and J.); CaA'_2 , anhydrous (N. and R.) + 2H₂O (Noyes); $\text{BaA}'_2 + 4\text{H}_2\text{O}$ (N. and R.), + 5H₂O (Noyes), glistening leaflets; $\text{CuA}'_2 + \text{H}_2\text{O}$, greenish-blue tables; AgA'_2 , needles.

Nitrile; from 3-nitro-*p*-toluidine by the

Sandmeyer reaction (Leuchart, Ber. 1886, 19, 175; Glock, *ibid.* 1888, 21, 2662; Weise, *ibid.* 1889, 22, 2429; Noyes, *l.c.*; Niemantowski, J. pr. Chem. 1889, (2) 40, 4; Ber. 1888, 21, 1535, 1902). Needles, m.p. 99° (G; W.), 100° (Noyes), 99.8° (Bogert and Hoffman, J. Amer. Chem. Soc. 1905, 27, 1293). It does not form an imino-ether when treated with alcoholic hydrochloric acid (Pinner, Ber. 1890, 23, 2919).

Amide; long hair-like needles, m.p. 152°–153° (N. and R.; cf. Weise, Ber. 1889, 22, 2430).

Chloride; small needles, m.p. 157° (C. and J.).

Some nitrotoluic acids of unknown orientation have been described by Ahrens (Zeit. f. Chem. 1869, (2) 5, 103); Fittica (Ber. 1874, 7, 1357); Ann. 1874, 172, 316); Landolph (Ber. 1872, 5, 937).

2:3-Dinitro-*p*-toluic acid; see below. Glistening rhombic prisms, m.p. 249°, more sparingly soluble than the 2:5-acid. With hydrochloric acid at 265° it yields 2:3-dinitrotoluene.

$\text{CaA}'_2 + \text{H}_2\text{O}$ (R.), or $+1\frac{1}{2}\text{H}_2\text{O}$ (C. and J.), long leaflets; $\text{BaA}'_2 + 3\text{H}_2\text{O}$ (C. and J.) or $+4\text{H}_2\text{O}$ (R.).

2:5-Dinitro-*p*-toluic acid; together with the 2:3-acid by treating 3-nitro-*p*-toluic acid with a mixture of 3 parts of sulphuric acid in 3 parts of nitric acid (D 1.51) (Rozafski, Ber. 1889, 22, 2675; Claus and Joachim, Ann. 1891, 266, 211). Fine needles, m.p. 188° (R.), or small glistening pillars, m.p. 194° (C. and J.). Hydrochloric acid at 250° yields 2:5-dinitrotoluene.

$\text{NaA}'_2 + 3\text{H}_2\text{O}$, yellow glistening scales; $\text{CaA}'_2 + 2\text{H}_2\text{O}$, reddish-brown glistening leaflets; $\text{BaA}'_2 + 2\frac{1}{2}\text{H}_2\text{O}$, fine yellow needles, or $+2\text{H}_2\text{O}$ (C. and J.).

2:6-Dinitro-*p*-toluic acid; by nitrating *p*-toluic acid or its methylamide at the ordinary temperature (van Scherpenzeel, Rec. trav. chim. 1901, 20, 149; cf. Brückner, Ber. 1875, 8, 1678); by nitrating 2-nitro-*p*-toluic acid with mixed acids (Cl. and J.); by oxidising 2:6-dinitro-*p*-tolualdehyde with potassium permanganate (Gattermann, Ann. 1906, 347, 347).

Yellow plates which sublime, m.p. 157°–158°. $\text{KA}'_2 + 2\text{H}_2\text{O}$; $\text{CaA}'_2 + 2\text{H}_2\text{O}$, thick red prisms; $\text{BaA}'_2 + 2\text{H}_2\text{O}$, fine needles; AgA' .

3:5-Dinitro-*p*-toluic acid; by heating the corresponding amide with concentrated hydrochloric acid at 220°–230° for 8 hours (Claus and Beysen, Ann. 1891, 266, 226). Slender plates or prisms, m.p. 226°, subliming in needles. $\text{BaA}'_2 + \text{H}_2\text{O}$, yellow pillars.

Amide; by boiling the nitrile with 60 p.c. sulphuric acid. Thin yellow needles, m.p. 255°–257°.

Nitrile; from 3:5-dinitro-*p*-toluidine. Golden-yellow needles, m.p. 103° (C. and B.).

2:3:5-Trinitro-*p*-toluic acid; by oxidising 2:3:5-trinitro-*p*-xylene. Lustrous white lamellae, m.p. 230°–231°, giving a brownish-red coloration with alkali hydroxide.

Methyl-ester, white needles, m.p. 114°–115°; *ethyl-ester*, colourless prisms, m.p. 87°–88° (Gina, Gazz. chim. ital. 1922, 52, i. 183).

ω-Chloro-2-nitro-*p*-toluic acid; by nitration of *ω*-chloro-*p*-toluic acid (Einhorn and Papastavros, Ann. 1900, 310, 200). Yellow needles, m.p. 180°.

2-Chloro-3-nitro-*p*-toluic acid; in small

quantity together with two isomeric acids, by nitrating 2-chloro-*p*-toluic acid (Claus and Böcher, Ann. 1891, 265, 362). Plates, m.p. 211°. CaA'_2 , glistening needles; $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$, rosettes.

2-Chloro-5-nitro-*p*-toluic acid; by hydrolysis of the nitrile derived from 2-chloro-5-nitro-*p*-toluidine (Claus and Böcher); by nitration of 2-chloro-*p*-toluic acid (Claus and Böcher); from 2-nitro-5-amino-*p*-toluic acid (Claus and Beysen, Ann. 1891, 266, 234). Needles, m.p. 164°–185°. $\text{KA}'_2 + \frac{1}{2}\text{H}_2\text{O}$, glistening leaflets; CaA'_2 , needles; $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$; CuA'_2 , green precipitate.

Nitrile; tables or smooth pillars, m.p. 157° (Claus and Beysen).

2-Chloro-6-nitro-*p*-toluic acid; together with the 5-nitro- and 3-nitro-derivatives by nitrating 2-chloro-*p*-toluic acid (Claus and Böcher); from 2-nitro-6-amino-*p*-toluic acid (Claus and Beysen). Fine silky needles, m.p. 159°. CaA'_2 , needles; $\text{BaA}'_2 + 1\frac{1}{2}\text{H}_2\text{O}$, pillars.

3-Chloro-2-nitro-*p*-toluic acid; by nitrating 3-chloro-*p*-toluic acid with nitric acid (D 1.48) in the cold (Claus and Davidsen, Ann. 1891, 265, 347). Needles, m.p. 192°. $\text{MgA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, needles.

3-Chloro-6-nitro-*p*-toluic acid; by boiling 3-chlorocymene or 3-chloro-6-nitrocymene with nitric acid (D 1.39) (Fileti and Crosa, Gazz. chim. ital. 1888, 18, 312); by nitration of 3-chloro-*p*-toluic acid with nitric acid (D 1.5 (Claus and Davidsen, J. pr. Chem. 1888, (2) 39, 495; Ann. 1891, 265, 341). Needles, m.p. 180°–181°. $\text{MgA}'_2 + 8\text{H}_2\text{O}$, large triclinic tables (Claus, Davidson and Beckenkamp, Ann. 1891, 265, 342).

$\text{BaA}'_2 + 3\frac{1}{2}\text{H}_2\text{O}$, needles, or $+3\text{H}_2\text{O}$ (C. and D.).

Ethyl-ester; tables or needles, m.p. 60°.

Nitrile; from the amine. Long needles, m.p. 93° (C. and D.).

ω-Chloro-2-nitro-*p*-toluic acid; by heating *p*-cyanobenzyl chloride with fuming nitric acid for $\frac{1}{2}$ hour at 100° (Banse, Ber. 1893, 27, 2168). It melts at 140°–141°. BaA'_2 , leaflets; AgA' , precipitate.

Amide; by keeping a mixture of *p*-cyanobenzyl chloride, potassium nitrate, and sulphuric acid for 24 hours. Microscopic needles, m.p. 125° (B.).

Nitrile; by treating a well-cooled solution of *p*-cyanobenzyl chloride in sulphuric acid with potassium nitrate. Prisms, m.p. 84° (B.).

3-Chloro-2:6-dinitro-*p*-toluic acid; by nitrating 3-chloro-2-nitro-*p*-toluic acid or 3-chloro-6-nitro-*p*-toluic acid (Claus and Davidsen, J. pr. Chem. 1889, (2) 39, 496; Ann. 1891, 265, 349). Small glistening needles, m.p. 233°. $\text{BaA}'_2 + \text{H}_2\text{O}$, large vitreous prisms.

Ethyl-ester, m.p. 71°.

2-Bromo-5-nitro-*p*-toluic acid; from 5-nitro-2-amino-*p*-toluic acid (Claus and Beysen, Ann. 1891, 266, 234). Needles, m.p. 181°.

2-Bromo-6-nitro-*p*-toluic acid; from 6-nitro-2-amino-*p*-toluic acid (C. and B.). Small needles, m.p. 181°. BaA'_2 , flat needles.

2-Bromonitro-*p*-toluic acid; by nitrating 2-bromo-*p*-toluic acid (Landolph, Ber. 1872, 5, 268). Needles, m.p. 170°–180° (decomp.). $\text{BaA}'_2 + \text{H}_2\text{O}$, needles.

3-Bromo-2-nitro-*p*-toluic acid; in small quantity, together with the 6-nitro-isomide, by

nitration 3-bromo-*p*-toluic acid (Claus and Herbabny, Ann. 1891, 265, 368). The acids are separated by means of their magnesium salts. The free acid forms fine needles, m.p. 214°, not volatile with steam. $\text{MgA}_2 + 3\frac{1}{2}\text{H}_2\text{O}$, leaflets; $\text{BaA}_2 + 4\text{H}_2\text{O}$, tables.

3-Bromo-5-nitro-*p*-toluic acid; by hydrolysis of the nitrile obtained from the corresponding amine (C. and H.). Small needles, m.p. 206°.

Nitrile; citron-yellow needles, m.p. 130°.

Amide; glistening needles, m.p. 171° (C. and H.).

3-Bromo-6-nitro-*p*-toluic acid; by boiling 3-bromocymene with nitric acid (D 1-29-1-39) (Fileti and Crosa, Gazz. chim. ital. 1886, 16, 297); or better, by boiling 3-bromo-6-nitrocymene with 15 times its weight of nitric acid (D 1-39) for 8 hours (Fileti and Crosa, Gazz. chim. ital. 1888, 18, 300); by nitrating 3-bromo-*p*-toluic acid (C. and H.). Thin tables, m.p. 203°. When heated with alcoholic ammonia at 180°, it yields 6-nitro-3-amino-*p*-toluic acid.

$\text{NaA} + 4\frac{1}{2}\text{H}_2\text{O}$, plates; $\text{KA} + \text{H}_2\text{O}$, needles; $\text{MgA}_2 + 8\text{H}_2\text{O}$, large tables; $\text{CaA}_2 + 5\text{H}_2\text{O}$, needles or prisms; $\text{BaA}_2 + 4\text{H}_2\text{O}$, long needles (F. and C.), or $+5\text{H}_2\text{O}$ (C. and H.).

Ethyl-ester; glistening needles, m.p. 61° (C. and H.).

Chloride; leaflets, m.p. 60° (C. and H.).

Amide; needles, m.p. 191° (C. and H.).

Nitrile; needles, m.p. 132° (C. and H.).

Chlorobromonitro-*p*-toluic acid; by heating chlorobromo-*p*-toluic acid (m.p. 186°) with 5-6 parts of fuming nitric acid (Willgerodt and Wolfen, J. pr. Chem. 1889, (2) 39, 411). Needles which sublime, m.p. 220°. $\text{BaA}_2 + \text{H}_2\text{O}$.

2-Amino-*p*-toluic acid; by reducing 2-nitro-*p*-toluic acid with tin and hydrochloric acid (Ahrens, Zeit. f. Chem. 1869, (2) 5, 104). Long hair-like needles, m.p. 164°-165°.

$\text{BaA}_2 + 1\frac{1}{2}\text{H}_2\text{O}$; CuA_2 , green crystalline precipitate; hydrochloride; platinochloride (Cahours, Ann. 1859, 109, 17).

Nitrile; by reducing ω -chloro-2-nitro-*p*-toluonitrile with tin and hydrochloric acid (Banse, Ber. 1894, 27, 2163). Prisms, m.p. 81°-82°.

Acetyl-derivative; m.p. 267°-270° (decomp. (Kunkell, Ber. deut. pharm. Ges. 1911, 21, 419).

Diethylaminoethyl ester (Soderman and Johnson, J. Amer. Chem. Soc. 1925, 47, 1390).

3-Amino-*p*-toluic acid; from the nitrile (Niementowski, J. pr. Chem. 1889, (2) 40, 15); by reduction of 3-nitro-*p*-toluic acid with tin and hydrochloric acid (Niementowski and Rozański, Ber. 1888, 21, 1997; Noyes, Amer. Chem. J. 1888, 10, 479). Needles, m.p. 177° (decomp.). $\text{CaA}_2 + 2\text{H}_2\text{O}$, scales; $\text{BaA}_2 + 4\text{H}_2\text{O}$, leaflets (Noyes).

Formyl-derivative; long silky needles, m.p. 183°-187° (Niementowski).

Acetyl-derivative; needles, m.p. 183° (Niementowski).

Amide; by boiling the nitrile for 2-3 hours with dilute aqueous potassium hydroxide (Niementowski). Very thin plates, m.p. 146°-147°.

ω -Amino-*p*-toluic acid; by heating *p*-carboxybenzylphthalamic acid with concentrated hydrochloric acid for 3 hours at 200°

(Günther, Ber. 1890, 23, 1060). Yellow scales. Hydrochloride, long needles or trimetric prisms; platinochloride, yellow amorphous substance (G.).

2:3-Diamino-*p*-toluic acid; by reducing the corresponding dinitro-acid with tin and hydrochloric acid (Claus and Joachim, Ann. 1891, 266, 216). Thin needles, m.p. 192°. It yields red flocks with ferric chloride (Kehrmann, Ber. 1889, 22, 1984). BaA_2 , reddish-yellow plates.

2:5-Diamino-*p*-toluic acid; by reducing the corresponding dinitro-compound with tin and hydrochloric acid (C. and J.). Glistening needles, m.p. 240° (decomp.).

2:6-Diamino-*p*-toluic acid; by reducing the corresponding dinitro-compound with tin and hydrochloric acid (C. and J.; Marckwald, Ann. 1893, 274, 357). Silky needles, m.p. 212°. Nitrous acid yields an intense yellow coloration. BaA_2 , glistening leaflets; sulphate $+3\text{H}_2\text{O}$, yellow needles (M.).

Methyl-ester; brown crystals with a peculiar fluorescence, m.p. 129° (Kauffmann and Weissel, Ann. 1912, 393, 1).

Diacetyl-derivative; colourless needles, m.p. above 280° (K. and W.).

5-Chloro-2-amino-*p*-toluic acid; by reducing the corresponding nitro-derivative (Claus and Davidsen, Ann. 1891, 265, 346). Needles, m.p. 220°.

5-Bromo-2-amino-*p*-toluic acid; tables, m.p. 186°-187° (Fileti and Crosa, Gazz. chim. ital. 1888, 18, 307).

5-Nitro-2-amino-*p*-toluic acid; by reducing an ammoniacal solution of 2:5-dinitro-*p*-toluic acid with hydrogen sulphide (Claus and Beysen, Ann. 1891, 266, 232). Long yellowish-red pillars or needles, m.p. 220° (decomp.). BaA_2 , yellowish-brown plates or prisms.

6-Nitro-2-amino-*p*-toluic acid; by reducing 2:6-dinitro-*p*-toluic acid with ammonium sulphide, or with stannous chloride and alcoholic hydrochloric acid (C. and B.). Citron-yellow needles which sublime, m.p. 214°.

$\text{NaA} + \frac{1}{2}\text{H}_2\text{O}$, yellow silky needles; $\text{MgA}_2 + 5\text{H}_2\text{O}$, yellow crystals; CaA_2 , deep yellow pillars; $\text{BaA}_2 + 4\text{H}_2\text{O}$, golden-yellow leaflets.

6-Nitro-3-amino-*p*-toluic acid; by heating the corresponding bromonitro-*p*-toluic acid with alcoholic ammonia at 180° (Fileti and Crosa, Gazz. chim. ital. 1888, 18, 303; cf. Niementowski, J. pr. Chem. 1889, (2) 40, 27). Long silky needles, m.p. 235°-236°. When heated with hydrochloric acid at 150°, it yields 6-nitro-*m*-toluidine.

2-Nitro- ω -amino-*p*-toluic acid; by heating 2-nitrocyanobenzylphthalimide with hydrochloric acid and acetic acid for 3 hours at 150° (Banse, Ber. 1894, 27, 2166). Pearly leaflets, m.p. 243° (decomp.). Hydrochloride, needles, m.p. 249°-250° (decomp.).

p-Toluic sulphinide, 'Methylsaccharin'; obtained similarly to saccharin (Randall, Amer. Chem. J. 1891, 13, 269); by heating 3-sulphonamino-*p*-toluic acid at 200°-220° for 3 to 4 hours (Weber, Ber. 1892, 25, 1737; B. A. S. F., D. R. P. 48583 of 1889); by hydrolysis of *p*-cyanotoluene *m*-sulphonamide with caustic alkalis (B. A. S. F., D. R. P. 48563 of 1889; cf. Basler Chem. Fabr., D. R. P. 122567 of 1900). Long fine needles $+1\frac{1}{2}\text{H}_2\text{O}$, which

lose the water of crystallization at 190°, and then sublimes gradually with decomposition. It melts at 249° (R.) or 246° (W.) and possesses an intensely sweet taste, but a bitter after-taste. On heating with a mixture of potassium hydroxide and potassium hypochlorite, followed by acidification of the product with acetic acid, *p*-toluidine 3-sulphonic acid is obtained. *Barium salt* + 5H₂O, triclinic crystals; *Calcium salt*, opaque white needles; *Silver salt* + 1½H₂O, colourless diamond-shaped crystals.

Ethyl imide: crystals, m.p. 106°; *methyl imide*, m.p. 153° (W.).

For the sulphonic acids, etc., of toluic acid, see Flesch (Ber. 1873, 6, 480); Bechler (J. pr. Chem. 1873, (2) 8, 170); Fittig (Ann. 1874, 172, 329); Iles and Remsen (Ber. 1878, 11, 230); Fischli (Ber. 1879, 12, 616); Hall and Remsen (Ber. 1879, 12, 1433); Remsen and Burney (Amer. Chem. J. 1880-1, 2, 411); Moyer and Baur (Ann. 1883, 220, 18); Kelbe and Baur (Ber. 1883, 16, 2565); Remsen and Emerson (Amer. Chem. J. 1886, 8, 264); Weinreich (Ber. 1887, 20, 982); Randall (Amer. Chem. J. 1891, 13, 258); Holmes (*ibid.* 1891, 13, 380); Weber (Ber. 1892, 25, 1741); Lyman (Amer. Chem. J. 1894, 16, 513); Meldrum and W. H. Perkin (Chem. Soc. Trans. 1908, 93, 1419; B. A. S. F., D. R. P. 48583 of 1889; Basler Chem. Fabr., D. R. P. 122567 of 1900; Jacobsen (Ber. 1878, 11, 895; 1881, 14, 39, 2355); Iles and Remsen (Amer. Chem. J. 1880-1, 1, 41); Jacobsen and Wierss (Ber. 1883, 16, 1959).

F. M. R. and J. S. H. D.

o-TOLYGLYCINE. Formed by heating *o*-toluidine with an aqueous solution of sodium chloroacetate (Friswell, Eng. Pat. 18149 of 1907).

TOLYLENE-DIAMINES. *Diamino-toluenes* v. AMINES.

TOLYLENE RED v. AZINES.

***p*-TOLYL- α -NAPHTHYLAMINE**

obtained by heating α -naphthylamine with *p*-toluidine and iodine, or α -naphthol with *p*-toluidine, or α -naphthylamine hydrochloride with *p*-toluidine. M.p. 78.5°, b.p. 230°/10 mm. The tolylnaphthylamines are described in Vol. IV., pp. 437, 451.

1-*p*-TOLYNAPHTHYLAMINE 8-SULPHONIC ACID. Prepared by heating 1-naphthylamine 8-sulphonic acid with *p*-toluidine in an autoclave at 150°, with or without hydrochloric acid or benzoic acid (Farb. f. F. Bayer & Co., D. R. P. 71168; Kalle & Co., D. R. P. 170630).

TOLYPYRIN, TOLYSAL, v. SYNTHETIC DRUGS.

TOMATO, *Solanum Lycopersicum* (Linn.) or *Lycopersicon esculentum vulgare*. A Peruvian plant now largely cultivated in many parts of the world for its fruit, which is esteemed as a vegetable. Several species and many varieties are known, differing greatly in size, shape, and colour of fruit.

König gives as the average composition—

Water	Protein	Fat	Sugar	Other extract	N-free	Crude fibre	Ash
93.4	1.0	0.2	3.5	0.5		0.8	0.6

About half the total nitrogen is present as true proteids.

Passerini (Staz. Sper. Agrar. 1891, 18, 545) found the fresh fruit to consist of skin 1.3 p.c., pulp and juice 96.2 p.c., and seeds 2.5 p.c., and the pulp to contain two colouring matters—a yellow amorphous substance and a red crystalline compound—both insoluble in water, but soluble in amyl alcohol or ether, and bleached by chlorine. He attributes the acidity to citric acid, which he estimates as forming about 9 p.c. of the total dry matter of the whole fruit. The ash he found to contain—

K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₂	SiO ₂	Cl
59.5	6.0	1.3	3.1	0.2	12.9	3.5	0.3	19.1

Albahary (Compt. rend. 1907, 145, 131) found in the fresh fruit—

Water	Protein	Fat	Carbo- hydrates	Malic acid	Citric acid	Oxalic acid	Ash
93.5	1.0	0.2	3.6	0.49	0.15	0.001	0.74

Traces of tartaric and succinic acids were also detected.

Stüber (Zeitsch. Nahr. Genussm. 1906, 11, 578) obtained somewhat similar results, but states that citric acid was the chief cause of the acidity (amounting to about 0.5 p.c. citric acid), and that he could not detect malic, tartaric, or succinic acids. The presence of citric acid may be detected by the formation of its triphenacyl ester.

The juice of tomatoes was found by Passerini (*l.c.*) to have a sp.gr. 1.01833 at 15°, to contain 2.44 p.c. of dry matter, of which rather more than ½ was protein, ¼ ash, and a little more than half carbohydrates and acids.

Other analyses of the juice were made by Stüber (*l.c.*), who found water 95.1, nitrogen 0.093, ash 0.56, total sugars, after inversion, 2.15, acidity (as citric acid) 0.65 p.c. The red colouring matter of the tomato was investigated by Arnaud (Compt. rend. 1886, 102, 1119), who believed it to be identical with carotin C₄₀H₅₆; Montanari (Chem. Zentr. 1905, i, 544) concluded that it had the composition C₅₅H₇₄; Willstätter and Escher (Zeitsch. physiol. Chem. 1910, 64, 47), who name it *lycopene*, find that it had the molecular composition C₁₁H₁₆, the same as that which Willstätter and Mig (Annalen, 1907, 355, 1) have ascribed to carotin. It, however, differs in its properties from that substance. It crystallises from light petroleum or a mixture of alcohol and carbon disulphide in dark, carmine-red, felted prisms; it melts at 168°–169° (corr.), but is less soluble in ether, alcohol, carbon disulphide, or light petroleum than carotin. It absorbs oxygen much more readily than does carotin, and forms a di-iodide C₄₀H₅₆I₂, a dark green, gelatinous, insoluble substance.

The leaves and stems of tomatoes were examined by Passerini (Staz. Sper. Agrar. 1893, 20, 471), who found in the fresh substance—

	Total dry matter	
Stems	8.8-9.9	1.6-2.0
Leaves	11.6-14.6	1.6-3.2
The ash contained—		

	K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	MnO	P ₂ O ₅	SO ₂	SiO ₂	Cl
Stems 25.0	11.1	3.2	7.9	0.5	—	0.3	4.7	0.0	1.4	1.4
Leaves 2.0	1.4	3.1	0.0	0.1	0.05	1.4	12.3	3.3	1.6	—

Lithium, boron, and copper were also present in the ash of the stems.

Salicylic acid occurs naturally in tomatoes although in very small quantity. Pellet (Ann. Chim. anal. 1907, 12, 10) considers that the presence of 10 mgm. of salicylic acid in 1 kilog. of tomatoes should not be regarded as proof of adulteration.

Tomatoes are often canned. American analyses (Bill. 28, U.S. Dept. of Agric.) give, as the mean of 19 samples—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
94.0	1.2	0.2	3.5	0.5	0.6

In the ash was included about 0.1 p.c. common salt. Tomatoes are largely used in the preparation of sauces and chutneys, in some of which the red colour is enhanced by the addition of eosin (König).

Air-dried tomato seeds give a yield of about 25 p.c. oil when extracted with ether, and about 18 p.c. when the seeds are pressed. Sp.gr. (average), 0.9190; refractive index at 25°, 1.4722; iodine No. (Hanūs), 122.5; sapon. No., 189.5; Reichert-Meißl No., 0.26; Polenski No., 0.55; acetyl value, 14.2; insol. fatty acids, p.c. 98.5; soluble fatty acids, 0.52; unsat. (liquid) acids, p.c. 78.5; sat. (solid) acids p.c. 16.4 (Jamieson and Bailey, J. Ind. Eng. Chem. 1919, 11, 850). The antiscorbutic value of fresh and canned tomatoes has been studied by Delf (Bio-Chem. J. 1924, 18, 674; Chem. Soc. Abstr. 1924, 126, i. 902). H. I.

TONITE v. EXPLOSIVES.

TONKA BEAN. *Tonquin bean* (Fève tonka, Fr.; *Tonkabohnen*, Ger.). The seed of the fruit of the leguminous tree *Dipterix odorata* (Willd.) which inhabits Guiana and Venezuela. Each pod contains a single seed, which is about 2 ins. long and $\frac{1}{2}$ in. wide. It has a dark-brown colour, is deeply wrinkled externally, and characterised by an agreeable odour and bitter aromatic taste. The tree flourishes in the forests of the Caracas district of Venezuela. The first crop of beans is gathered when the tree is three years old, but a full crop is not obtained until two years later. The fruit bears some resemblance to a small mango, and contains the odorous bean in its centre. The seed of *D. oppositifolia* (Willd.), the so-called English Tonka bean, has similar properties to that of *D. odorata*, but it is smaller and darker in colour.

Besides sugar, gum, malic acid, and woody fibre, tonka bean contains fixed oil and about 1.5 p.c. of coumarin (Boullay and Boutron-Charlard, J. Pharm. Chim. 11, 480). It is to the presence of coumarin that the odour and taste of the seed are due, and crystals of this compound often occur as an efflorescence on commercial specimens. To extract the coumarin, the finely-chopped beans, according to Gössmann, are heated for some time nearly to boiling with an equal bulk of 80 p.c. alcohol; the whole is then filtered and the residue again heated in the same manner; the extracts are mixed together, and the alcohol removed by distillation until the residue becomes turbid, when it is mixed with four times its volume of water, which precipitates the coumarin in somewhat impure crystals. Adhering fat may be removed by heating the mixture to boiling, and filtering through a

moistened filter. On cooling, the crystals which re-dissolve in the hot liquid again separate, and they may be further purified, if necessary, by treatment with animal charcoal (Annalen, 98, 86), v. COUMARIN.

Tonka bean is used to flavour tobacco, and especially snuff, as an ingredient of sachet powder, and in alcoholic solution as a flavouring essence.

TOPAZ (*Topaze*, Fr.; *Topas*, Ger.). A gemstone composed of aluminium fluo-silicate $(\text{AlF})_2\text{SiO}_4$ crystallised in the orthorhombic system. As shown by S. L. Penfield and J. C. Minor (Amer. J. Sci. 1894, 47, 387) the fluorine (15.48–20.37 p.c.) is replaced isomorphously by hydroxyl (0.18–2.50 p.c., as shown by analyses), so that the formula becomes $[\text{Al}(\text{F},\text{OH})]_2\text{SiO}_4$; and, chemically, a fluor-topaz and a hydro-fluor-topaz may be distinguished. Although these two varieties show slight differences in sp.gr. (3.574 in the former, and 3.523 in the latter), and in optical constants, the distinction is of no practical importance. The mineral is very resistant to acids, and water is expelled only at an intense heat. Topaz usually occurs as crystals in granitic and gneissose rocks, and is often associated with tin-ore. An important character is the presence of a perfect cleavage in one direction, perpendicular to the prism. The crystals may be dull and opaque, or more often clear and transparent, and colourless, bluish, greenish, yellow, or pink. The sherry-yellow crystals from Brazil become pink when heated ('burnt topaz'). Most of the gem material comes from Brazil and Russia, but it is also found in many other countries. Colourless topaz, when faceted, is sometimes mistaken for diamond, and much yellow quartz ('Spanish topaz,' 'Scotch topaz,' 'occidental topaz') is passed off as topaz. The more valuable yellow corundum, on the other hand, is known as 'oriental topaz.' The distinguishing characters of these are shown in the following table:—

	Topaz	Quartz 'Occidental topaz'	Corundum 'Oriental topaz'
Comp.	$(\text{AlF})_2\text{SiO}_4$	SiO_2	Al_2O_3
Cryst.	Orthorhombic	Rhombohedral	Rhombohedral
Sp.gr.	3.55	2.65	4.0
H.	8	7	9
Refr.			
Indices	1.61–1.63	1.54–1.55	1.76–1.77

L. J. S.

TOPAZ, ORIENTAL, v. CORUNDUM.

TOPAZ, SCOTCH, v. CAIRNGORM.

TOPAZ, SPANISH, v. CAIRNGORM.

TOPE-LIVER OIL. According to Chapman (Analyst, 1922, 203), the oil obtained by steaming the livers of the tope (*Galeus galeus*, family *Carchariidae*), found on all the coasts of the British Isles, has the following characteristics:—

Specific gravity (15°/15°)	0.9249
Iodine value (Wijs)	152.2
Saponification value	195.1
Unsaponifiable matters	1.14 p.c.
Refractive index at 15°	1.4803
at 20°	1.4778
Specific dispersion ($n_{\text{H}\beta} - n_{\text{H}\alpha}$)	0.0101
Brominated glycerides	42.5 p.c.
Insoluble in ether	

It is a pale-coloured oil, having a strong but not unpleasant odour, and is very similar to cod-liver oil. It is used* medicinally by local fishermen and in the dressing of leather.

TORBANITE or TORBANEHILL MINERAL v. PARAFFIN.

TORBERNITE or CUPRO-URANITE (*Kupferuranit*, Ger.). A mineral consisting of hydrated phosphate of uranium and copper

It crystallises as square (tetragonal) plates which possess a perfect micaceous cleavage with pearly lustre, parallel to their surface. The colour is bright grass-green, which distinguishes cupro-uranite at a glance from the closely-allied mineral autunite (*q.v.*) or calco-uranite. Sp.gr. 3.5; H. 2½. It is a mineral of secondary origin, occurring in the upper portion of lodes containing pitchblende and copper ores, and sometimes as an incrustation on the joint faces in granite. Fine specimens have been found at Gunnislake, Grampound Road, and Redruth in Cornwall. Other localities are Joachimsthal in Bohemia, Johanngeorgenstadt in Saxony, Sabugal in Portugal, Mount Painter in South Australia, Katanga in Belgian Congo, &c. To a limited extent the mineral has been mined, together with autunite, as a source of uranium and radium. L. J. S.

TORMENTILLA. The underground stems of *Potentilla Tormentilla* (Neck.) have been occasionally substituted for those of rhubarb in medicine. They contain from 5 to 6 p.c. of tannin, giving a dark-green precipitate with ferrous sulphate, bluish-red with ferric acetate; is also precipitated by gelatin and by tartaric acid (Stenhouse) (v. TANNINS).

TORREFACTION. Roasting ores in order to expel volatile substances, e.g. sulphur, arsenic, &c.

TOSCA. v. TUFF.

TOULOUOUNA or TULUCANA OIL. An oil obtained by pressing the kernels of *Caraia tuianensis* (Aubl.), v. CARAPA OIL.

TOULOURON OIL. A brown oil obtained from *Papirus Latro*. Used in Senegal as a remedy for rheumatism.

TOURMALINE (*Turmalin*, Ger.; from the Anglose *turamali*). A complex boro-silicate of aluminium, together with variable and mutually replaceable amounts of ferrous oxide, magnesia, and alkalis. As chemical types there may thus be distinguished iron-tourmaline, magnesian tourmaline, and alkali-tourmaline. Analysis shows: SiO_2 , 35-38; TiO_2 , 0-1; B_2O_3 , 9-11; Al_2O_3 , 30-42; Cr_2O_3 , 0-10 (rarely); Fe_2O_3 , 1-8; FeO , 0-17; MnO , 0-2; MgO , 0-1; CaO , 0-2; Na_2O , 0-2; K_2O , 0-2; Li_2O , 0-1; I_2O , 1-4; F, 0-1 p.c. Many different formulae have been suggested. Penfield and Foote (1899) regard the several varieties as salts of the hypothetical aluminoboro-silicic acid

With these wide differences in chemical composition, the sp.gr. ranges from 3.0 to 3.2, and the refractive indices (Na) = 1.6123-1.6155, = 1.6318-1.6354 (E. A. Welfing, 1900), but there are only very slight variations in the

by Penfield and Foote to the mass effect of the large acid radicle). The crystals are rhombohedral-hemimorphic, there being a different development of faces at the two ends. The habit is almost invariably prismatic, with deeply-grooved prism faces, the striations being parallel to the edges of the prism; the cross-section of the prism is triangular with straight or curved outlines. These peculiarities of form render tourmaline a mineral readily recognisable. As a consequence of the hemimorphism the crystals are pyroelectric. The material ranges from colourless to jet-black in colour, and may be any shade of red, yellow, green, or blue. In one and the same crystal there are often striking contrasts in the differently coloured zones. The more darkly coloured crystals are strongly dichroic, the ordinary ray vibrating perpendicularly to the principal axis being almost completely absorbed. On this property depends the use in polarising apparatus (e.g. the well-known tourmaline-tongs) of tourmaline plates cut parallel to the principal axis of a crystal.

Common black tourmaline (*schorl*) is of abundant occurrence in granite and metamorphic rocks, and is a frequent associate of tin ores. Coloured tourmalines are much used in jewellery, either as clear faceted stones or, when cloudy, as beads (H. 7½). The red is often called *rubellite*, and the blue *indicolite*, whilst fanciful names such as 'Brazilian emerald,' 'Siberian ruby,' &c., are also sometimes used. Within recent years large quantities of gem material have been quarried from the pegmatites of California, Madagascar, and the Usakos district, South-West Africa.

L. J. S.

TOUS-LES-MOIS is a species of arrowroot procured from the tubers of *Canna edulis* (Ker-Gawl. nat. ord. *Marantaceae*). The starch is obtained in the same manner as other descriptions of arrowroot. Under the microscope the granules show themselves to be unusually large, measuring from 0.0015 to 0.0037 inch in length and from 0.001 to 0.0027 in breadth; broad, flat, ovate. The hilum is situated at the narrow extremity, and the rings are very close, firm, and regular.

Tous-les-mois is used in admixture with cocoa preparations and as a food for infants, for which latter purpose it is bleached. V. STARCH.

TOXICODENDROL. The active principle of the 'Poison Ivy' (*Rhus Toxicodendron* Linn. and *R. venenata* [DC.]), is an oily substance possessing intensely irritating properties, found in all parts of the plant, the fruits giving 3.6, the leaves 3.3, and the stem 1.6 p.c. The degree of activity varies in the case of different persons; in some cases 1 mgm. produced hundreds of vesicles, and even 100 mgm. proved active in one case. The vesicant action was not immediate, a period of 24 hours to 7 or 9 days elapsing before the eruption appeared (Pfaff, J. Soc. Chem. Ind. 1897, 1037).

The poisonous substance is probably a glucoside; it is decomposed by acids yielding gallic acid, fisetin, and rhamnose. Cases of poisoning are said to be best treated with potassium permanganate* (Acree and Syme, Amer. Chem. J. 1906, 301).

The 'poison oak' (*Rhus diversiloba*, T. & G.) which is very similar in appearance to *R. toxicodendron*, has been examined chemically

by McNair (J. Amer. Chem. Soc. 1916, 38, 1417), who finds that the leaves and branches contain a substance of which the alcoholic extract is poisonous. The poisonous material is not, however, a glucoside of fisetin, rhamnose, and gallic acid, since none of these substances is produced on hydrolysis. Fisetin, rhamnose, and gallic acid are found in non-poisonous species of *Rhus*, and the natural glucoside of these substances is non-toxic.

TOXINS and ANTITOXINS.

TOXINS.

Infective diseases of man and animals, that is diseases which are contagious, infectious, or transmissible by inoculation, are caused by pathogenic (i.e. disease-producing) living organisms which are parasitic on or in the individual attacked. The parasitic organisms may be minute vegetable ones, principally bacteria, minute animal protozoa, or higher and large forms such as moulds, insects, and worms. The bacteria, and presumably also the protozoa, as a rule produce their deleterious effects principally by means of substances which are poisonous to the host, and which are elaborated by, or are derived from, the parasitic organisms. Even the larger parasites, such as worms, though acting mechanically and in other ways, may also elaborate poisonous substances.

In the early days of bacteriology, under the influence of the work of Panum, Selmi, Nencki and others on the products of putrefaction attempts were made to isolate from the cultures of the pathogenic organisms and from the tissues of the disease-stricken patients nitrogenous bodies of a basic and alkaloidal nature similar to the ptomaines of putrefaction, and Brieger in particular isolated such substances as typhotoxine from cultures of the typhoid bacillus and tetanine from the tissues of a case of tetanus (see art. PTOMAINES). It was soon found, however, that such basic substances are not, as a rule, the essential or specific toxic agents of the pathogenic bacteria, and some of those described by Brieger are quite likely artifacts, due to the methods of extraction employed.

The specific toxic agents of the bacteria, or *toxins*, as they may conveniently be termed, are substances of complex composition, which, so far as they have been investigated, seem occasionally to be protein in nature, or to be allied to the proteins or to the enzymes. The whole subject of the nature of toxins is still in a very indeterminate condition, so that any views expressed here must be regarded as tentative. In some instances the toxin appears to be a substance *sui generis*, in others it may be proteose in nature (tox-albumose), and in others it may be albuminous (tox-albumin). Of late, the conception has been gaining ground that toxins and other 'antigens' (v. *infra*, under *Antitoxins*) may be lipid substances or lipid-protein complexes. The toxin may be an excretory product, as it were, of the micro-organism, e.g. tetanus toxin (S. Martin), or may be formed by the action of enzymes, excreted by the micro-organism, on the constituents of the culture medium or of the tissues, e.g. anthrax toxin, or it may be a mixture of these two, e.g. diphtheria toxin (S. Martin), or it may be a protein or other con-

stituent of the bacterial cells themselves, e.g. typhoid toxin. Toxins which are excretory products, or are formed by the action of the organism on the culture medium, are termed *exo-toxins* or simply *toxins*, e.g. diphtheria, tetanus, and botulism toxins; those which are intimately associated with the bacterial cells are termed *endo-toxins*; the toxins of the majority of pathogenic bacteria belong to the latter class. The term toxin has also been extended so as to include various toxic bacterial extracts, such as tuberculin, the toxic proteins, &c., which are found in the higher plants and animals, e.g. abrin and ricin of the jequirity and castor-oil beans respectively, substances like eel serum, which is toxic on injection into other animals, and snake venom.

The bacterial *exo-toxins* may be prepared by cultivating the organisms in a suitable fluid culture medium under appropriate conditions for 1-4 weeks, and then filtering the fluid culture through a Pasteur-Chamberland porcelain, or a Berkefeld, filter. The filtrate is more or less toxic, and may be termed the toxin broth, the actual toxin contained in it may be concentrated in various ways, but extraction in a pure condition is at present impossible, owing to the difficulty of separating it from the constituents of the culture medium. Bacterial *endo-toxins* may be obtained by growing the organisms on a solid culture medium and extracting the bacterial mass with weak alkalis, &c., or by grinding up the bacterial paste in a mechanical disintegrator, such as Macfayden and Rowland's or Barnard's, and subsequent filtration through a porcelain filter (Proc. Roy. Soc. 1912 and 1911).

The bacterial toxins generally are unstable bodies, disappearing, or being converted into non-toxic modifications, on keeping, and destroyed by light, warming to 60°-70°, by acids, alkalis, and oxidising agents, and by digestive enzymes; owing to the last-named fact, the toxins usually are not toxic when taken by the mouth, but only on inoculation. They are much more stable in the dry condition than when in solution. They are insoluble in and are precipitated by strong alcohol, and are precipitated on saturation of their solutions with ammonium sulphate. Diphtheria and tetanus toxins dialyse very slightly through parchment, and they will pass through a gelatin-coated porcelain filter, which does not permit of the passage of serum albumin, suggesting that their molecules are smaller than those of the latter (Brodie, Journ. Path. and Bacter. 1897). They are probably levorotatory. The 'toxin,' in some instances at least, may contain more than one toxic constituent.

Diphtheria toxin was first investigated by Löffler. By precipitating broth cultures of the diphtheria bacillus with alcohol, he obtained a white toxic powder which he classed among the enzymes (Deut. med. Woch. 1890, Nos. 5 and 6). Roux and Yersin, by the cautious addition of calcium chloride, obtained the toxin entangled with the precipitate of calcium phosphate which comes down, and similarly regarded it as an enzyme (Ann. Inst. Pasteur, iii.). Brieger and Fränkel concluded that the toxin is a protein ('tox-albumin'); they found that it is precipitated by ammonium sulphate, but not by magnesium

sulphate, contains a relatively high percentage of sulphur and gives the biuret and Millon's reactions (Berl. klin. Woch. 1890, 241, 1133).

Brieger and Fränkel's method of preparing the diphtheria toxin was to saturate broth cultures with magnesium sulphate at 30°, filter from the precipitated globulin, &c., saturate the filtrate with ammonium sulphate at 30°, wash and dissolve the precipitate, dialyse to remove as much adherent salts as possible, and remove remaining traces of ammonium sulphate by the cautious addition of barium chloride; evaporate the filtrate to half the volume *in vacuo* at 40°, and precipitate with absolute alcohol. The precipitate was collected, redissolved, and precipitated with alcohol 6-8 times. Ultimate analysis gave the following figures: C 45.35, H 7.13, N 16.33, S 1.39, O 29.80.

Brieger and Boer subsequently prepared the diphtheria toxin in as pure a form as it has yet been obtained by precipitating broth cultures with a 1 p.c. solution of zinc sulphate or chloride. The precipitate of the zinc double salt is washed with feebly alkaline water and decomposed with carbon dioxide. The purified product gave the xanthoproteic, biuret, Adamkiewicz's, and Millon's reactions. A litre of broth culture gave about 3 grm. of the zinc double compound (Zeitsch. Hygiene, xxii. 267).

Sidney Martin isolated from diphtheritic membrane and from the spleen and other organs of diphtheria cadavers proteoses, chiefly deutero-albumose, and from the membrane alone an organic acid which was not identified. The latter is a yellowish amorphous body, becoming deep brown with alkalis, and is soluble in water and absolute alcohol, but not in ether, chloroform, or benzene. The proteoses were extracted by placing the minced tissues in absolute alcohol until the ordinary proteins were coagulated and rendered insoluble, extracting with water, and precipitating this extract with alcohol many times. Similar proteoses were obtained from cultures in alkali-albumin of the diphtheria bacillus (Brit. Med. Jour. 1892, i.).

Ehrlich concluded that the diphtheria 'toxin' contains two or more toxic constituents, as well as non-toxic bodies, 'toxoids,' derivatives, or degradation-products, of the toxin (*v. infra*, under *Antitoxins*).

Warden, Connell and Holly regard diphtheria toxin as a fat complex derived from dead and disintegrating bacilli in an emulsified or colloidal form which then becomes adsorbed upon colloidal particles in the broth culture medium, forming, with electrolyte, an adsorption entity constituting toxin (Journ. of Bacteriology, vi. 1921, p. 103).

Tetanus toxin was obtained in a somewhat concentrated form by Kitasato from anaerobic broth cultures of the tetanus bacillus (which produces lock-jaw), and he gave a detailed account of the action of heat and of a number of chemical reagents on the toxin broth (Zeitsch. Hygiene, x. 267). Brieger and Cohn precipitated veal-broth cultures by saturation with ammonium sulphate (*ibid.* xv. 1). The toxin formed a flocculent precipitate which floated; it was purified by redissolving, precipitating the protein with basic lead acetate, removing other soluble impurities by dialysis, and finally pre-

cipitating the dialysed solution with alcohol. Thus prepared, the tetanus toxin formed pale yellow, odourless, easily soluble scales, having a gummy taste; the solution was feebly laevorotatory. It contained only a trace of ash, did not give the Millon's and xanthoproteic reactions, and gave no precipitate with potassium ferrocyanide and acetic acid, nitric acid, or mercuric chloride. Boiled with ferric chloride it gave no red colour. With copper sulphate and sodium hydroxide it gave a slight violet colour. It contained no phosphorus and only a trace of sulphur, and ultimate analysis gave the following figures: C 52.08, H 8.1, N 15.71 (Brieger, Zeitsch. Hygiene, xix. 101). Subsequently, Brieger and Boer obtained the toxin by the method employed by them for isolating the diphtheria toxin (*vide ante*). On these facts Brieger considered that the tetanus toxin is not a true protein.

Hayashi, however, employing the Brieger-Boer method, or a modification of it, came to the conclusion that the tetanus toxin is a protein, and is a primary proteose (Arch. f. exper. Pathol. xlvii. 9). S. Martin also isolated proteoses, chiefly deutero-albumose, from the spleen of a cadaver, but they did not induce tetanic convulsions on inoculation. Tetanus cultures contain methyl-mercaptan and other sulphur compounds (Nencki, Monatsch. x.); but Fermi and Pernossi were unable to extract any basic substance from them (Zeitsch. Hygiene, xvi. 385). Besides the convulsive constituent, 'tetano-spasmin,' the toxin broth also contains a substance, 'tetano-lysin,' which is a solvent for red-blood corpuscles. The purified tetanus toxin is probably the most toxic substance known, less than 0.5 mgrm. being a fatal dose for a man.

Anthrax toxin. Hankin obtained proteoses from cultures of the anthrax bacillus, and Brieger and Fränkel a tox-albumin from animals dead of anthrax. Marnier, by precipitating cultures with ammonium sulphate, isolated a toxic substance which he considered to be neither protein nor basic (Ann. Inst. Pasteur, ix. 533). S. Martin (*loc.*) obtained both from cultures in alkali albumin, and from animals dead of anthrax, proteoses, chiefly deutero-albumose, and a nitrogenous basic substance, both of which were toxic. The toxins are formed mainly by the action on the culture medium of enzymes excreted by the bacillus. Endo-toxins may also be formed.

The toxins of the majority of other pathogenic bacteria are endo-toxins. That is to say, if the organisms be grown in a fluid medium, the filtrate is almost non-toxic, but the dead and disintegrated bacterial cells yield toxic substances. Toxins of protozoan organisms are not known with certainty.

Tuberculin. The original or old tuberculin of Koch is obtained by boiling, concentrating over a water-bath and filtering glycerin broth cultures of the tubercle bacillus. It is toxic to healthy animals only in large doses, but minute doses cause considerable disturbance in tuberculous patients and animals, and this reaction is made use of for the detection of tuberculous infection. It contains small quantities of proteoses, extractives, and salts, and traces of basic bodies. Small quantities of an acid

substance, probably teraconic acid, possibly derived from the bacillar cells, are also present in cultures of the tubercle bacillus. Other tuberculous and bacterial extracts have been prepared.

It must be clearly recognised that in those cases in which the toxin is supposed to be protease or other protein, the latter may be merely constituents of the culture medium by which the toxin is entangled or adsorbed.

[On toxins, &c., see Oppenheimer in Kolle and Wassermann's *Handbuch der Pathogenen Mikroorganismen*, vol. i. (Bibliog.); Vaughan and Novy, *Cellular Toxins*, 1902 (Bibliog.); S. Martin, *Man. of Gen. Pathology*, 1904, and *Reps. Med. Off. Loc. Gov. Bd.* 1889-1900; also various papers in the *Ann. Inst. Pasteur*; *Zeitsch. Hygiene, Centr. Bakteriol.* Abstracts also in chemical journals.]

Snake venom. Poisonous snakes are divided into two groups, the colubrine and viperine. The venom, which is secreted by glands in connection with the mouth, may be limpid or syrupy, pale yellow, orange or greenish in colour, odourless and tasteless, sp.gr. 1.04 (rattlesnake), 1.11 (cobra), 1.08 (Russell's viper). Microscopically, it contains few elements, and when dry resembles dry albumin. The reaction of the pure venom is acid; it contains C, H, O, N, and S in the proportions found in proteins, gives the protein reactions, is precipitated with alcohol, ammonium sulphate, sodium chloride, and coagulates on heating. Viperine venoms lose their toxicity on heating to 80°-85°, but colubrine venoms require to be heated to 120° to destroy their toxicity. The active toxic substances of venom are coagulable proteins (globulin), proteases, toxins allied to bacterial toxins, and Faust has separated a non-nitrogenous toxic substance, *ophiotoxin*. The proteases are chiefly proto- and hetero-protease. The venoms are complex mixtures containing some, but not in any venom all, of the following active substances: 1. *Neurotoxins* acting on (a) respiration, (b) heart, (c) muscle, particularly the diaphragm; 2. *Cytolysins*, solvents for (a) blood corpuscles, (b) vascular endothelium, (c) other cells; 3. *Fibrin ferment* inducing blood-clotting, and others. The venoms thus produce paralysis of voluntary muscles and of the heart and respiration, solution of the red- and white-blood corpuscles and hæmorrhages, and the blood may be either fluid or coagulated in the vessels, and the bodies of the dead putrefy rapidly owing to the destruction of the anti-bacterial properties of the blood. The venom is most active when injected into a blood-vessel, whereas in the subcutaneous tissues it may take some time to act: it is also readily absorbed from the eye. Taken by the mouth, provided there are no cracks or ulcers, colubrine venom is harmless, but viperine venom may cause gastritis, &c., and even death. The hæmolysins which cause solution of the red corpuscles are of the nature of 'amboceptors,' requiring a 'complement' (c. *infra* under *Bactericidal sera*) to activate them. In some cases the venom alone can hæmolyse washed red corpuscles *in vitro*, e.g. man, dog, &c., in others it has no action on washed corpuscles but becomes active on the addition of serum. Some corpuscles, therefore, contain the activating 'complement,' others do

not, and, hence, are not hæmolyzed when washed. Kyes, Sachs, Flexner, and Noguchi have shown that lecithin and lecithides in the corpuscles are the complement-like activators of the hæmolytic amboceptors. A venom which is inactive on washed corpuscles becomes active on the addition of lecithin or even of oleic acid or other fatty acids and soaps.

By the cautious treatment of an animal with increasing doses of venom an antitoxin ('antivenin') is formed which has the power of neutralising the particular venom.

The venom of scorpions (against which an antitoxin can be prepared) and spiders is probably protein in nature; of mosquitos and gnats it may be the products of certain bacteria or moulds present in the oesophageal sacs; of bees a protein-free organic base. The formic acid present in the 'venom' of ants, bees, &c., is probably not the active toxin. Many fish are also poisonous by their bites or by spines connected with special glands. Toads and salamanders have acid and basic poisons in the skin glands. Jelly-fish and sea-anemones have stinging glands. Extracts of intestinal worms may be toxic.

[On snake venom, see Martin and Lamb in Allbutt and Rolleston's *System of Med.* vol. ii. pt. ii. (Bibliog.); *Sc. Memoirs of the Gov. of India*, Nos. 1, 3, 4, 5, 7, 10, 16, 17; Faust, *Die Tierischen Gifte* (Braunschweig, 1906, Bibliog.); Noguchi, *Journ. Exper. Med.* viii. and ix.; and *Snake Venoms* (Smithsonian Inst. Publication); Calmette, *Venoms and Venomous Animals* (Bale). On other animal toxins, see Castellani and Chalmers, *Manual of Tropical Med.* (Bibliog.).]

ANTITOXINS.

It is a remarkable fact that proteins on injection into a suitable animal (the domestic mammals generally) give rise to the formation of 'anti-bodies'—substances having properties in some way opposed to those of the proteins injected—which accumulate in the blood of the treated animal. This property of generating anti-bodies, according to Abderhalden, is characteristic of the animal body and is most active against injected cells, proteins, and allied substances. The substance which generates the anti-body is termed the 'antigen.' Antigens, with certain doubtful exceptions, seem to be proteins or substances related to proteins, or possibly lipoids or lipid-protein complexes. Hence mineral poisons, alkaloids, carbohydrates, &c., form no anti-bodies. If a protein such as human serum is injected into a rabbit, the serum of the treated rabbit gives a white precipitate when mixed with human serum, and to a less extent with apes' serum, but with no other sera—a specific 'precipitin' for human serum has been formed. By this means bloodstains, flesh, &c., can be identified with great certainty. By injecting an enzyme, such as rennin, anti-enzyme is formed which inhibits the action of the enzyme; by injecting red-blood corpuscles 'hæmolysin,' solvent for red-blood corpuscles, is formed. If a poisonous protein is injected (in properly graduated doses so as to avoid killing the animal), such as ricin or snake venom, an anti-body is generated which completely neutralises the poisonous

action of the substance injected. The same is the case with toxins like diphtheria and tetanus toxins. By repeated injections of a horse with increasing doses of the toxin, the animal becomes less and less susceptible, so that it can finally tolerate huge doses of the toxin without harm, and coincident with the development of this insusceptibility antidotal substances appear in its blood, and may be obtained in the blood-serum by bleeding the animal and allowing the blood to clot. The antidotal or neutralising substance to toxin is termed antitoxin; it is a fairly stable substance, and by obtaining and bottling the serum aseptically it may be preserved, and is employed to treat the respective disease in man.

The antitoxic serum contains a variable amount of the antitoxic constituent and for therapeutic use must be standardised.

The antitoxic constituent is probably protein (globulin) in nature, or at least is associated with the globulin constituent of the serum. The globulin content of the blood of antitoxin-yielding horses is frequently higher than normal, and the antitoxin may be precipitated by saturation of the serum with magnesium sulphate, or by partial saturation with ammonium sulphate; it comes down with the eu-globulin fraction of the serum globulin.

Brieger and Boer (*l.c.*) separated the antitoxic constituent by the following methods: (a) 4 grms. of potassium iodide or chloride are added to 10 c.c. of the antitoxic serum diluted with an equal quantity of distilled water. After solution, 4-5 grms. of finely-powdered sodium chloride are added, the mixture is kept at 30°-37° for 18-20 hours, and the precipitate (0.4 gm.) is collected; it is the antitoxic portion of the serum with a slight admixture of protein and salts.

(b) The proteins of the antitoxic serum are precipitated with basic lead acetate containing a trace of ammonia, the precipitate is filtered off and the filtrate is saturated with ammonium sulphate. The precipitate is collected and redissolved, the solution is dialysed, and evaporated to dryness. A light powder is obtained (0.06 gm. from 10 c.c. serum) which contains the antitoxic constituent.

(c) 10 c.c. of the serum are diluted with 50 c.c. of distilled water, and 20 c.c. of a 1 p.c. solution of zinc sulphate or chloride are added. The precipitate is collected, dissolved in feebly alkaline water, and the zinc compound is decomposed with carbon dioxide. The antitoxic constituent is present in solution when the precipitant is zinc chloride, but is entangled in the zinc carbonate precipitate when the precipitant is zinc sulphate.

Homer has elaborated a very exact method by partial saturation of the serum with sodium chloride and ammonium sulphate, whereby practically the whole of the antitoxin may be concentrated and recovered from a weak antitoxic serum (*Journ. of Hygiene*, 1918, 22, 51); also MacConkey, *ibid.* 1924, 22, 413.

Anti-venin, the antidotal serum for snake-bites, is a truly antitoxic serum.

In the case of pathogenic micro-organisms which do not form an exo-toxin, an antidotal anti-serum can also be prepared by the injection of the bacterial cells, first killed cultures, and sub-

sequently the living organisms, but such serums are not nearly so potent as the antitoxic serums produced by exo-toxins, and many are practically useless for treating the respective diseases, e.g. typhoid and cholera serums. The principal action of such an anti-serum is bacteriolytic, i.e. it brings about solution of the micro-organism.

In this bacteriolytic reaction (and similarly in the solution of red-blood-corpuscles by a 'hemolytic' serum) two protein substances seem to be concerned. The fresh anti-serum is solvent for bacteria, but not the old, nor the heated (to 56°C.) anti-serum. The two latter may be rendered active again by the addition of fresh normal serum. That is to say, by injection of the bacteria (or blood corpuscles), a new and relatively stable substance is formed, which reacts with an unstable normal constituent of the serum, the two together bringing about bacteriolysis (or hemolysis). To the former, the name of 'immune body' or 'amboceptor,' to the latter, 'alexin' or 'complement,' is given.

Specificity is the distinguishing feature of the anti-bodies; the anti-body produced by an antigen always reacts most actively with this particular antigen.

The formation of anti-bodies is usually explained by Ehrlich's 'side-chain theory.' This supposes that the protoplasmic molecules of the cells of the animal have an affinity for the substance injected (the 'antigen') which gives rise to the anti-body, so that the antigen becomes incorporated with the protoplasm. The union of the antigen with the protoplasm is assumed to be brought about by the combination of atomic groups comparable to the side-chains of a ring nucleus, those of the protoplasmic molecule being termed 'receptor groups,' those of the antigen 'haptophore' (=binding) groups. The poisoning caused by a toxin is thus due to the union of the toxin with the protoplasm by the combination of the haptophore groups of the toxin with the receptor groups of the protoplasm. Should the animal's protoplasm not possess receptor groups having an affinity for the haptophore groups of the toxin, the toxin would not be poisonous to this animal. This is often the case—a toxin is never poisonous to all animals. Now Ehrlich assumed that the protoplasmic receptor groups fulfil physiological functions in the animal, e.g. nutrition, &c., so that when a toxin becomes united with the protoplasm a defect is created, whereby the latter cannot properly fulfil its physiological functions. Provided the dose of toxin be not too large, recovery ensues, due to the regeneration by the protoplasm of the particular receptor groups involved. This process is repeated again and again, and as a result of the continued stimulation by the numerous doses of toxin, the protoplasm ultimately forms the receptor groups in question in large excess—much more than is necessary simply to repair the damage done. A considerable proportion of the now very numerous receptor groups then becomes detached from the protoplasm, accumulates in the blood, and constitutes the anti-body. The antidotal property of antitoxin is, therefore, due to the fact that it saturates the haptophore groups of

the toxin so that the latter is then unable to combine with the protoplasm.

[On antitoxins, &c., see Ehrlich, *Die Wertbemessung des Diphtherieheilserums*, 1897; *Trans. Jenner Inst. of Prev. Med.* ii.; Croonian Lect. Roy. Soc. Lond. 1900; and *Collected Papers on Immunity*, 1909; Hewlett, *Serum and Vaccine Therapy*, Churchill, 1910 (Bibliog.); Kolmer, *Infection, Immunity and Biologic Therapy* (Saunders, 3rd ed. 1923, Bibliog.)]

Toxin-antitoxin reaction.—The neutralisation of toxin by antitoxin is approximately quantitative, and the toxin and antitoxin unite. This is shown by the fact that if a recently-made mixture of toxin and antitoxin be filtered through a gelatin-coated porcelain filter, the toxin passes through into the filtrate, but not the antitoxin (see *ante*). If, however, the mixture be allowed to stand so that interaction may occur, the toxin can no longer be separated from the antitoxin by this method. The interaction between the two is slow, is retarded by cold, and is hastened by warming (Brodie, *l.c.*; Martin and Cherry, *Proc. Roy. Soc. Lond.* lxxiii.).

The exact nature of the union of toxin with antitoxin, 'the toxin-antitoxin reaction,' has been the subject of much controversy, and three principal hypotheses have been formulated to explain it. Ehrlich held that the union is comparable to the combination of a strong acid with a strong base, i.e. the reaction is a complete one, and there cannot be at the same time in a mixture of toxin and antitoxin, free toxin and antitoxin, together with neutralised toxin. The strictly quantitative relation of toxin and antitoxin supported this view, viz. if 10 equivalents of antitoxin exactly neutralise 10 equivalents of toxin, then 100 equivalents of antitoxin will exactly neutralise 100 equivalents of toxin. But it is found that if 100 fatal doses of toxin (for the guinea-pig) are just neutralised by 100 equivalents of antitoxin, 101 fatal doses of toxin + 100 equivalents of antitoxin is *not* a fatal mixture, and generally 108–116 (sometimes many more) fatal doses of toxin must be added to the 100 equivalents of antitoxin to render the mixture a fatal one (the Ehrlich phenomenon). Ehrlich explained this by supposing that the 'toxin broth' contains not one toxic substance only, but is a mixture of toxin and toxone, the latter being much less toxic than toxin, though requiring as much antitoxin to neutralise it as toxin does. Toxin has, however, a greater affinity for antitoxin than toxone has, so that when more toxin is added to a neutral mixture of toxin broth (containing toxin and toxone) and antitoxin, the toxone-antitoxin complex present is dissociated, and the antitoxin set free then combines with the added toxin, and it is not until the added toxin is more than can be neutralised by the freed antitoxin that the mixture becomes fatal. Ehrlich, in fact, was forced to conclude that toxin broth contains diverse toxic bodies. The second hypothesis, that of Arrhenius and Madsen, while admitting that the union of toxin with antitoxin takes place in definite proportions, regards it as comparable to the neutralisation of a weak base by a weak acid, e.g. ammonia and boric acid, the reaction is incomplete, though resulting in equilibrium, so that free toxin and antitoxin exist in the mixture, together with the toxin-

antitoxin complex. The quantity of free toxin would be a function of the relation existing between the initial quantities of the two substances. The Ehrlich phenomenon is quite explicable on this hypothesis, and there is no need to postulate the existence of toxone or other toxic constituents in toxin broth. But other phenomena concerning the neutralisation of toxin by antitoxin do not seem explicable by either of these hypotheses. One of these is what is known as the 'Danysz effect,' which is obtained with many different toxins and their corresponding antitoxins. If a mixture consisting of *a* parts of toxin and *b* parts of antitoxin is exactly neutral, when the whole of the toxin *a* is mixed with the antitoxin; a similar mixture of *a* parts of toxin and *b* parts of antitoxin, prepared by adding the toxin in several fractions to the antitoxin is *still toxic*. This is explained according to Arrhenius and Madsen as being analogous to the neutralisation of chloracetic acid by sodium hydroxide. If equivalent quantities of the acid and base are taken, and only half the acid is added in the first instance to the whole of the hydroxide, the acid is wholly neutralised, leaving half the base free. This then slowly reacts upon the sodium chloracetate forming sodium chloride and glycolate, and the solution ultimately becomes neutral. (Communications from the Nobel Institute, I, iii. 1906). The Danysz effect has its counterpart in the neutralisation of arsenious acid with ferric hydroxide. Bordet maintains that the union of toxin with antitoxin takes place in variable proportions, and resembles the phenomenon of adsorption, similar to the colouring of filter-paper with a dye. Thus, if pieces of filter-paper be placed in a dilute solution of a dye at sufficiently long intervals, the first pieces become distinctly coloured, but the last pieces remain colourless through lack of free dye in the solution. On the other hand, if all the pieces of paper are simultaneously placed in the solution, they all become similarly coloured. Likewise, a mixture of toxin and antitoxin, in which the latter is in insufficient quantity to render the mixture completely innocuous, does not contain, according to Bordet, a certain quantity of free toxin, together with neutralised toxin, but contains only molecules of toxin insufficiently neutralised, because the antitoxin is diffused over all the molecules of toxin, each of which, therefore, fixes an amount of antitoxin too small completely to inactivate it. In a series of mixtures containing increasing quantities of antitoxin for a uniform amount of toxin, each molecule of the latter will, therefore, be united to increasing quantities of antitoxin. The toxicity of the poison will thus become weaker and weaker, and such a series of mixtures will possess all degrees of toxicity. From this conception, reversibility of the toxin-antitoxin combination should exist, and toxin can sometimes be recovered from the toxin-antitoxin complex, showing that it is not destroyed in the interaction. Reversibility can be demonstrated in the case of some antigen-antibody systems, a reversibility which is variable and generally incomplete. On the whole, almost every phenomenon of the toxin-antitoxin reaction seems to be explicable on Bordet's adsorption hypothesis, which is not the case with other hypotheses. Specificity is not explained by

it, nor is it explained by other hypotheses; it may be due to secondary interactions.

[On the toxin-antitoxin reaction, see Ehrlich, Deutsch. med. Woch. 1898; Arrhenius, Immunochimistry (Macmillan Co., 1907), and Quantitative Laws of Biological Chemistry (Bell, 1915), Ergebnisse der Physiol. vii. Jahr., 1908, and Jour. of Hygiene, viii.; Bordet, Ann. Inst. Pasteur. 1899, 1900, 1903; Craw, Jour. of Hygiene, vii., ix.; McKendrick, Proc. Roy. Soc. Lond. B. 1911; Gengou, Jour. State Med. 1912, xx. (Summary and full Bibliog.). Many abstracts in J. Chem. Soc.]

Anaphylaxis. Under certain conditions, an antigen on injection instead of conferring insusceptibility gives rise to increased susceptibility, and this may occur not only with definite toxins but also with proteins, such as egg-white and blood-serum, which are ordinarily innocuous. Thus, if a minute dose of horse-serum be injected into a guinea-pig and three weeks later a second somewhat larger dose be injected, the animal will collapse and probably die in a few minutes. This state of increased susceptibility is known as 'anaphylaxis.' If a course of serum injections be given at intervals not exceeding 14 days, anaphylaxis does not occur. The production of anaphylaxis has been explained as follows: the first serum injection is followed by the formation of an anti-body. This anti-body then reacts with the second dose of serum and in the presence of complement generating a substance, 'anaphylatoxin,' which causes spasm of the bronchial muscles and suffocation. R. T. H.

TOXYNONE. Trade name for sodium m-acetylaminomercuribenzoate

TRACHYTE. A volcanic rock composed mainly of alkali-felspar with usually only small amounts of ferro-magnesian minerals. The presence of the latter give the varieties hornblende-trachyte, augite-trachyte, and mica-trachyte. In mineral and chemical composition they correspond to the coarse-grained plutonic aenities; whilst in appearance they are very like the rhyolites, differing from these in having little or no free silica (when present this is often tridymite rather than quartz). The rock is fine-grained and usually light-greyish in colour. Owing to its more or less cellular structure, it is harsh and rough to the touch, hence the name, from *τραχύς*, rough. Sp.gr. 2.2-2.7; porosity 3-6 p.c.; crushing strength 455-730 tons per square foot. In the normal potash-trachyte the felspar is orthoclase of the sanidine variety, which, besides being present in the groundmass, may form porphyritic crystals sometimes of large size (e.g. on the Drachenfels on the Rhine). In the soda-trachytes anorthoclase and albite are also present. With increasing alkalis there is a passage to phonolite (q.v.). The following analyses are of trachyte from: I, Plateau de l'Angle, Auvergne. II, mica-hypersthene-trachyte, from Monte Amiata, Tuscany (also SO₂ 0.08, Cl 0.01, x 0.33, Li₂O, trace). III, Algersdorf, Midland Mountains of Bohemia (also BaO 0.06, Cl, F, traces: contains sanidine 60, plagioclase 30, augite 5, magnetite 2, sphene 0.8, apatite 0.5 p.c.). IV, 'Piperno' from Arecco quarries, Pianura, Naples (also NaCl 0.19). V, Whitton Hill, Jedburgh, Scotland (Old Red

Sandstone age). VI, Garleton Hills, Haddingtonshire (Carboniferous age).

Recent and Tertiary trachytes are found in the Rhenish and Eifel district, Auvergne, central Italy, Canary Islands, &c. These are used on the Continent for building stones, and occasionally for millstones. A variety called locally *piperno* is distinguished by dark flame-like streaks parallel to the lines of flow in a lighter ground; this is from Pianura and Soccavo near Naples, where it is used as a building stone. In the British Isles the trachytes of the Exeter district are of Permian age, and those of the central valley of Scotland of Carboniferous age; these are quarried for road-stones. L. J. S.

TRAGACANTH. *Tragacanthin v. Gums.*

TRASS v. TUFF.

TRAUMATOL v. SYNTHETIC DRUGS.

TRAVERTINE, Calc-sinter, or Calcareous Tufo (*Tuf calcaire*, Fr.; *Kalktuff*, *Tuffstein*, Ger.). A porous, cellular variety of limestone formed by the direct chemical precipitation of calcium carbonate, as the mineral calcite, from calcareous springs. It is of common occurrence in limestone districts, more particularly in those of declining volcanic activity. The liberation of carbon dioxide, on which the precipitation depends, is assisted by the agitation of the water in rapidly-running streams and cascades, and also to a considerable extent by water plants and algae, the material being often deposited around and encrusting reeds, twigs, and mosses. Even in the hot springs at Karlsbad in Bohemia microscopic plants have been found to be important agents in determining the deposition of the calcareous tufo or *Sprudelstein*, which here consists of the mineral aragonite.

The typical locality is at Tivoli, the ancient Tibur, near Rome; hence the name, from the Latin *lapis tiburtinus*, through the Italian *tiburtino* and its corrupted form *travertino*. Here the most important deposit, with a thickness of 500 feet, occupies the site of an ancient crater lake into which issued the sulphuro-calcareous waters of the Acque Albule thermal springs. The material is being deposited under the same conditions at the present day in the Lago di Zolfo in the Roman Campagna. It is also seen in process of formation at the cataracts of the Anio at Tivoli. Travertine is the principal building stone of ancient and modern Rome. The quarries of Barco, on the Anio, furnished the stone for the Colosseum, and those of Fosse the material for St. Peter's church. To supply modern Rome new quarries have been opened at the Villa Adriana below Tivoli. Roman travertine has also been exported, being used,

for instance, for the columns supporting the arched roof of the new (1910) railway station in New York. The stone is whitish or light cream-coloured, porous, and with wavy lines of lamination; sp.gr. 2.35. When freshly quarried it is soft enough to be cut with a saw, but it hardens on exposure (N. Pelati, I Travertini della Campagna Romana, Rome, 1882; P. Zezi, in H. J. Johnston-Lavis's *South Italian Volcanoes*, Naples, 1891, 83).

Similar deposits of travertine are formed by the thermal springs at Clermont and Vichy in the Auvergne, Hieropolis in Asia Minor, &c. Analyses of travertine from Vichy (C. Girard and F. Bordas, C.R., 1891, 132, 1423) show CaCO_3 , 91.71-97.17, MgCO_3 , 1.01-2.10 p.c., with small amounts of carbonates of sodium, potassium, manganese, and iron, sodium phosphate, aluminium sulphate, ferric arsenate (trace to 0.342 p.c.), alumina, silica, insoluble residue, and traces of copper, barium, lithium, and chlorine. In the British Isles small deposits are found in limestone districts, e.g. at Matlock Bath in Derbyshire, Knaresborough in Yorkshire, and it was formerly quarried at Dursley in Gloucestershire and elsewhere as a building stone, but now it is employed only for rock-gardens and aquaria. In all these instances the travertine is of recent formation, but material of the same mode of origin, though now more compacted, is met with in the geological series of sedimentary rocks

L. J. S.

TREACLE *v.* SUGAR.

TREE WAX *v.* *Insect wax*, art. WAXES.

TREHALOSE *v.* CARBOHYDRATES.

TREMOLITE *v.* ASBESTOS AND HORNBLENDE.

TRENT SAND. A sand found in the Trent, Severn, and in other rivers; used for polishing.

TRICALCOL. Trade name for a combination of tricalcium phosphate and albumen.

TRICARBIN (*Glycarbin*). Glyceryl carbonate.

TRIDECOIC or **TRIDECYLIC ACID** $\text{C}_{13}\text{H}_{25}\text{COOH}$ is obtained by the oxidation of methyl tridecyl ketone; it crystallises in thin plates; m.p. 40.5°; b.p. 236° (100 mm.) (Krafft, Ber. 1879, 1668).

TRIDYMITE. One of the three crystalline modifications of native silica, SiO_2 , of much less common occurrence than quartz (*q.v.*) but more frequent than cristobalite (*q.v.*). The crystals have the form of thin hexagonal plates or scales, which are often grouped with a fan-like arrangement or in rosettes. These crystals are, however, pseudo-hexagonal, since, when examined under the polarising microscope, they are seen to be built up of two or more optically biaxial individuals, the symmetry of which is probably orthorhombic. At a temperature of 117° these optical anomalies disappear, and the crystals are then optically uniaxial and truly hexagonal. The hexagonal plates themselves are also twinned together, often in radial groups of three; hence the name of this mineral, from *tridymos*, threefold. Other more complex types of twinning also exist, producing at times pseudocubic forms. The crystals are dull and of a white or greyish colour. They are quite small, usually 1 or 2 mm. across, and only exceptionally as much as $\frac{1}{2}$ cm. Sp.gr. 2.28-2.3; H. 7; mean refractive index (Na) 1.477. In addition

to the much lower sp.gr., the mineral also differs from quartz in being soluble in a boiling solution of sodium carbonate. The crystals are, however, often altered to an aggregate of differently orientated grains of quartz, being, in fact, paramorphs of quartz after tridymite.

Tridymite occurs principally in acid volcanic rocks—rhyolite, andesite, and especially trachyte—the crystals being attached to the sides of cavities in the rock. It is also found in blocks of sandstone and quartzite that have been caught up and baked by lavas. Well-known localities are in trachytes at the Euganean Hills near Padua, the Drachenfels on the Rhine, Mont Dore in Auvergne, &c. At the Cerro San Cristobal, near Pachuca in Mexico, it occurs together with cristobalite in andesite. Other modes of occurrence are: as crystals embedded in opal; in zeolitised Roman tiles at the hot springs of Plombières in France; in fulgurites produced by the fusing of siliceous rocks by lightning; and rarely (as 'asmanite') in meteoric stones and irons. It has also been observed as a furnace product, e.g. in the vitrified walls of zinc muffles, and as fibrous concretionary masses in blast furnaces; and it has been formed by the burning of stacks of straw. It has been produced artificially by a variety of methods, both by wet methods (hot solutions under pressure) and by dry fusion. The silica skeleton obtained by dissolving silicates in blowpipe beads of microcosmic salt consists of tridymite. The best crystals are obtained from quartz in a sodium tungstate fusion. The products are only to be distinguished by their optical characters under the microscope. But the very frequent formation by artificial means unintentionally has only recently been recognised. As noted below, quartz is converted into tridymite at 870° with a considerable increase in volume (16.2 p.c., corresponding to the change in sp.gr. from 2.65 to 2.28). This has an important bearing on the siliceous refractory materials used for furnace linings and silica-bricks. Coarsely powdered quartzite quickly heated to 1400° in presence of a small quantity of a catalyst is converted after five or six hours into almost pure tridymite (Rebuffat, Trans. Ceram. Soc. 1923-24, 23, 14; J. Soc. Chem. Ind. 1924, 43, B. 514).

In addition to the reversible inversion of α -tridymite to β -tridymite at 117° noted above, the heating curve shows a second break at 163°, indicating another inversion β -tridymite \rightarrow β' -tridymite. Here there is no observable change in the optical characters, and the change is perhaps one of degree of symmetry, analogous to α -quartz \rightarrow β -quartz at 575°. At ordinary temperatures quartz is the only stable crystalline modification of silica, but at 870° it passes over into tridymite with an accompanying increase in volume. At 1470° this tridymite is changed into cristobalite, which melts at 1625°. Tridymite is therefore the stable form between the temperatures 870° and 1470°, but the velocity of transformation being slow it can also exist at lower temperatures. In this connection we

¹ C. N. Fenner, *The Stability Relations of the Silica Minerals*, Amer. J. Sci. 1918, 26, 331, 37, also Shepherd, Rankin, and Wright, *ibid.* 1909, 28, 332; C. Johns, *Geol. Mag.* 1906, 3, 118. Ferguson and Merwin, *Amer. J. Sci.* 1918, 46, 417 give the melting-point of tridymite as 1670° and of cristobalite as 1710°.

may recall the frequent occurrence in nature of paramorphs of quartz after tridymite; and also the fact that tridymite is not found in older (pre-Tertiary) volcanic rocks. L. J. S.

TRIFOLIN v. GLUCOSIDES.

TRIGEMIN, TRIPHENIN, v. SYNTHETIC DRUGS.

TRIGONELLINE (*Methyl betaine of nicotinic acid*) $C_7H_{11}NO_3$ is an alkaloid which occurs in the seeds of *Trigonella Foenum-graecum* (Linn.); in ordinary peas (*Pisum sativum* [Linn.]); in hemp seeds (*Cannabis sativa* [Linn.]) (Jahns, Ber. 1885, 18, 2518; Schulze and Frankfurt, *ibid.* 1894, 27, 769; Schulze and Winterstein, Landw. Versuchs. Stats. 1895, 46, 23); in commercial strophanthine and in the seeds of *Strophanthus hispidus* (DC.) and *S. Kombé* (Oliver) (Thoms, Ber. 1898, 31, 271, 404; Karsten, Chem. Zentr. 1902, ii. 1514). Trigonelline has also been found in an animal, the sea-urchin (*Arbacia pustulosa*) (Holtz, Kutscher and Thielmann, Z. Biol. 1924, 81, 57; Chem. Soc. Abstr. 1924, 126, i. 907).

Preparation.—The powdered seeds are extracted with alcohol; after distilling off the latter, lead acetate and caustic soda are added, and the alkaloid is separated by means of potassium bismuth iodide and sulphuric acid. The precipitate is then treated with caustic soda to separate albuminoids, the filtered solution is neutralised with sulphuric acid and precipitated with mercuric chloride. The choline so precipitated is removed by filtration, the filtrate acidified with sulphuric acid, and the trigonelline in the form of its mercury iodide salt is then precipitated. The free base is obtained by decomposing the double salt with a sulphide (see Schulze, Zeitsch. physiol. Chem. 1909, 80, 155).

Trigonelline has also been obtained by treating nicotinic acid with methyl iodide, and the product of the reaction with silver hydroxide (Hantzsch, Ber. 1886, 19, 31); or by the oxidation of nicotine *iso*-methoxyhydroxide, with potassium permanganate (Pictet and Genequand, Ber. 1897, 30, 2117, 2122).

Trigonelline crystallises with one molecule of water, forming colourless, flat prisms of feeble saline taste and neutral reaction. It is hygroscopic, is readily soluble in water, sparingly soluble in alcohol, insoluble in ether, benzene, and chloroform. When heated, it loses its water of crystallisation and dissolves or melts in the latter at 130°. The anhydrous alkaloid darkens when heated at 200°, and melts at 218° (decomp.). When heated with barium hydroxide at 120° trigonelline evolves all its nitrogen as dimethylamine, and when heated with excess of hydrochloric acid, it yields nicotinic acid and a gas, probably methyl chloride (Jahns, Ber. 1887, 20, 2840). It gives the usual reactions of an alkaloid with reagents.

On reduction of trigonelline with hydrogen in presence of platinum black it forms products resembling, but apparently not identical with, those of arecaidine (Winterstein and Weinhegen, Zeitsch. physiol. Chem. 1917, 100, 170).

A *hydrochloride*, *platinohydrochloride*, and two *aurochlorides* $C_7H_{11}NO_3 \cdot HCl \cdot AuCl_3$, m.p. 198°, and $4(C_7H_{11}NO_3) \cdot 3HCl \cdot 3AuCl_3$, m.p. 186° (Jahns, l.c.; Schulze and Frankfurt, l.c.), are known. The ferrocyanide and ferricyanide crystallise in red and yellow prisms respectively (Roeder, Ber.

1913, 46, 3724). For the physiological action of trigonelline, see Kohlrausch, Chem. Zentr. 1909, ii. 465; Zeitsch. Biol. 1911, 57, 273; for its origin, see Schulze and Trier, Zeitsch. physiol. Chem. 1910, 67, 46 (v. BETAINES).

TRIHIDROXYBENZENE v. PHENOL AND ITS HOMOLOGUES.

TRIKETOHYDRINDENE v. KETONES, INDENE.

TRIKETONES v. KETONES.

TRIMETHOL. Trimethylmethoxyphenol.

TRIMETHYLACETIC ACID v. VALERIC ACIDS.

TRIMETHYLBENZENES v. CUMENES.

TRIMETHYLENE v. PROPYL.

TRIMETHYLHISTIDINE v. BETAINES.

TRIMETHYLHYDROXYBENZENE v. PHENOL AND ITS HOMOLOGUES.

TRIMYRISTIN. Piettre and Roeland (Compt. rend. 1924, 278, 2283; Analyst, 1924, 49, 437) obtained 2 grms. of trimyristin (see Vol. IV., p. 405) by dissolving the fat from one litre of milk in a mixture of ether and alcohol and allowing the solution to cool slowly.

TRINITRIN. Syn. for nitroglycerin.

TRINITROPHENOL v. PICRIC ACID.

TRIONAL (*diethylsulphonemethylethylmethane* or *methyl sulphonol*) $CH_3(C_2H_5)_2C(SO_2C_2H_5)_2$ is prepared, like sulphonol and tetronal, from methyl ethyl ketone and ethyl mercaptan (Fromm, Annalen, 1889, 253, 150; D. R. P. 49073; Frdl. 1887–1890, ii. 521). It forms colourless, odourless, lustrous square tablets, m.p. 76°, soluble in 320 parts of cold water, but more readily so in boiling water, in ether, and in alcohol. It is employed in medicine for the same purposes as sulphonol and tetronal, v. SYNTHETIC DRUGS. For its detection, v. SULPHONAL AND TETRONAL.

TRIPHANE v. SPODUMENE.

TRIPHENIN. *p*-Propionyl-phenetidine, used as an antipyretic.

TRIPHENYLMETHANE COLOURING MATTERS.

TERS. This is the generic name of a very large and varied class of artificial dye-stuffs which have been obtained by very different methods. Some of the oldest artificial dye-stuffs belong to this group. Their generic connection was, in many instances, not known until their constitution was fully ascertained. When this had been done, a large number of new dye-stuffs belonging to the same class was prepared by direct synthesis. The members of this group vary more than those of any other in their physical properties; they represent almost every possible shade, and include dye-stuffs suitable for almost every kind of dyeing and printing process. They are applicable to silk, wool, and cotton dyeing; as a rule, they are of very pure and brilliant shades—in fact, the most brilliant of all colouring matters are found amongst them. Many are rather fugitive, especially the older ones—magenta-red and its congeners. It is for this reason that aniline dyes generally have been declared fugitive and unstable by people of hasty judgment. This want of stability is, however, not characteristic of the triphenylmethane group; some of the best and most permanent dye-stuffs belong to it. It may be well to remark at once that resistance to light and other influences seems not to be directly related to the chemical constitution of these substances, as it is frequently observed that of two

dye-stuffs of very similar constitution one may be very fugitive, whilst the other is remarkable for its fastness. The fastness of these and other dye-stuffs also depends to some extent on the manner in which they are applied to the textile fibre.

The members of this family are not, like those of the azo- group, connected by one generic method, by which all of them might be produced from various materials. Nor is it possible to enumerate a number of general synthetic methods which result in their production. The methods applicable are so numerous that no generalisation is possible. The only connecting link between all these dyes is their chemical constitution, which is now well established in almost every case; it is also in this constitution that we find the necessary criteria for the subdivision of the group. Some introductory remarks about the constitution of these dyes are therefore necessary for a complete revision of the subject.

If we consider the constitution of these colouring matters, we observe that there is but one characteristic feature common to them all. This is the presence of an atom of carbon connected by three of its valencies to three aromatic radicles. The compound of the simplest constitutional formula in which this 'central carbon' (as we will henceforth call it) is observed is the hydrocarbon triphenylmethane, the formula of which is $C_{19}H_{15}$.

Triphenylmethane thus becomes the prototype of all the members of this group; it is for this reason that the name of *triphenylmethane colouring matters* was chosen.

Triphenylmethane was first prepared by Kekulé and Franchimont, in 1872, by heating benzylidene chloride with mercury diphenide to 150° (Ber. 5, 907). Its formation has since been observed in numerous reactions. The best method for preparing it consists in treating a mixture of two parts of chloroform and seven parts of benzene with aluminium chloride, until no more hydrogen chloride is given off. The resulting liquid is washed with water and dried. On distillation it yields benzene, diphenylmethane, and triphenylmethane. The last may be purified by crystallisation. This method was indicated by Friedel and Crafts (Ann. Chim. Phys. [vi.] 1, 489). Triphenylmethane is obtained in colourless crystals; m.p. 92° ; b.p. 355° - 359° . It is capable of forming a molecular compound with benzene. Of its derivatives the following three are important on account of their relations to the colouring matters under consideration.

Triphenylcarbinol $C_{19}H_{16}O$ is the tertiary alcohol derived from triphenylmethane:

It is easily obtained by oxidising the hydrocarbon by means of chromic acid. It forms

colourless crystals, melting at 159° and boiling at 360° (E. and O. Fischer, Annalen, 194, 271).

In boiling glacial acetic acid it is readily reconverted to triphenylmethane either by hydriodic acid (Tschitschibabin, Ber. 1911, 44, 441) or by trioxymethylene in presence of a small quantity of conc. sulphuric acid (Banda, Anal. Fis. Quim. 1913, 11, 599; cf. J. Chem. Soc. 1914, i. 279). For the use of formic acid for this purpose, see Guyot and Korache (Comp. rend. 1912, 154, 121, and 1913, 156, 1324).

Trinitrotriphenylmethane $C_{19}H_{13}N_3O_6$ is obtained by treating the hydrocarbon with strong nitric acid. Crystals, melting at 203° . Chromic acid transforms it into trinitrotriphenylcarbinol (E. and O. Fischer, *ibid.* 194, 250).

Tri-*p*-nitrotriphenylcarbinol $C_{19}H_{13}N_3O_7$:

is best crystallised from glacial acetic acid and forms small crystals, melting at 171° - 172° and soluble in alcoholic potash solution with a beautiful reddish-blue colour.

None of the above substances is a colouring matter, nor are they even coloured. But if we reduce trinitrotriphenylcarbinol by adding zinc-dust to its solution in acetic acid, we obtain triaminotriphenylcarbinol, which is identical with pararosaniline. By showing this identity, E. and O. Fischer solved the problem of the constitution of this very important colouring matter. Leucaniline, the reduction product of rosaniline, was shown to be identical with triaminotriphenylmethane. This discovery became the starting-point for very important theoretical and practical work. All the congeners of rosaniline were shown to be derivatives of triphenylmethane or analogous hydrocarbons, and new synthetical methods were devised by which such derivatives could be obtained.

It is quite obvious that not only triphenylmethane, but also all its homologues and analogous hydrocarbons, are parent substances of dye-stuffs. The number of such hydrocarbons indicated by theory is very large, since every one of the three phenyl radicles connected with the central carbon may be replaced by any other aromatic radicle. Every one of the hydrocarbons thus formed is capable of yielding, like triphenylmethane itself, a very large number of colouring matters, as will be seen from subsequent considerations. It thus becomes evident that the theoretical number of possible triphenylmethane colouring matters is almost unlimited. It has, however, been shown that the variation of the aromatic radicles connected with the central carbon is not the only point of importance as regards the variation of the shades and properties of the resulting

dye-stuffs. The triphenylmethane colouring matters in actual use are the derivatives of a very few hydrocarbons, of which triphenylmethane itself is by far the most important. Tolyldiphenylmethane, ditolyldiphenylmethane, tritolyldiphenylmethane, and naphthyldiphenylmethane are the principal parent substances of a large number of colouring matters, which at present form the object of regular and extensive manufacture, and of several hundred more which have been prepared and patented without coming into general use. The extensive range of shade and general applicability, so characteristic of the colouring matters of this class, and unequalled by any other class of dye-stuffs known, is not so much a result of the variation of the hydrocarbons forming their parent substances, as of the extremely large number of coloured derivatives which may be produced from every one of these hydrocarbons. No other branch of the chemistry of dye-stuffs is so extremely fertile in the synthetical methods at its disposal as this, and every one of these methods forms an easy way for the production of a considerable number of dye-stuffs, which can generally be produced by this one method alone. Many of these methods, both empirical and synthetical, have been patented, and some of these patents are of great value and importance. They are generally 'process' patents, claiming new methods of manufacture; in this respect they form the exact counterpart of the still more numerous 'substance' patents for azo-colouring matters, which, being all based on the same method of work, only claim the novelty of the product obtained by varying the ingredients of the process.

Before entering into the details of the constitution of triphenylmethane dye-stuffs, and the connection of this constitution with the properties of the dyes, we have to describe another substance closely related to triphenylmethane, some of the derivatives of which are dye-stuffs similar to those derived from triphenylmethane itself, whilst others play an important part in the process for the production of triphenylmethane colouring matters. This substance is also a hydrocarbon, derived from methane by replacing only two of its hydrogen atoms by the aromatic radicle phenyl. This hydrocarbon is *diphenylmethane*, or benzyl-benzene $C_{11}H_{12}$:

It was discovered by Zincke in 1873 (Annalen, 159, 374), and is best prepared by the method indicated by Friedel and Baisohn (Bull. Soc. chim. [ii.] 33, 337), by adding aluminium chloride to a mixture of 1 part benzyl chloride with 5 parts of benzene. It melts at 26° - 27° , and boils at 261° - 262° . It forms white crystals, possessing an agreeable odour of oranges. Of its derivatives the following are of practical importance:—

Diphenylcarbinol or benzhydrol $C_{11}H_{12}O$ is the corresponding alcohol:

It is prepared by boiling benzophenone with alcoholic potash solution and zinc-dust. It forms white crystals, melting at 67.5° - 68° , boiling at 297° - 298° (Linnemann, Annalen, 133, 6; Zagumenny, *ibid.* 184, 174).

Benzophenone $C_{13}H_{10}O$ is the second product of oxidation of diphenylmethane, to which it stands in the same relation as that which exists between propane and acetone. Benzophenone is the typical ketone of the aromatic series

It is prepared by the process which led to its original discovery, by distilling calcium benzoate, or, better still, by distilling a mixture of calcium and zinc benzoate. Another process consists in adding aluminium chloride to a solution of carbonyl chloride $COCl_2$ (phosgene) in pure benzene, or to a mixture of benzene with benzoyl chloride. Benzophenone forms beautiful prismatic crystals, melting at 48° - 48.5° , distilling at 305° (Péligot, Annalen, 12, 41; Chancel, *ibid.* 72, 279; Friedel, Crafts and Ador, Ber. 10, 1854) (*v.* QUINONES).

The amino derivatives of diphenylmethane diphenylcarbinol, and benzophenone, which are of special importance in the chemistry of the triphenylmethane dye-stuffs, will be described subsequently in connection with the dye-stuffs to which they give rise.

The substances mentioned so far, although the parent substances of so many beautiful dyes, are all perfectly colourless. Even triaminotriphenylcarbinol, which is identical with *p*-rosaniline, is perfectly colourless; it only becomes a dye-stuff by being dissolved in an acid, a reaction from which one might infer that *p*-fuchsin, the typical magenta colour, is merely a salt of *p*-rosaniline. This is, however, not the case, although colour-makers are apt to call, for simplicity's sake, the rosanilines 'magenta bases.' In this connection a decision of the U.S.A. Customs Authorities is of interest, in that they upheld the claim of an importer; that rosaniline, not being itself a dye, should be subject to duty (20 p.c. ad. val.) as 'a coal-tar product not being a colour or dye,' and not to the duty (30 p.c. ad. val.) levied upon coal-tar colours or dyes (U.S.A. Cust. decision, Oil Paint and Drug Rep. Nov. 3, 1913, *cf.* J. Soc. Chem. Ind. 1913, 1060). The dissolution of any or either of the aminocarbinols in an acid is invariably accompanied by a condensation in the molecule, and a loss of one molecule of water. The basic triphenylmethane colouring matters are therefore free from oxygen (unless they contain it in the shape of water of crystallisation); if we decompose the salts, by the addition of an alkali, coloured bases are formed, which, however, are very unstable. They take up, at once, one molecule of water, and re-form the original colourless or faintly-coloured carbinol base. If the precipitation is carried out by means of ammonia instead of sodium hydroxide or carbonate, or if ammonia be present in the liquid, the carbinol base is partly or wholly transformed into the corresponding amino compound.

as has been shown by Villiger and Kopetschni, Ber. 45, 2910, and by Nölting and Saas, *ibid.* 46, 952. By this observation it is clearly shown that something more than the presence of the 'central carbon' is necessary for the formation of a triphenylmethane colouring matter. We have, therefore, to consider the constitution of the colouring matters themselves to obtain a knowledge of the chromophoric group of these dye-stuffs. This consideration leads at the same time to an easy and useful classification, to a subdivision into a series of small groups, the members of which show a closer connection in their methods of formation, their physical properties, and their manner of application.

The constitution of parafuchsin is now established beyond any doubt. It may be represented by the following formulæ:

which are practically identical, II. corresponding to the modern way of expressing 'quinonoid' structure. This formulation will therefore be used exclusively in this article to explain the constitution of the dyestuffs to which it refers, whilst formulæ corresponding to I. have been used in the first edition of this work. For alternative formulæ more recently suggested by Kauffmann, see Ber. 1912, 45, 781. For consideration of the salts of triphenylmethane bases which are formed in strongly acid solutions, see Kehrman, Ber. 1918, 51, 468. The formulæ chosen show also the typical constitution of all the congeners of magenta, every one of which may be represented by similar formula, in which either one or more of the phenyl radicles is replaced by other aromatic radicles, or one of the amino groups replaced by hydrogen, or one of the six available hydrogen atoms of the amino groups replaced by radicles of the fatty or aromatic series, or several of these changes introduced at the same time. It will at once be obvious that several thousand different combinations may thus be produced, all colouring matters of different shades, but showing in their properties a general resemblance to parafuchsin. The constitutional formulæ of all these colouring matters have but one thing in common besides the 'central carbon' (which is, as has been said, characteristic not only of these, but also of all the other triphenylmethane colouring matters); this one essential feature is the quinonoid nature of the substance, expressed in the structural formula either by the connection between the central carbon atom and the pentavalent nitrogen (as shown in formula I.), or, as it has become customary of late, by shifting the double valencies in the benzene hexagon and connecting it accordingly with the other parts of the molecule, as shown in formula II. We

have, therefore, a perfect right to claim this invariably present quinonoid configuration as the essential feature of the whole molecule, and as the cause of its being a colouring matter. It forms a part of the chromophoric group of the fuchsin family.

It is, however, important to notice that, no matter how we write the structural formula of *p*-fuchsin or any of its congeners, whether we use the older or the more modern way of expressing the quinonoid nature of the substance, one of the amino groups present is always taking part in the quinonoid chromophoric group and therefore is no longer available as an auxochromic group. To supply this, at least one more amino-group must be present, and this is the reason why only di- or poly-amino derivatives of triphenylmethane can become mother-substances of dye-stuffs belonging to this group. On the other hand, both the amino groups of auxochromic nature, as well as the one entering into the chromophoric part of the molecule, may be replaced by other suitable groups. The hydroxyl group with its tendency to form salts by combining with metallic ions is as important an auxochromic group in the series of triphenylmethane dye-stuffs as in any other. And the quinonoid imino group contained in the chromophore, may, as in other dye-stuffs, be replaced by an oxygen atom acting in similar capacity. Thus we obtain two separate groups of dye-stuffs, the first of which, generally called the *fuchsin group*, is characterised by the presence of nitrogen and the basic nature of its members; the second, called the *aurin group*, by the absence of nitrogen and the phenolic character of the dyestuffs it embraces. In addition to these two groups, a third one, the *phthalein group*, has been established by the common consent of all authors on the subject. This group contains a large number of important dye-stuffs of both basic and acid nature, which have this in common, that they are all derived from phthalic acid and take their 'central carbon' from one of the carboxyl groups of this acid, whilst the other, remaining available, enters the molecule of the dye-stuff and thus renders the latter a true organic acid, which is not necessarily the case amongst the members of the fuchsin and aurin group. Moreover almost all the phthalein dye-stuffs of any practical importance contain, in addition to the typical chromophore of the triphenylmethane colouring matters, an additional one in the shape of the 'pyrone' ring, formed by the elimination of water from certain suitably placed hydroxyl groups of the molecule. This pyrone ring will be easily recognised in the formulæ of the members of the phthalein group to be given subsequently. The fact that only those phthaleins, which contain this pyrone ring, are colouring matters of any practical value, greatly diminishes the number of possibilities for the synthesis of such dye-stuffs, which might be made to form a class of their own, if it had not become customary to treat them as a special division of the triphenylmethane group of colouring-matters.

We now proceed to give a detailed account of these three groups and their various members, of which, however, we shall enumerate only those which are, either scientifically or practically, important. For a complete list we refer the

reader to the well-known tables of Schultz and Julius,¹ or the more recent "Colour Index."²

I. THE FUCHSIN GROUP.

(A) Diaminotriphenylmethane derivatives.—

The simplest type of these colouring matters is

1. Benzaldehyde violet $C_{15}H_{11}N_2Cl$ or

which may be prepared from diaminotriphenylmethane by oxidation. The yields are, however, very poor, and the colour itself is of no great value. Its manufacture has, therefore, never been taken up.

The derivatives of this substance, however, in which the hydrogen of its two amino groups is replaced by various radicles of either the fatty or aromatic series, are of great value and importance. Of these, the oldest, best known, and simplest in its constitution, is

2. Benzaldehyde green. (Syn. *Malachite green*, *New green*, *Victoria green*, *Fast green*, *Diamond green*, *Benzoyl green*, *Benzal green*.)

This product was discovered almost simultaneously by Otto Fischer (1877; Ber. 10, 1625) and O. Döbner (1878; *ibid.* 11, 1236), who prepared it by different methods. For some time it was believed that Döbner's product was different from Fischer's until their identity was finally established. Döbner's process was patented (D. R. P. 4322). Fischer's process found, however, more favour with the majority of manufacturers, and has mostly been adopted.

Fischer's process gave bad yields and a poor product at first, until the best method for its manufacture was worked out. It consists in the following operations:—

(a) Manufacture of tetramethyldiaminotri-

¹ *Gustav Schultz und Paul Julius. Tabellarische Uebersicht der künstlichen organischen Farbstoffe* Berlin (Fifth edition, 1914.)

² "Colour Index," published by the Society of Dyers and Colourists, Bradford, 1925-6.

phenylmethane by the action of benzaldehyde on dimethylaniline:

The base obtained in this reaction is generally called 'green leuco base' by the manufacturers. For preparing it one molecule of benzaldehyde is mixed with very little more than two molecules of absolutely pure dimethylaniline, a substance capable of absorbing the water formed in the reaction being added. Dry zinc chloride was originally employed, and is still used by many manufacturers. In quantity it should be equal in weight to the aldehyde employed. Hydrochloric, sulphuric, or anhydrous oxalic acid, or acid sodium sulphate may be used instead of the zinc salt. The mixture is heated in a jacketed still to 100°–110° for about forty-five to forty-eight hours. The product is then transferred to a still, a sufficient quantity of caustic soda is added to make the mixture alkaline to test-paper, and a current of steam is blown through the liquid in order to remove every trace of dimethylaniline and benzaldehyde. The leuco base is not volatile; it remains in the still in the shape of a viscid mass, which solidifies into white crystals after a while. This base is now subjected to the second operation.

(b) Oxidation into green. It is here that great difficulties were encountered in the beginning of the manufacture. Special conditions are required to obtain a good crystallisable dye-stuff. If these are not strictly adhered to, a non-crystallisable green is the result. The latter is different from the crystallisable substance in composition, containing one methyl group less, which is lost in the shape of formaldehyde by a too powerful action of the oxidising agents. The following conditions give excellent results: 33 kilos of leuco base are dissolved in 25 kilos of ordinary hydrochloric acid, and diluted with 200 litres of water; 30 kilos of ordinary acetic acid of 45–50 p.c. are then added. It is necessary that these two acids should be present; neither of them can be replaced by another acid of equal strength. The solution is then oxidised in the cold (in the summer it is advisable to add some ice) with a paste of lead peroxide of known strength. The peroxide should be tested by the oxalic acid method (determination of the CO_2 evolved from an excess of oxalic acid by the peroxide in question), and not by the iodometric method, as the latter gives too high results. Every kind of lead peroxide contains a certain amount of crystalline peroxide, which neither acts on the leuco base, and is therefore quite irrelevant in its oxidation into green, nor on oxalic acid, whilst the iodometric method gives values for both modifications indiscriminately. For oxidising the leuco base the exact quantity of peroxide should be taken, which is indicated by the following equation:

One molecule of active peroxide is, therefore, required for every molecule of the base.

As soon as the peroxide has been added

with constant stirring, the liquid turns a deep green. From this liquid the dye-stuff may be separated by various methods; an addition of zinc chloride solution is generally recommended. This, however, precipitates both the crystalline green and the tarry modification which is never quite absent. The following process has given excellent results in the hands of the writer.

The green liquid obtained by oxidation is saturated with common salt. On standing small glittering scales of the lead double chloride of the crystallisable green very soon make their appearance, and are collected on a filter. From the mother-liquor an inferior quality of green may be obtained by adding a solution of sodium sulphate, filtering, and precipitating with zinc chloride and common salt. The crystals of the lead double chloride are dissolved in hot water, and sufficient sodium sulphate is added to precipitate the lead. The liquid is then filtered and precipitated with ammonia. The 'green base' (a mixture of tetramethyl-diaminotriphenyl-carbinol with the corresponding amino derivative

discovered by Villiger and Kopetschni) settles out in the shape of a pink precipitate, which is filtered off and washed. From it the 'green crystals' of commerce may be prepared, either by dissolving it in a hot solution of oxalic acid and allowing the liquid to cool very slowly, or by dissolving it in dilute hydrochloric acid and adding a solution of zinc chloride. Besides these two the iron double salt is also occasionally met with in commerce. The picrate is also sold under the name of 'spirit green.'

Döbner's process.—This consists in heating dimethylaniline with benzotrichloride in presence of metallic chlorides. This process has certain advantages if benzotrichloride is available at a low price. It may be represented by the following equation:

The following proportions are recommended in the patent:

3 parts dimethylaniline,
2 „ benzotrichloride,
1.5 „ zinc chloride.

These are to be heated for three hours to 110° in an enamelled iron vessel with constant stirring. The resulting melt is transferred to a still, and steam is blown through it to remove all excess of trichloride. It is then thoroughly extracted by boiling water. The filtrate is now precipitated by salt, and the precipitate recrystallised from water. The dye-stuff is always obtained in the shape of the zinc double chloride.

The oxalate of benzaldehyde green forms large plates of an intense grass-green colour, which dissolve easily in hot water. It contains three molecules of oxalic acid to every two of green base.

The zinc double chloride, which has the composition $3(\text{C}_{23}\text{H}_{22}\text{N}_2\text{Cl}) \cdot 2\text{ZnCl}_2 \cdot 2\text{H}_2\text{O}$, forms green crystals with a fine yellow metallic lustre. It is not quite so easily soluble as the oxalate.

The application of these salts is similar to

that of all the basic dye-stuffs, and need not here be described.

3. Brilliant green. (Syn. *Ethyl green*, *Emerald green*; also all the other names given for the preceding compound, with the addition of the letters G, J, or Y (meaning *gelb*, *jaune*, or *yellow*).

is prepared from diethylaniline by exactly the same process as described for benzaldehyde green. After precipitating the free green base, it is transformed into its sulphate by mixing it with the theoretical quantity of sulphuric acid diluted with its own weight of alcohol. The mixture forms a thick tar at first, but suddenly solidifies into a mass of well-defined crystals.

The shade of this green is considerably yellower than that of the ordinary benzaldehyde green.

4. Victoria green 3 B. $\text{C}_{23}\text{H}_{22}\text{N}_2\text{Cl}_3$. This is a colouring matter prepared from dichlorobenzaldehyde instead of the ordinary benzaldehyde. It is considerably bluer in shade than the ordinary benzaldehyde green. A large number of similarly constituted bluish-greens and greenish-blues is manufactured and sold, especially by the Swiss colour-works.

Acid greens. Considerable importance has always been attached by dyers to the sulpho derivatives of basic colouring matters, because these are more easily and evenly dyed on wool than the hydrochlorides and other salts of the bases themselves. Many attempts have, therefore, been made to obtain acid greens. They were at first only partly successful; at present there are, however, several acid greens in commerce, ranging in shade from a yellowish-green to a clear greenish indigo blue. They are very largely used in wool dyeing, especially for mixed shades.

The oldest of these acid greens, which appeared in the market in 1878, was called

5. Helvetia green or Acid green C. It was the sodium salt of the mono-sulpho derivative of the ordinary benzaldehyde green, prepared either by sulphonating the green itself by means of chlorosulphonic acid, or by sulphonating tetramethyldiaminotriphenylmethane and oxidising the resulting colourless acid by means of lead peroxide. Neither of these two methods works satisfactorily. For this reason the product has gradually been abandoned, and replaced by the benzyl derivatives, which are more easily prepared, and at the same time much more brilliant in shade.

6. Benzyl acid greens. In the various attempts to prepare acid greens it was found that the phenyl groups, combined with the central carbon, show little tendency to permit of the introduction

tion of the sulpho group. This reluctance is, indeed, quite characteristic of all triphenylmethane derivatives. It is the cause of the difficulties experienced in preparing sulphonated derivatives of these dye-stuffs. It was, therefore, a happy thought to introduce into the molecule of the green an independent radicle, capable of receiving the sulpho group without influencing more than necessary the shade and other properties of the green. Such a radicle was found in the benzyl group. If we introduce this, instead of methyl and ethyl, into the amino groups of the green, it acts in the manner of a radicle of the fatty series, influencing the shade of the green very little. The C_6H_5 group, however, brought into the molecule as a constituent of the benzyl radicle, is capable of being sulphonated with the greatest facility. Various dye-stuffs have been prepared according to this principle. Of these *Guinea green B* is the simplest. It is the disulpho derivative of diethyl-dibenzyl-diaminotriphenyl-carbinol

obtained by combining benzaldehyde with two molecules of ethylbenzylaniline sulphonic acid, and oxidising the leuco compound thus obtained. This product was discovered by G. Schultz and Streng, in 1883, and patented (D. R. P. 50782, 1889; Eng. Pat. 7550, 1889). It is an excellent and very useful dye-stuff. *Guinea green B*, which dyes a more yellowish shade, is obtained in the same manner, using *m*-nitrobenzaldehyde instead of the ordinary benzaldehyde, whilst if *o*-chlorobenzaldehyde is used the resulting dye is *Benzyl green B*.

The various shades of *light green* or *acid green* sold by the majority of manufacturers are prepared somewhat differently. Benzaldehyde is combined with two molecules of benzyl-methyl- or benzyl-ethylaniline. The base thus obtained is treated with sulphuric acid, when three sulpho groups enter the molecule, one of which is linked to the phenyl radicle containing no amino group, whilst the two others are combined with the benzyl radicles. The resulting trisulpho derivatives are oxidised in the usual manner, yielding the dye-stuffs in the shape of a very soluble green powder.

7. A curious product, belonging to the class of acid greens, was described by R. Meldola, under the name of *Viridin* (Chem. Soc. Trans. 1882, 187; Ber. 14, 1385). It was prepared by oxidising benzyl-diphenylamine, and sulphonating the resulting green, dissolved in spirit. This green, or a substance very similar to it, had already been prepared by Ch. Girard (Wurtz, Progrès de l'Ind. des Mat. col.; Paris, 1876; p. 134).

8. *Patentblau*, *Patent blue*, a product of the Farbwerke vorm. Meister, Lucius and Brüning, in Höchst-am-Main. This is a dye-stuff closely allied to the acid greens. It was discovered by Hermann, and patented by the Farbwerke (D. R. P. 46384, 1888, and many additional patents; see also Fritsch, Ber. 1896, 29, 2291, and Erdmann, Annalen, 1897, 294, 376). It is prepared by a somewhat complicated method.

m-Nitrobenzaldehyde is combined with two molecules of dimethylaniline. The resulting base is reduced, the amino derivative diazotised, and, by boiling with water, transformed into *m*-hydroxytetramethyldiaminotriphenylmethane. This is sulphonated by treatment with sulphuric acid. The resulting sulpho derivative is oxidised and transformed into a calcium salt, which is delivered into the market. The constitution of the dye-stuff is represented by the following formula:

This dye-stuff dyes wool and silk a beautiful greenish-blue of great brilliancy and clearness. Several other dye-stuffs of very similar composition are on the market.

(B) *Derivatives of triaminotriphenylmethane*.—This group contains some of the oldest artificial dye-stuffs, which were prepared by strictly empirical methods. When the constitution of the triphenylmethane group was established, synthetical methods for producing dye-stuffs of this group were gradually introduced. At the present time the old empirical processes hold their own for the production of the old colouring matters, whilst the synthetical methods, which are mostly patented, are used for preparing new dye-stuffs of great beauty and perfection.

The prototype of this group is—

1. *Parafuchsin*, *Paramagenta*, the anhydrochloride of triaminotriphenylcarbinol $C_{18}H_{15}N_3Cl$ the constitution of which is:

It always crystallises with four molecules of water of crystallisation, which should be added to the above formula.

This is the dye-stuff which was used by O. and E. Fischer for the elucidation of the chemistry of this class of substances (O. and E. Fischer, Annalen, 1878, 194, 242; Ber. 11, 1079; 13, 2204). It is one of the oldest artificial dye-stuffs; it was discovered in 1858 by A. W. Hofmann (J. 1858, 351); and re-discovered by Rosenstiehl in 1869 (Bull. Soc. Ind. Mulhouse, 36, 264). For a long time it was considered a substance of merely theoretical interest, because its shade is almost identical

with that of ordinary fuchsin or magenta (see under 2), which is much more easily prepared. At present, however, it is manufactured on a large scale, not as a dye-stuff for sale, but as a raw material for certain blues, which will be mentioned later on.

A large number of reactions have been observed and described which result in the formation of pararosaniline. Of these the following may be mentioned :

(a) Pure aniline heated with carbon tetrachloride yields parafuchsin. This method was used on a manufacturing scale by Monnet and Dury in Lyons.

(b) Pure aniline, heated with iodoform, gives a fair yield of parafuchsin hydriodide.

(c) Pure aniline, heated with *p*-nitrobenzyl chloride in the presence of iron filings or iron salts gives a good yield of parafuchsin. This method, or modifications of it, form the substance of Greiff's and Baum's patents (D. R. PP. 15120 and 19304 Grieff, and 14929 Baum).

(d) Pure aurin (rosolic acid), which will be described subsequently, yields parafuchsin if strong ammonia be allowed to act on it for a long time at a high temperature.

(e) It has been shown (v. introduction) that the reduction-product of parafuchsin is paraleuco-aniline, and that the latter is identical with triaminotriphenylmethane. The latter may easily be prepared from triphenylmethane by nitration and reduction, and by various other methods. Attempts have not been wanting to work out a method for the production of parafuchsin from synthetical leucaniline. No good method, however, has hitherto been discovered for this purpose, and all the patents based on this reaction have proved failures. It is very easy to produce a trace of fuchsin in a solution of leucaniline; but no method is known for finishing the reaction.

(f) Mixtures of pure aniline with pure *p*-toluidine yield parafuchsin if subjected to oxidation. This is the usual practical way for the production of parafuchsin. The oxidation may be effected either by arsenic acid or by nitrobenzene. Other oxidising agents—such as mercuric chloride, stannic chloride, &c.—produce the same result, but at a higher cost. The arsenic acid process (which will be described later on) was for some time almost exclusively used for the production of parafuchsin. The chemical reaction which takes place is very simple. Arsenic acid is reduced to arsenious acid. The oxygen which is thus obtained combines with hydrogen of the aromatic bases :

The methyl group of *p*-toluidine is used up for yielding the central carbon around which the other radicles are grouped.

(g) Diaminodiphenylurethane, mixed with aniline and heated with oxidising agents, yields parafuchsin. This synthesis forms the basis of a more modern manufacturing process.

It has already been said that parafuchsin has no advantages over ordinary magenta red for dyeing purposes. It is, therefore, rarely to be met with as a dye-stuff in the market. As a

rule the melts are worked up in the same manner as ordinary magenta melts, but the resulting crystals of the pure hydrochloride are redissolved and precipitated in the shape of pararosaniline base by the addition of soda or milk of lime. The base is then used for the production of blues.

Parafuchsin hydrochloride forms small glistening crystals having a metallic green lustre. As a rule, they are very small, much smaller than the crystals of ordinary magenta. Parafuchsin acetate is similar in appearance and crystallises much more easily than the ordinary magenta acetate.

Pararosaniline is important because it is the parent substance of all the various violets, and of some of the blues, which will be described subsequently.

2. Ordinary fuchsin, magenta red, rosein (*rubesine, harmaline, aniline red, azalein, solferino, erythrobenzine*) $\text{C}_{20}\text{H}_{12}\text{N}_2\text{Cl}$, is an article of great importance and of very general application. The latter is due to the fact that it was one of the first artificial dye-stuffs, although not one of the best. A great demand for it has gradually been established, which forces the manufacturers to carry on its production on a large scale, even now, when much better dye-stuffs may be prepared by other methods.

Chemically, this colouring matter may be defined as the higher homologue of parafuchsin, in which one of the phenyl groups has been replaced by a tolyl group :

The product of commerce, though chiefly composed of this substance, invariably contains an admixture of parafuchsin as well as of the higher homologues ($\text{C}_{21}\text{H}_{12}\text{N}_2\text{Cl}$ and $\text{C}_{22}\text{H}_{14}\text{N}_2\text{Cl}$). Like parafuchsin, it contains four molecules of water of crystallisation.

Fuchsin is invariably prepared by oxidising a mixture of aniline with *p*-toluidine and *o*-toluidine. This mixture is generally known as 'aniline for red,' and was originally produced by the nitration and subsequent reduction of a certain fraction of crude benzene, which consisted of benzene and toluene. Sometimes it even contained some xylene; in this case xylylene entered into the composition of 'aniline for red.' At present most of the 'aniline for red' is a mixture of pure aniline with crude toluidine. By the latter we mean the mixture of *o*- and *p*-toluidine which is obtained by the nitration and subsequent reduction of pure toluene. Crude toluidine consists as a rule of 55 p.c. *o*-toluidine and 45 p.c. *p*-toluidine. The quantity of aniline added to crude toluidine

in order to produce the 'aniline oil for red' varies according to the recipes of various manufacturers. As a rule, half of the weight of the toluidine is added. A certain boiling-point (for instance, 188°-200°) and a certain specific gravity (for instance 1.010) are prescribed, and should be strictly adhered to by the aniline oil manufacturer. In some cases an addition of xylidine is necessary in order to produce a product of the desired boiling-point and density. Theoretically, an oil containing equal molecules of the three bases would be required; but for practical work an excess of aniline and o-toluidine is used, because a part of these two compounds escapes the reaction, whilst the p-toluidine is entirely used up.

Of all the methods which in the course of time have been proposed for oxidising this mixture, only two have survived, one of which is also rapidly disappearing. They are known under the names of the *arsenic acid melt* and the *nitrobenzene process*. From a practical point of view they are of equal value, but the arsenic acid melt is being abandoned on account of the poisonous nature of the arsenic compounds required.

Magenta was originally prepared by Natan-son, in 1856, by heating aniline with ethylene chloride. In 1858 Hofmann observed its formation when allowing carbon tetrachloride to act on aniline. In 1859 Verguin prepared it by the action of stannic chloride on aniline. Verguin's employers, the dyers Renard Frères and Franc, in Lyons, took up its manufacture on a large scale, and invented the name *fuchsin*. Later on a company was formed, under the name of 'La Fuchsin,' for working Verguin's patent. Gerber-Keller invented a process for oxidising aniline by means of mercuric nitrate. The dye-stuff thus obtained was believed to be different from fuchsin, and received the name *azalein*. In 1860 Medlock invented the arsenic acid process, which for a long time was considered the only practical method of manufacturing magenta. His patent was invalidated owing to a clerical error contained in the description. In 1869 Couper described his process for producing fuchsin by the nitrobenzene process. This method, which did not give good results at first, was gradually worked out by various manufacturers, and is now equivalent, if not superior, to the best forms of the arsenic acid process.

Various salts of rosaniline were formerly in commerce. The original fuchsin was the hydrochloride, azalein was the nitrate; whilst magenta and rosein were the names applied to the acetate, produced by Nicholson, the first to manufacture this colouring matter in a practical and rational manner. Gradually the nitrate and acetate disappeared from the market. At present the hydrochloride is the only salt produced, to which, therefore, the original name of fuchsin should be applied. English manufacturers still use the names magenta and rosein for the hydrochloride. A large quantity of the fuchsin manufactured is transformed into rosaniline, which is delivered into the market either under this name or as 'magenta base,' 'red base,' or 'rosein base.' These names are not quite correct, because rosaniline may not strictly be considered as the true base of the hydrochloride of fuchsin.

The true base of fuchsin is

which, in the moment of its formation, undergoes a molecular transformation into

Manufacture of Fuchsin.

1. *Arsenic acid process*.—The properties of the 'aniline oil for red' have already been discussed. The mixture of bases known under this name is transformed into the dye-stuff by heating it with arsenic acid. The latter is prepared by oxidising arsenious acid (white arsenic) by means of nitric acid in closed earthenware pots. The escaping nitrous fumes are condensed in a tower, in which they meet an opposing current of water and air. The nitric acid is thus regenerated, and may be used again. Practically, therefore, the formation of the arsenic acid is accomplished by the oxygen of the air. The arsenic acid solution obtained has a sp.gr. of 1.85-2.3, and contains from 60-75 p.c. of arsenic acid H_2AsO_4 . 1,500-1,700 kilos of this solution are required in order to oxidise 1,000 kilos of 'aniline oil for red.' These quantities of the reagents are introduced into enamelled cast-iron pots, closed by lids; a mechanical stirrer and a tube for the escape of the vapours should be provided. The mixture is then gradually heated to 180°. This temperature should be strictly maintained during the whole operation. If the temperature rise above 190°, the dye-stuff already formed is decomposed. From eight to ten hours are required in order to complete the reaction. During the whole time vapours escape, which should be condensed in a leaden coil connected with the escape tube, and cooled by a current of water. At first the distillate consists chiefly of the water introduced with the arsenic acid. Later on, the water formed in the reaction distils; at the same time some aniline oil goes over. The total quantity of the aniline escaping the reaction is one-third, or even one-half, of the quantity originally used. The melt, which is very thin at first, gradually becomes viscid; at the same time it assumes a brown, metallic lustre. Samples should be taken from time to time. When the melt becomes brittle on cooling, the reaction is finished, and the fire should be drawn. The melt is then at once removed from the pot. In some factories an opening is provided for this purpose in the

lowest part of the pot, which is closed by a lid and screw whilst the heating lasts. As a rule, however, it is preferred to remove the cover of the pot, and to ladle out the melt. The latter is spread on trays made of sheet iron. On cooling, it solidifies into cakes, which are very brittle, and break up into small lumps on being handled.

The crude melt contains the colouring matter in the shape of arsenite, together with an excess of arsenious and arsenic acids, some coloured by-products (*v. infra*), and a large quantity of tarry impurities. In order to obtain the pure dye-stuff, the crude melt is introduced into horizontal wrought-iron boilers, in which an eccentric horizontal stirrer is made to rotate. Water is added, the lid of the boiler is closed, and steam is introduced at a pressure of from four to five atmospheres. After several hours' vigorous stirring, the greater part of the rosaniline arsenite has been dissolved by the water. The liquid is then forced through felt into iron tanks, where it is allowed to cool down to 50°. A sufficient quantity of salt is then added to precipitate the whole of the colouring matter. By the addition of the salt a mutual decomposition takes place. Sodium arsenite is formed, and remains in the liquid, whilst the colouring matter is precipitated in the shape of chloride. It settles out as a thick green tar of metallic lustre, which solidifies into a brittle substance on cooling. The supernatant aqueous liquid is then drawn off, the crude fuchsin is chipped out, and introduced into another extractor, similar to the one used for treating the melt. A very small quantity of soda ash or chalk (about $\frac{1}{2}$ p.c. of the weight of the crude dye-stuff) is added, and a second extraction takes place. The liquid is again forced through felt into large wooden vats, in which some wooden boards are suspended. When the vats are filled, a small quantity of hydrochloric acid and clean butter-salt is added to each vat. In these vats the dye-stuff separates out, in the shape of fine glistening green crystals. The largest crystals are generally deposited near the surface of the liquid. When the crystallisation is finished, the mother-liquor is drawn off, and the crystals are collected and sorted according to their shape and size. The largest crystals are sold under the name of 'diamond fuchsin.'

By-products.—The residues of the first boiling may be subjected to a second extraction; as a rule, some hydrochloric acid is added in this case. A deeply-coloured solution is thus obtained, from which an impure colouring matter may be precipitated by the addition of salt. This colouring matter is sold under various names (*magenta cake, cerise, grenadine, maroon*), and finds a ready market. It dyes a magenta colour, which is less brilliant than the shade obtained with the crystals. A third boiling is sometimes necessary. The colouring matter obtained from this is very impure. It is, therefore, dissolved in weak hydrochloric acid, and some zinc-dust is added, which reduces the magenta contained in the liquid. On precipitating with salt, a colouring matter of a brown shade is obtained, which is sold as 'Nanking,' or 'leather brown.' The black insoluble residue of the third boiling still contains some dark-blue colouring matters of the induline series, which are, however, not worth the trouble of extracting.

The mother-liquors from the crystals contain a yellow colouring matter of great fastness and purity. This substance, known under the name of *phosphine*, belongs to another group of dye-stuffs, being a salt of diaminophenylacridine. For extracting it from these mother-liquors, the latter should be acidified with hydrochloric acid, and some zinc-dust added until all the fuchsin present in the liquid is reduced. The phosphine, which is not so easily reduced by zinc-dust, may then be precipitated by the addition of sodium nitrate. The amount of phosphine formed varies according to the composition of the aniline oil and the temperature of the melt. It is never considerable, and very often the quantity present is so small that it is not worth while to separate it (*v. CHRYSANILINE*, vol. ii. 246).

Recovery of the arsenious acid.—Formerly the residues of the manufacture of magenta were left in the factory yards or thrown into the sea. At present this is not allowed, and the manufacturers are invariably forced to recover their arsenious acid, so as to prevent the poisoning of wells and streams. The recovery, as it is now carried out, is so economical that the value of the arsenious acid obtained covers the cost of working the process. The process, which was worked out by A. Leonhardt, consists in burning the solid residues and using the heat for evaporating the arsenical liquids. The dry residue of the evaporation is introduced into the furnace, and burned along with the solid residues. Care is taken to introduce no more air than is necessary for burning the organic matter. By this precaution a complete volatilisation of the arsenic in the metallic state is obtained. The vapours of arsenic are led into a highly-heated combustion-chamber. Here they are mixed with the necessary quantity of hot air to completely burn the metallic arsenic into arsenious oxide As_2O_3 . The vapours of the latter are then led through condensing chambers similar to those used in the manufacture of white arsenic. In these chambers the arsenious acid is deposited in the shape of a white powder. From time to time the chambers are opened, the arsenic is removed, and used again for the manufacture of syrupy arsenic acid by the aid of nitric acid. A certain stock of arsenic is thus sufficient to carry on the manufacture of fuchsin for an indefinite period.

2. *The nitrobenzene process.*—This process was originally invented by Couper, of Paris; but it was for the first time successfully worked on a large scale by the firm of Meister, Lucius und Brünig, of Höchst-am-Main. Other firms followed in the course of time, and at present this process has practically superseded the one with arsenic acid.

It was originally supposed that the nitrobenzene used in this process enters into the rosaniline formed, after having served as an oxidiser. At present it is generally recognised that the nitrobenzene merely acts as an oxidising agent, and that, in so doing, it is transformed into tarry matters, which are useless and remain in the residues. The nature of the nitro compound used is, therefore, of no influence on the composition of the dye-stuffs obtained. Pure nitrobenzene, or a mixture of nitrobenzene with nitrotoluene, may be used. *o*-Nitrotoluene acts

more easily than any other nitro compound; it has, therefore, been used with advantage by the writer. *p*-Nitrotoluene has little tendency to act as an oxidiser. If, therefore, a mixture of nitrobenzene with the two nitrotoluenes (the so-called 'nitrobenzol for red') be used, the *p*-nitrotoluene escapes with the distillate.

The advantage of the nitrobenzene process consists, therefore, not in an economy of ingredients, but in the fact that by its application magenta free from arsenic may more easily be obtained. The yield in good crystallised fuchsin is slightly larger (if only the aniline used be taken as basis of the calculation) than in the arsenic acid process. This increase of yield pays for the increased price of the oxidising agent. In times when commercial benzene is cheap the process compares favourably with the arsenic acid process, whilst it was at a disadvantage when the prices of benzene were high. At the present time, benzene is so cheap and plentiful that the nitric acid consumed in this process is perhaps a more important item in the calculation of its cost than the benzene. For working this process it is a condition that the manufacture of aniline be carried on in the same works; the distillates are a mixture of aniline and nitrobenzene, which must be returned into the reduction process before they can be used again.

The process is worked with different proportions and in a different manner in different works. It is based on the following facts: aniline and nitrobenzene do not react upon each other; nor does a reaction take place if aniline hydrochloride be added. But if a small quantity of iron chloride be present, a reaction sets in, at a temperature of 160°. If the aniline and aniline salt used are pure, a dyo-stuff of the induline group is obtained; but if *p*-toluidine and *o*-toluidine be present in the necessary proportions ordinary fuchsin is the result of the reaction. The nitro compound, however, attacks the fuchsin already formed, and part of it is therefore decomposed again. For this reason, quantitative yields cannot be obtained. At 190° the action of the nitrobenzene becomes so violent that all the colouring matter is destroyed. The greatest care is, therefore, required in this process, and the temperature should never be allowed to rise over 175°. Cold-air flues, and even arrangements for cooling with water or ice, are therefore invariably provided in connection with the melting-pots. The size of the latter has been constantly increased, because it is easier to keep large vessels at a constant temperature than small ones. Enormous pots, capable of working one or two tons of melt, have been used. Excellent arrangements for stirring should be provided. It is a good plan to make the melting-pots of spherical shape, and to give the stirrer an oblique position in this spherical pot. No water should be present in the mixture, as in this case the nitro compound is simply reduced into aniline by the ferrous chloride, and the reaction stops. The hydrochloric acid used should, therefore, be mixed with the necessary quantity of the aniline and the mixture evaporated until it solidifies into 'aniline salt cake' on cooling. Sometimes the iron chloride solution is added, so that the cake obtained is intimately mixed with the iron salt. This cake is then dissolved

in the rest of the aniline, the nitro compound added, and the mixture heated until the reaction sets in. Other manufacturers prefer to add iron filings or dry ferrous chloride to the mixture of aniline with aniline cake and nitrobenzene. An ingenious patent, taken out by Herran and Chaudé, proposed the use of certain double salts of the general formula $R_2Cl_2 \cdot 2RCl$, such as ferric ferrous chloride, ferric zinc chloride, aluminium zinc chloride, and others. The addition of iron filings, originally proposed by Coupier is not customary at present. Anhydrous zinc chloride, which has also been proposed as a means of starting the oxidising action of the nitro compound, has not proved satisfactory.

The following proportions have been proposed:

100 parts aniline for red,
50 „ nitrobenzene,
3-5 „ iron filings,

and a sufficient quantity of hydrochloric acid to neutralise two-thirds of the aniline (Häussermann). The quantity of nitrobenzene is too large; it may very well be reduced to 40 parts, or even less.

Wurtz gives the following proportions:

38 parts aniline,
17-20 „ nitrobenzene,
18-22 „ hydrochloric acid,
2 „ iron filings.

The following is Coupier's mixture:

67 parts toluidine,
95 „ nitrotoluene,
65 „ hydrochloric acid,
7 „ ferrous chloride.

The large quantity of nitrotoluene proposed in this prescription is due to the fact that only the *o*-nitrotoluene, of which about 50 parts are present in the mixture, acts as an oxidiser. The *p*-nitro compound is recovered in the distillate.

The following proportions were used by the writer in regular factory work:

400 kilos aniline for red,
222 „ hydrochloric acid, 20° Bé.,
247 „ *o*-nitrotoluene,
and the ferrous chloride prepared from
9 kilos iron borings, and
41 „ hydrochloric acid.

Half of the aniline is dissolved in the 222 kilos of hydrochloric acid, the solution of the ferrous chloride is added, and the whole evaporated in a stone still before being mixed with the remainder of the aniline and the nitrotoluene.

The nitrobenzene melt cannot be pushed so far as the arsenic acid melt. When finished it should not solidify into a brittle mass on cooling. It should be still soft, owing to a proportion of uncombined aniline which it still contains. This aniline must be extracted by boiling with a small quantity of dilute hydrochloric acid. After its removal, the melt becomes brittle on cooling. It is worked up in the Leonhardt extractors, in exactly the same manner as described for the arsenic acid melt.

Later improvements.—It has already been said that several synthetical methods have been

proposed for the manufacture of magenta, which met, however, with no success. Gradually, however, improvements have been introduced into the old melting processes, which, being based on theoretical considerations, have given favourable results. The most important of these improvements is the one described in the German patent 53937 (and additional patent) of the Farbwerke vorm. Meister, Lucius und Brüning in Höchst-am-Main, dated November 27, 1889. It consists in replacing, in the nitrobenzene process, the 'aniline for red' by a mixture of diamino-diphenylmethane and aniline. The patents refer only to the production of the diamino-diphenylmethane, which is prepared by first acting with formaldehyde (the well-known 'formalin' of commerce) upon aniline. The methylene-aniline obtained is heated with aniline and aniline hydrochloride, by which means diamino-diphenylmethane is easily formed. If instead of $C_6H_5N:CH_2$, methylene-aniline, any of its higher homologues be heated with the corresponding bases, the homologues of diamino-diphenylmethane are produced. By introducing these bases instead of *p*-toluidine into the magenta melt, very large yields of the dye-stuff are said to be obtained. The dye-stuff prepared by this method is sold under the name of 'Neu-Fuchsin' (new magenta).

Later on a patent was obtained by Cassella & Co., of Frankfurt-am-Main, the essence of which is probably the same. It consists in introducing methyl alcohol into the arsenic acid melt. Formaldehyde is probably thus produced, which is at once transformed into diamino-diphenylmethane. By introducing chlorinated anilines into the pararosaniline melt the chlorine substitution products of rosaniline have been obtained, which are remarkable by being much more bluish in shade than either pararosaniline or ordinary magenta (Cassella & Co., D. R. P. 21923, 1913).

Acid magenta.—The ordinary fuchsin or magenta has been used for dyeing cotton, wool, and silk. But its properties make it necessary to use neutral or very slightly acid baths. This is a considerable drawback to its use on silk or wool, especially in combination with other dye-stuffs which require distinctly acid dyebaths for their successful application. It was, therefore a decided advance to introduce a sulpho derivative of magenta into the market. This step was realised by H. Caro in 1877 (Eng. Pat. 3731, 1877; D. R. P. 2096, Badische Anilin- & Soda-Fabrik). Caro proved that magenta, which shows a marked resistance to ordinary sulphuric acid, may easily be converted into a trisulpho derivative by treatment with fuming sulphuric acid. The ordinary crystallised hydrochloride of magenta is used. It is introduced in a finely-powdered condition into fuming sulphuric acid; the mixture is then heated to a temperature not below 120° and not above 170° . Hydrogen chloride is given off, and the sulpho derivative is formed. When the operation is finished, it is diluted with water and worked up in the usual manner, by first preparing the lime-salt and then converting it into the sodium salt. The para derivative has the composition $C_{18}H_{12}N_2O_3S_3Na_3$, the higher homologue $C_{20}H_{14}N_2O_3S_3Na_3$; the ordinary acid magenta is a mixture of the two. The constitution of

the para derivative may be represented by the following formula:

from which it will be seen that the sulpho-groups occupy the *ortho* positions relative to the amino groups. It forms a metallic green powder, very soluble in water with magenta colour, which disappears completely on addition of caustic alkali, the sulpho derivative of the colourless triamino-triphenyl carbinol being formed.

Acid magenta may also be obtained by acting with chlorosulphonic acid upon dry magenta base (E. Jacobsen, D. R. P. 8764, 1879; Eng. Pat. 2828, 1879).

By using the various by-products of magenta instead of the pure dye-stuff, acid derivatives of these may be obtained which prove particularly valuable for dyeing mixed shades.

Magenta base (red base, rosein base). A large proportion of the fuchsin produced is transformed into the corresponding base, the composition of which has already been discussed. For the production of a good base, crystallised fuchsin only should be used. This is dissolved in a large volume of boiling water, and made alkaline either with milk of lime or with ammonia. In the latter case, the product obtained consists partly of the amino derivative already mentioned. No caustic alkali should be used. From the filtered solution the base settles out on cooling in crystals, which have the shape of a fern-leaf of pale-pink colour. In the air they generally become darker, because a certain amount of magenta carbonate is formed on their surface. The base thus prepared is sold for conversion into violets and blues (*q.v.*).

COLOURING MATTERS DERIVED FROM ROSANILINE.

The brilliant researches of A. W. Hofmann proved, at an early period, that rosaniline is capable of having the hydrogen atoms of its amino groups replaced by alkyl groups, and that the substances so formed are remarkable not only for the brilliancy, but also for the great variety, of their shades. Hofmann himself introduced the alkyl radicals of the fatty series into the molecule of rosaniline, and thus obtained the colouring matters which for a long time played an important part under the name of Hofmann's violets. Girard and De Laire discovered a method of introducing the phenyl and other aromatic groups into the molecule of rosaniline, and thus inaugurated the manufacture of aniline blues. It was then attempted, first by Lauth, to produce alkylated rosanilines by direct oxidation of alkylated aniline, and this method proved of great practical importance in the hands of Bardy, although the theory of this

process was only understood at a much later period. Finally, a synthetical method for the production of certain alkylated rosaniline derivatives which cannot be produced by direct alkylation of rosaniline itself, was discovered by Kern, whose processes are based on the theoretical researches of Michler.

All these colouring matters will now be described, and the methods of their formation discussed.

1. Hofmann's violet $C_{26}H_{32}N_3Cl$, hydrochloride of triethyl-rosaniline

is obtained by heating magenta base with ethyl iodide, bromide, or chloride, and a sufficient quantity of alcoholic soda solution to neutralise the acid formed in the reaction. The magenta base is prepared by decomposing a very weak fuchsin solution with milk of lime or ammonia. From the filtered solution the base crystallises in small leaflets of a pink colour. The alkylation is effected in closed vessels of copper or cast-iron, which are heated to 80° – 100° by steam or in a water-bath. The trimethyl-rosaniline hydrochloride, which is slightly bluer in shade, was formerly also prepared. This is no longer employed. By using less of the alkyl haloids than is necessary for completing the reaction, redder shades were obtained, which were mixtures of the mono- and di-ethyl- or methyl-rosanilines. In commerce, the more or less reddish tinge of their shade is marked by the addition of the letter R, thus: Violet R, RR, up to 5 R.

2. Methyl violet B. C. Lauth, wishing to find a new method for the production of Hofmann's violets, tried to oxidise methylated aniline. He obtained a violet of much bluer shade. Bary worked out the method, which was patented by Poirrier and Chappat (Fr. Pat. 71970, dated June 16, 1866). The product obtained was proved to be the hydrochloride of pentamethyl para-rosaniline $C_{24}H_{28}N_3Cl$ —

This dye-stuff, which became of great importance, was for a long time known under the name of *Violet de Paris*. At present it is sold by the various colour works under the name Methyl Violet B to 3 B.

The mode of formation of this colouring matter is very interesting. Many researches have shown that it is best prepared from pure dimethyl-aniline, which should be as free as possible from every trace of monomethyl-aniline. If three molecules of dimethylaniline be oxidised into one molecule of the dye-stuff, one of the six methyl groups present serves to form the central carbon atom, whilst the other five remain combined with the amino groups of the dye-stuff formed.

The process of oxidation employed is totally different from those resorted to in the manufacture of magenta or fuchsin. Cupric chloride is used as an oxidiser at a temperature which is little above that of the atmosphere. The cuprous chloride formed is again transformed into cupric salt by the oxygen of the air. The air should, therefore, have ready access to the mixture. To fulfil this condition, a porous condition is given to the melt by the admixture of sand or other indifferent materials. Cakes are formed of the mass, and these are left on trays in a hot chamber. The following proportions have been recommended:

100 parts sand,	
10 „ dimethylaniline,	
3 „ cupric nitrate,	
2 „ sodium chloride,	
1 „ weak acetic acid.	

The cakes, which show a dull greenish colour at first, gradually assume a bronze lustre and become hard and brittle. They now contain the violet formed as an insoluble compound with cuprous chloride. To obtain the violet the cakes should be powdered, and all soluble substances extracted with water. The double salt of violet and cuprous chloride should then be decomposed. Various means have been adopted for this purpose.

The original process consists in treating the material with a weak solution of sodium sulphide. Insoluble copper sulphide is formed, and the free violet is dissolved. From the filtered solution it may be precipitated by the addition of salt. It comes out in the shape of a gold-coloured tar of metallic appearance, which is collected and dried in jacketed pans. When dry it forms a brittle mass of metallic aspect, showing no tendency whatever to crystallise. It is sold under the name of 'Methyl violet B' or 'direct violet.'

The use of sodium sulphide has this inconvenience, that any excess of the reagent acts as a reducing agent on the violet, transforming it into its leuco compound, which cannot be separated from the violet, and impairs its strength, besides producing other complications. To remedy this drawback, several factories used gaseous hydrogen sulphide instead of the 'sodium' compound. Hydrogen sulphide has no reducing action on the violet in neutral or slightly acid solutions. The use of this gas on a large scale is, however, extremely dangerous, and accidents, which happened

repeatedly, have led to the abandonment of its use.

The following methods admit of the extraction of the violet without the use of sulphides.

The first is based on the fact that, although the violet combines with cuprous chloride in the shape of its hydrochloride, this is not the case if the two be present as sulphates. If, therefore, the crude insoluble melt is boiled with dilute sulphuric acid, the violet goes into the solution together with the copper. The solution is then filtered off from the sand. If now salt were added in order to precipitate the violet, the insoluble compound would rise from chlori-

for precipitating the violet, which comes out as sulphate, whilst the copper remains in the solution. The violet sulphate is now carefully washed, re-dissolved, and re-precipitated in the shape of chloride by the addition of common salt.

Another process, which gives equally good results, is based upon the fact that the insoluble compound becomes soluble if the cuprous chloride contained in it be oxidised into cupric salt. For this purpose the crude cake is triturated with a solution of ferric chloride. It is then filtered off and washed. The violet, which has become soluble, may now be extracted with water, and precipitated by the addition of salt.

Great improvements have been effected in the melt itself. First of all, it was recognised that the cakes, if left to themselves, were apt to lose too much dimethylaniline by evaporation; they also remained insufficiently oxidised in their interior. To obviate this, the use of bread-kneading machines was resorted to, through which a current of air was blown. This current was made to pass through a vessel containing sulphuric acid, after leaving the machine. Complete oxidation was thus obtained, whilst the base which distilled over was recovered in the acid.

Later on, the quantities of the copper salt were reduced, and some potassium chlorate was added to the mixture. This yielded the necessary oxygen, the presence of a current of air became superfluous, and the evaporation of the base could be stopped by using closed vessels or kneading machines.

Another great inconvenience is the sand. It is necessary as a diluting agent, but in the after-operations it is very troublesome, being very heavy and producing great wear of the apparatus. It was, therefore, a great improvement to use clean salt instead of sand. The salt is quite as indifferent as the sand, but after having done its duty, it may be easily removed by solution, leaving the insoluble compound of the violet and cuprous chloride in the shape of a fine dark powder, which is admirably fitted for being worked up into soluble product.

By such improvements it was possible to raise the yield of colouring matter, which at first hardly reached 45 or 50 p.c. of the dimethylaniline used, to 90 p.c. and more. If we remember that 30 p.c. of pure colouring matter is a fair yield in the manufacture of magenta, we may well understand that methyl violet, although manufactured from a much more

expensive raw material than fuchsin, soon became much cheaper than its parent substance.

The yields of violet have been further increased by a curious procedure. It consists in adding some phenol to the mixture. The action of the phenol, which may be recovered, is that of a solvent; by its use the yield of violet becomes very nearly theoretical.

In the manufacture of violet, especially by the older methods, there is always some tri- and tetra-methylrosaniline formed along with the penta-methyl derivative, because the methyl groups are attacked, and transform the violet is, therefore, slightly redder than it ought to be. To compensate for this loss, Bardsy treated his direct violet with benzyl chloride, and thus introduced benzyl groups wherever methyl was wanting. The violet of very blue shade thus obtained was brought into commerce under the name of *Methyl violet 5 B* or *Benzyl violet*. It has now lost its importance, having been to a great extent replaced by the very beautiful crystallised violets obtained by the synthetical method of Kern.

3. *Iodine green* and *Methyl green*. It has already been said that Hofmann's process of direct alkylation of rosaniline does not go beyond the tri-alkyl derivatives. If the action of alkyl halides be still continued, ammonium bases are formed. Thus by heating Hofmann's violet with methyl iodide in a methyl alcohol solution, Keisser obtained (1866) a green colouring matter, which was manufactured and sold for many years under the name of *iodine green*. A very similar dye-stuff was prepared from methyl-violet in a like manner by Bardsy, who used, however, methyl nitrate instead of the iodide. After several explosions, the use of the nitrate was abandoned, and methyl chloride or bromide, also ethyl bromide, were used instead. The dye-stuff thus obtained was sold under the name of *methyl green*. It did not contain any iodine, and was therefore much cheaper than the iodine green, which it quickly replaced.

Chemically, the two may be considered as homologues of similar constitution, viz. as methyl ammonium derivatives of hexamethyl-rosaniline and hexamethyl-pararosaniline. *Iodine green*, being a derivative of ordinary rosaniline, contains one tolyl group:

The methyl groups in this formula may also partly be replaced by ethyl groups if ordinary Hofmann's violet were used as a raw material.

Methyl green is the corresponding derivative of pararosaniline:

Both these dye-stuffs were brought into commerce in the shape of their zinc double chlorides. The iodine green formed a dark powder, whilst the methyl green formed pretty green needles or leaflets.

To prepare these dye-stuffs the violets were simply heated with the alkyl halides in closed enamelled iron vessels to 120° . Some wood spirit, or common alcohol, was added as a solvent. A pressure of 10–12 atmospheres was observed, which decreased when the reaction was finished. The crude product was dissolved in water. This solution was of dark-blue colour, because there was always some violet which remained unattacked. To separate this, the solution was shaken up with amyl alcohol, which dissolved out the violet. The green remained in the aqueous solution, from which it could be precipitated by the addition of zinc chloride and common salt. To obtain crystals, the crude green was re-crystallised from spirit.

These greens have now almost entirely been replaced by the diaminotriphenylmethane derivatives already described, which are not only more brilliant in shade, but also much more stable and at the same time very much cheaper. Iodine green and methyl green are decomposed and turn a dirty violet even by the action of a gentle heat, as produced in the process of cylindering fabrics, and on many other occasions.

Pararosaniline derivatives prepared by Kern's method.—Another way of preparing alkylated pararosanilines was indicated by Kern, who started from the observations published by W. Michler (Ber. 1876, 9, 716). This chemist had shown that by acting with carbonyl chloride COCl_2 upon dimethylaniline, dimethylaminobenzoyl chloride is formed, which acts again on dimethylaniline, yielding tetramethyldiaminobenzophenone:

At the same time, as Michler observed, an intense blue colouring matter is formed. A. Kern (1883) followed up Michler's observations, and discovered not only the nature of the blue colouring matter, but also the conditions under which it may be obtained as the sole product of the reaction. The colouring matter proved to be pure hexamethylpararosaniline, the forma-

tion of which is due to the action of another molecule of dimethylaniline upon tetramethyldiaminobenzophenone. This action is, however, not very energetic, and must be intensified by the addition of certain substances, or by substituting for the ketone certain of its more active derivatives. A number of different processes have thus been worked out, the more important of which will now be described.

A. Kern's original modification of Michler's experiment is based upon the fact that tetramethyldiaminobenzhydrol, the secondary alcohol derived from the ketone tetramethyldiaminobenzophenone, acts readily upon aromatic bases, forming triphenylmethane derivatives. This process is described in Kern's Eng. Pat. 5450 (1883), and the corresponding D.R.P. 27032, Bad. Anilin- und Soda-Fabrik. Tetramethyldiaminobenzhydrol:

which had already been obtained by Michler by the action of sodium-amalgam upon the ketone may, according to this patent, be prepared industrially by boiling a solution of the ketone in amyl alcohol with caustic soda and zinc-dust. When the reduction is finished, the alcohol is blown off with steam, the residue dissolved in hydrochloric acid, and purified by fractional precipitation with caustic soda.

The product thus obtained may be condensed with primary, secondary, and tertiary aromatic bases, yielding in every case alkylated derivatives of paralucaniline; thus, for instance, with dimethylaniline the leuco base of hexamethylrosaniline is formed, if the two be brought together in a solution in weak sulphuric acid

This leuco base may be oxidised into the corresponding dye-stuff by the method indicated for the production of benzaldehyde green—viz. by the action of lead peroxide upon the hydrochloride of the leuco base. The hexamethylrosaniline hydrochloride thus obtained is a beautifully crystalline substance, which forms green crystals if anhydrous, $\text{C}_{26}\text{H}_{30}\text{N}_3\text{Cl}$, or bronze-coloured prisms if containing water of crystallisation. In the latter case, its composition is $\text{C}_{26}\text{H}_{30}\text{N}_3\text{Cl} \cdot 8\text{H}_2\text{O}$. The power of crystallisation of this substance is very remarkable if we compare it with the ordinary violet obtained by direct oxidation of dimethylaniline; this, being a mixture of the tetra-, penta- and hexamethylrosanilines, shows no tendency whatever to crystallise.

If in the process described diethyl-aniline be substituted for dimethyl-aniline, both for the

production of the hydrol base and its subsequent transformation, the result is, of course, hexaethylrosaniline, which cannot be prepared by any other process. This product is manufactured and sold under the name of '*Ethyl-purple, 6 B*' (ethyl violet). It is a very beautiful colouring matter, dyeing fine bluish-purple shades.

Very soon a simpler method than the one described was discovered by Kern and Caro (D. R. PP. 26016 and 29943; Eng. Pat. 4428, 1883). It was based upon the fact that the action of tetramethyldiaminobenzophenone upon dimethylaniline, which, in Michler's experiment, already had yielded a small amount of colouring matter, may be modified by the addition of certain substances, such as aluminium chloride, zinc chloride, and others. If these be present, the reaction of phosgene gas (carbonyl chloride COCl_2) upon dimethylaniline does not result in the formation of tetramethyldiaminobenzophenone; this is only formed as an intermediate product, which reacts at once upon another molecule of the base, forming hexamethyl-pararosaniline:

Many modifications of the processes here described have also been indicated and patented. Thus, instead of the carbonyl chloride, thio-carbonyl chloride (CSCl_2) may be used, which yields with dimethylaniline the thioketone

The latter may replace the oxygen compound in all its applications.

Again, trichloromethyl chloroformate

and similar substances have been proposed as substitutes for the carbonyl chloride.

The following is the method used at present for preparing *Crystal violet* and *Ethyl purple 6 B*: 100 kilos of dimethylaniline (or diethylaniline) are acted upon in a high-pressure pot at a temperature of 20° with 19–20 kilos of carbonyl chloride; after 24 hours' standing another 50 kilos of the base and 30 kilos powdered zinc chloride are added. The mixture is now heated to 40° – 50° , and 20 kilos more of the carbonyl chloride are introduced. After 6 hours' heating to 50° , the reaction is finished. The mixture is now introduced into a still, made alkaline with caustic soda, and the excess of dimethylaniline driven off with steam. The base of the colouring matter is then dissolved in weak sulphuric acid, and precipitated in the shape of its chloride by the addition of common salt. It is then recrystallised from water.

This process leads, of course, only to para-rosaniline derivatives in which the three amino-groups are substituted in the same manner. Besides the hexamethyl- and hexaethyl derivatives, the trimethyltriphenyl derivative has been obtained from methyldiphenylamine (Amer. Pat. 327953, Kern and C. Müller). It was, therefore, a great improvement when a method was found for effecting the condensation of tetramethyldiaminobenzophenone with all kinds of primary, secondary, and tertiary bases. This method, which was worked out by Kern and H. Caro, consists in the intermediate formation of the tetramethyldiaminobenzophenone chloride:

which, being more active than the ketone itself, reacts most easily upon bases of ever description. For the manufacture of colouring matters it is not necessary to isolate the chloride, an extremely unstable substance. It is sufficient to react with phosphorus trichloride upon a mixture of the ketone with the base which is to be introduced into the triphenylmethane derivative.

This process is described in the D. R. P. 277891, the Eng. Pats. 4850 and 5038, 1884, and a large number of corresponding American patents, which contain many examples of its application to the production of dye-stuffs. Of these, however, only few have obtained lasting importance. These are basic colouring matters of a beautiful blue shade, and interesting because they are the only members of the triphenylmethane group which contain the naphthyl radicle.

Victoria Blue B $\text{C}_{22}\text{H}_{22}\text{N}_3\text{Cl}$ has the constitutional formula:

It is prepared by mixing together

10 kilos tetramethyldiaminobenzophenone and

9 kilos α -naphthylphenylamine, and adding

7 kilos phosphorus trichloride to the mixture.

The reaction, which sets in at once, is finished by heating to 110° . The product is dissolved in water, and the solution precipitated with salt.

A similar dye-stuff, analogous in its constitution, but of a somewhat more reddish shade, is obtained if instead of α -naphthylphenylamine, monoethyl- α -naphthylamine be used. It is known under the name *New Victoria blue R*.

If α -naphthyl-*p*-tolylamine be taken instead of the naphthylphenylamine, and condensed with tetra-ethyl-diaminobenzophenone, a blue of a very greenish shade is obtained. It is sold under the name *Night blue (Nachtblau)* and has the composition $\text{C}_{22}\text{H}_{22}\text{N}_3\text{Cl}$:

Another blue of very red shade is the one sold under the name *Victoria blue 4 R*

It is prepared from tetramethyldiaminobenzophenone and α -naphthylmethylphenylamine. Its constitution is probably

In describing both the green dye-stuffs derived from diaminotriphenylmethane and the old and important magenta group, it has been mentioned how much the dyer values the possibility of dyeing the useful shades which these colouring matters supply from an acid bath and of thus being enabled to combine them with all the other wool dyes capable of such application, especially the azo colouring matters. The same necessity exists for the various shades of violet here described.

This want was at first supplied by the means which had proved successful in the case of magenta, viz. by the direct sulphonation with fuming sulphuric acid of the various violets, especially the redder shades obtained by the reaction of alkyl halides upon magenta base. The colouring matters thus produced were introduced at the end of the seventies under the name of *Acid violets* to which letters denoting the shade (R and B) were added. But they did not meet with the same ready reception that had been offered to acid magenta. It is now known that the sulphuric anhydride of the fuming acid is very apt to attack the alkyl groups and thus to tarnish the shade of the violets.

The new synthetical method which had produced *Crystal violet* and its many congeners and which is apparently analogous to the synthesis of *Victoria green* and its numerous homologues, could not fail also to indicate rational methods for the production of acid violets of every conceivable shade.

Some of these methods consisted—in strict analogy to what had been done in the group of the *greens*—in introducing the benzyl group into the molecule of the dye-stuff and utilising the capacity of this radicle for sulphonation. All the variations of this method given in the description of the acid greens are admissible in the violet group. In this way the following dye-stuffs have been obtained, the structural formulæ of which need not be given:—

Acid violet 4BN, 6B, 7B and N, prepared by the sulphonation of pentamethylbenzyl-pararosaniline or by the oxidation of the monosulpho derivative of pentamethylbenzyl-leucaniline.

Acid violet 6B or Guinea violet 4B. This is a disulpho derivative, obtained by oxidising the acid, which may be obtained by the condensation of dimethyl-*p*-aminobenzaldehyde with ethylbenzylaniline sulphonic acid. The corresponding derivative of diethyl-*p*-aminobenzaldehyde is also manufactured.

Another class of acid violets is derived from methyldiphenylamine, which may be introduced instead of dimethylaniline by all the synthetical processes described. The additional

phenyl group entering into the molecule of the leuco base of the dye-stuff derived from it by oxidation is capable of carrying a sulpho group which may be introduced into it by the usual means. Thus *Alkali violet 6B* and *Acid violet 7B* can be prepared, whilst in *Acid violet 7BN* ready formed methyldiphenylsulphonic acid is condensed with dimethyl-*p*-aminobenzoic acid.

The process of introducing elements capable of being sulphonated into the synthesis of rosaniline derivatives may be carried still farther. Thus a useful dye-stuff, called *Wool green*, is manufactured by several firms by condensing tetramethyldiaminobenzophenone (Michler's ketone) with β -naphthol and subsequently sulphonating the insoluble dye-stuff so obtained.

Rosaniline blues or phenylated rosanilines. These are of great importance, forming by far the majority of blue aniline dyes in the market. The chemistry of these compounds is, however, extremely complicated. The blues sent into commerce are not chemically pure substances, but mixtures of various isomerides; it is very difficult to classify them. Moreover, they are known under a great variety of fancy names, many of which are applied to products of different composition by different firms. The following is an attempt to classify the various blues.

The method of phenylation is very remarkable, and quite different from the methods of substituting fatty radicles for hydrogen in the amino groups of rosaniline. The general method in this case consisted in treating rosaniline base with the halogen derivatives of these radicles. Owing to the great stability of chlorobenzene C_6H_5Cl , the same process cannot be applied to the phenylation of rosaniline. This takes place, however, with great facility if we allow aniline to act upon rosaniline, ammonia being given off as a by-product:

It has already been shown that a consider-

able difference exists between pararosaniline hydrochloride or parafuchsin and the ordinary fuchsin of commerce. The former is a uniform compound $C_{15}H_{11}N_3Cl \cdot 4H_2O$, whilst the latter is a mixture of parafuchsin with at least two isomeric homologues. Both these substances may be phenylated; their phenyl derivatives are blue colouring matters of great intensity and beauty. But a greater difference is found to exist between the phenyl derivatives of pararosaniline and those of ordinary magenta than even between the two kinds of fuchsin themselves.

This method of phenylation, which has been indicated by Ch. Girard and G. de Laire, is invariably resorted to. It cannot, however, be applied on a practical scale to the hydrochloride, as assumed for simplicity's sake in our equation. Experience has shown that organic acids must be used in order to get good results. The majority of organic acids have been tried for the purpose; at present, however, only two are used, which give distinctly different results, viz. acetic and benzoic acids. The reason for this difference has not been definitely ascertained, but it is a fact known to every manufacturer that blues of a greenish shade can only be obtained with benzoic acid, whereas acetic acid yields more reddish compounds.

The phenylation of rosaniline cannot be pushed further than the formation of triphenylrosaniline. The tetra-, penta-, and hexaphenyl derivatives are not known. But even the formation of triphenylrosaniline, such as it is indicated by our equation, takes place in three successive stages, the phenyl groups entering the molecule one after another. It is, however, practically impossible to separate these stages. If, in the beginning of a blue melt, a certain amount of mono-phenylrosaniline be formed, the reaction proceeds simultaneously on this and on rosaniline, which has not yet been attacked; thus, in a second phase, monophenyl and diphenyl rosaniline, and rosaniline (which has not yet been attacked) will be present together. To these the triphenyl compound will presently be added, a very complex mixture being the result. By a more prolonged action it is possible to eliminate rosaniline itself and its monophenyl derivatives completely from the mixture. But some diphenylrosaniline will always remain present. Moreover, all these compounds seem to exist in various isomeric modifications. It is a mixture of these which forms the ordinary *crude* or *Opal blue*.

If, instead of pararosaniline, the ordinary rosaniline of commerce be used for the production of the blue (as is the case in most instances) the product becomes even more complicated by the presence of the homologous compounds. Some process of separation which splits up the crude product into fractions of different shades and reactions must be resorted to; and although some of these are crystallised, it cannot be said with certainty that they represent chemically pure individuals.

Mono- and di-phenylpararosaniline have hitherto not been prepared in a pure state. Nothing can, therefore, be said of their properties.

hydrochloride

is the purest and brightest blue known. It is now invariably prepared by the phenylation of pararosaniline, but it may also be obtained by melting together diphenylamine and oxalic acid. The formic acid evolved in the decomposition of oxalic acid serves to link together three molecules of diphenylamine into one of triphenyl leuco aniline, which is then slowly oxidised into the rosaniline compound. It was this method which was formerly used for the production of this blue, which therefore is still frequently described as *Diphenylamine blue*; it is also sometimes called *Methyl blue*, because methyldiphenylamine was occasionally used for its production. Other names for the same product are:

Bleu direct, bleu lumière, bleu de Lyon, bleu de Mulhouse, bleu de nuit, bleu de Paris, light blue, night blue, Paris blue, Bavarian blue.

This product forms a microcrystalline powder of a bronzy appearance, completely insoluble in water, sparingly soluble, with a brilliant blue colour, in spirit. Its transformation into the soluble diphenylamine blues of commerce will be described hereafter.

When the same process of phenylation (the particulars of which will be given below) is applied to the ordinary rosaniline of commerce—which is, as will be remembered, a mixture—various products are obtained. Of these the following may be said to have been isolated:—

Monophenyl-rosanilines. These are the product of a very moderate phenylation. They are still soluble, in the shape of their acetates, in water, and dye fine purple shades. They have now, owing to the greater cheapness of methyl violets, almost completely disappeared from the market, in which they formerly played an important part under the name of *Regina purples* or *Regina violets*. It was customary to prepare them, not by the action of pure aniline on magenta acetate, but rather by that of the recovered oils or *échappés* from the magenta process, which contained a large proportion of *o*-toluidine. The action of the latter is slower than that of aniline; it is, therefore, easier to stop the reaction before a considerable proportion of the diphenyl or ditolyl rosaniline is formed. The regina purples consisted, therefore, to a great extent of the *o*-tolylrosaniline, the acetate of which is represented by the following formula:

Regina purple.

Diphenylrosanilines. These were invariably obtained, together with the regina purples, from which they are distinguished by their complete

insolubility in water. They are, however, still of a purple shade; they are invariably present to some extent in crude tri-phenylrosaniline blue, if the latter be prepared with acetic instead of benzoic acid. This is the reason why such blue is always of a redder shade than the blue prepared with benzoic acid, in which the proportion of diphenyl derivatives is reduced to a minimum. A product which consists chiefly of diphenyl-rosanilines, is known under the name of *spirit purple*, *spirit violet*, or *opal violet*; it has also been sold as *regina spirit purple*. From it the *soluble violets* and *purples*, and *alkaline purples* of commerce are derived by sulphonation.

Triphenylrosanilines (see Supplement). The triphenyl derivatives of ordinary rosaniline may be subdivided into two classes: crystalline and uncrystallisable blues. The former may be extracted from every crude blue melt prepared with benzoic acid. They represent in a state of approximate purity the triphenyl derivative of the higher homologue of pararosaniline, and may therefore be represented by the following formula:

It is to this product, which forms the base of the high-class alkaline and water blues of commerce, that one should reserve the name of *Opal blue*, which has, however, been indiscriminately applied to a number of various products. This opal blue forms, in the shape of its pure hydrochloride, a mass of distinct, though very small, glistening crystals of a greenish brass-colour. It is completely insoluble in water and in spirit. If it be treated with alcoholic caustic soda, the free base is obtained in the shape of a tarry substance from which the acetate may be prepared by dissolving it in glacial acetic acid, and re-precipitating with water. This acetate is soluble in spirit, and, though sparingly, also in water. It was formerly sold and used under the name of *Opal blue 6 B for cotton*, *Gentian blue*, *Hessian blue*; also the names of *Bleu lumière*, *Bleu de nuit* (originally used for the para derivative), were occasionally applied to it. In Germany it was sold under the name of *Feinblau*, *Spirit-blau*. The latter expression is applied, however, to all blues soluble in spirit, not only to this acetate. Its use has been much restricted of late, owing to the unwillingness of the dyer to use spirit in the dye-bath.

The second class of triphenyl derivatives of ordinary rosaniline, comprises the uncrystallisable portions of crude blue melts. They contain a mixture of triphenyl and diphenyl-

rosanilines in various proportions, quite inseparable by the means which are at our disposal. They are (in the shape of hydrochlorides) insoluble in water, soluble in spirit. Caustic soda transforms them into a mixture of the corresponding bases, which are tarry masses. Their shade varies from a purplish-blue to a distinct clear blue of great strength and purity which, however, always shows a purplish hue if looked at by artificial light. This blue forms the starting-point for the production of innumerable brands and qualities of alkaline and water blues, varying in their shade and in the purity and strength of their colour. They are designated, according to the redness of shade, by the letters 3 R, 2 R, R, B, 2 B, and 3 B, whilst 4 B, 5 B, and 6 B may be said to be reserved for the derivatives of the true opal blue of varying purity. A large number of fancy names, such as *China blue*, *Marine blue*, *Serge blue*, &c., have been invented for this kind of blues.

Besides these blues a special kind of low-class blue should be mentioned which, under the name of *Blackley blue*, has enjoyed, and still enjoys, much favour, especially for dyeing paper-pulp, and also for the production of cheap woollen materials. This is the sulphonation product of a peculiar kind of phenyl rosaniline, prepared by acting with aniline upon crude magenta. It is consequently very impure, but also very cheap. It contains a mixture of the phenylation products of all the substances contained in crude magenta.

Tri-*p*-tolylrosaniline has been prepared by acting with *p*-toluidine in the presence of benzoic acid upon ordinary rosaniline base. It is a blue of remarkable beauty and brilliancy of shade, which offers, however, great resistance to the process of sulphonation. It has, therefore, only been manufactured and sold in the shape of its hydrochloride, which is soluble in spirit. It is sold for dyeing cotton under the name of *Grünlichblau* (Höchst) or *6 B extra opal blue* (English manufacturers). It has largely gone out of use of late years.

Manufacture of blues.—An immense number of prescriptions for blue melts has been published, and a larger number still circulates amongst manufacturers. It would be perfectly useless to reproduce any of them. The principles upon which they are based may be thus briefly stated:—

For the production of good blues a perfectly pure magenta base is the first requirement. For its preparation crystallised fuchsin only should be employed. If crude magenta or any of the magenta residues (*cerise*, *grenadine*, &c.) be used, the base obtained can only be employed for the production of *Blackley blues*. Pure pararosaniline, the base prepared from parafuchsin (*Neufuchsin*), should be used for the production of the so-called diphenylamine or methyl-blues (direct blues); whilst crystallised base from ordinary fuchsin forms the starting-point for all the ordinary blues from 4 R to 6 B, as well as for regina purples.

The second condition for the production of good blues is the use of very pure aniline, perfectly free from toluidine. It was in the manufacture of blues that the necessity of operating with pure aniline was first felt. The term *aniline*

for blue was, therefore, and is still occasionally, applied to perfectly pure aniline, boiling within one degree, and having a specific gravity of 1.0268-1.0270. Such aniline can only be prepared from pure crystallisable benzene.

If these two conditions—pure magenta base and pure aniline—be fulfilled, the shade of the blue obtained is still dependent upon :

1. The proportions of base and of aniline in the melt. It may be said that greenish blues will only be obtained if a very large excess of aniline be used, whilst reddish blues are produced in melts rich in magenta base.

2. The time and temperature of the melt. The formation of blue begins below 100°. It proceeds quickly at a higher temperature; 120°-140° may be assumed to be the most favourable temperature. From 140°-180° certain impurities (diphenylamine?) are formed, which impair the tendency of crystallisation of the blue. The temperature of high-class blue melts should therefore not be raised above 140°. The time required by a blue melt depends upon the proportion of base to aniline, and, to some extent, the quantities operated upon. The process proceeds quickly in highly-concentrated melts. Melts for high-class blues, which contain a large proportion of aniline, require prolonged heating—20 hours, and even more, before being finished. As a rule, the progress of the melt is tested by placing a drop of the melt on filter paper moistened with spirit. The gradual change of colour may thus be observed with great accuracy. When the melt is finished, there should be no reddish rim visible in the spot produced on the paper.

3. The nature and proportion of the acid used in the melt. It has already been said that organic acids only should be used, the action of hydrochloric acid being too slow. Acetic and benzoic acids are now used exclusively. The action of acetic acid is quicker than that of benzoic acid, but it seems impossible to transform all the rosaniline into its triphenyl derivative by the use of acetic acid. Benzoic acid acts more slowly, but it continues its action until all the rosaniline is transformed into the triphenyl derivative. At the same time, the whole of the melt is, even with benzoic acid, not entirely transformed into crystallisable opal. Moreover, acetic acid produces (by its simultaneous reaction on aniline) some acetanilide, which remains in the blue and is apt to prevent its subsequent crystallisation, whilst no benzanilide is formed by heating aniline with benzoic acid. For these reasons acetic acid is employed in the production of low-class reddish-blues (in concentrated melts), whilst benzoic acid is used only for the production of high-class opals. The greater part of the benzoic acid may be recovered from the melt, whilst the recovery of the acetic acid does not pay.

There is no advantage in using other acids instead of acetic and benzoic acid. As a rule, it may be said that the fatty acids (formic, butyric, valeric acids) act similarly to acetic acid, whilst the aromatic acids (toluic, phthalic, cinnamic acids) may take the place of the benzoic acid.

Upon these conditions all the prescriptions for blue melts are based. Taking the quantity of magenta base to be operated upon as unity,

the quantity of aniline added varies from four to twenty-five times its weight, the quantity of the organic acid from $\frac{1}{10}$ to $\frac{1}{2}$. The conditions of time and temperature have already been stated.

The apparatus necessary for blue-making is very simple so far as the melt is concerned, enamelled cast-iron pots with a lid and stirrer being always used. In the early times of the manufacture of aniline colours it was believed that blue melts could only be made in glass, and on a very small scale. In the 'Fuchsin' factory at Lyons the blue was therefore manufactured in large numbers of glass flasks heated in a sand-bath. At present it is believed that blue melts are best under control in large quantities; large melting-pots are therefore used as a rule. While the melt is in progress ammonia is given off, which carries a certain amount of aniline away. It is advisable to condense this aniline, and to absorb the ammonia by water or sulphuric acid.

When the melt is finished it must be worked up. This may be done by a variety of methods. Of these the simplest—which is, as a rule, resorted to in the manufacture of low-class and Blackley blues—consists in neutralising the melt with a quantity of caustic soda just sufficient to saturate the acid added to the melt. The excess of the aniline is then driven off with steam and recovered. The blue base remains in the still, and is run out whilst still hot, in a tarry state, together with the water. On cooling, it solidifies into a very brittle mass, which may be powdered, dried, and subjected to the process of sulphonation to be described hereafter.

For the production of high-class blues this simple process cannot be adopted. A separation of the crystallisable opal from the uncrystallisable blue, which invariably accompanies it, must take place, and for this separation the melt requires a special treatment. For this there are two distinct processes, of which one is very complete, although costly, because it requires large quantities of spirit. We may call it the *English process*, because it was worked and carried out chiefly in English factories. The other process, which is now used in most of the German works, is very rapid, and requires but little spirit. On the other hand, it does not give so pure a product; we may call it the *German process*.

The *English process* is the final outcome of the original French process for working up the blue melts, which consisted in boiling them out with dilute hydrochloric acid. The aniline was dissolved out together with the organic acid present, whilst the blue remained in the shape of its hydrochloride as a fine blue precipitate, which was filtered off and washed. It was then ready for sulphonation. When it was discovered that this blue was a mixture of different colouring matters it became customary to separate these by boiling the crude blue with spirit. This dissolved out the lower-class blues, leaving a better product as a residue. By repeating this process frequently, a residue was obtained at last which was quite insoluble in spirit. This represented the purest opal blue obtainable. It was by this tedious process that the once famous 'Bleu Mavi,' or 'Bleu MAVI' was obtained in

France and Switzerland. The improved English process much simplified things, and at the same time gave better yields and a purer colour by producing the opal blue in a crystallised condition, in which it is totally insoluble in spirit. This process consisted in adding to the melt (prepared with benzoic acid and a large excess of aniline), while still hot, a certain quantity of aniline hydrochloride; on cooling, the opal blue, being gradually converted into the hydrochloride, settled out in small glistening crystals, whilst the low-class blue remained dissolved in the aniline. The opal was then filtered off, and washed with spirit until quite pure. If necessary, it could be re-converted into base by treatment with alcoholic caustic soda. The base, re-dissolved in aniline, could again be converted into hydrochloride by again adding aniline hydrochloride. The opal then came out in very fine crystals, which represented the blue in a state of greatest purity. The aniline liquors obtained from these crystallisations had to be distilled in order to recover the spirit. They were then made alkaline in order to decompose the aniline hydrochloride present, the aniline was driven off by steam, and the remaining low-class blue obtained in the shape of base as described. Owing to the large quantities of spirit used for washing the crystallised opal, and the consequent loss of spirit by evaporation, this process (which may be recommended for laboratory experiments) was costly, and unable to compete with the rapid and cheap German process.

The German process is based upon the fact that the crystallisable blue opal is insoluble in a very hot solution of aniline hydrochloride, whilst the common non-crystallisable blues are soluble in this liquid. The solution of the aniline salt must, however, be so concentrated (in order to act properly) that it would solidify into a mass of crystals if cooled in the least degree. It is rather fused aniline hydrochloride that is required, and not an actual solution of the salt in water. In order to operate properly with such liquids, closed vessels must be used. The following is the principle upon which the plant in the majority of German works is constructed.

Near the melting-pot a battery of closed iron vessels, lined with lead, is erected. The first of these is filled with a quantity of hydrochloric acid, just sufficient to neutralise the aniline contained in the blue melt. The melt, when finished, is introduced into this vessel by means of air pressure. The vessel is fitted with a stirrer, which stirs up the mixture into a homogeneous mass. This is then pressed into a second vessel, which contains some filtering arrangement, upon which the blue crystals are deposited. The liquid which issues from this vessel is diluted with water, when the common blue hitherto dissolved in it is quickly deposited. The blue crystals remaining on the filter are washed with water, and may be purified by boiling them with spirit.

Blues soluble in water.—Very little of the blue that is manufactured is used in the opal state, viz. soluble in spirit. By far the largest proportion of it must be transformed into products soluble in water in order to become a marketable article. For this purpose sulphonation is resorted to.

The sulphonation of triphenylrosaniline takes place very easily, the phenyl radicles attached to the amino groups being readily substituted by the sulpho group SO_2H . As there are three of these phenyl radicles present, three sulpho groups may be introduced into the molecule of the blue. The pure, crystallisable, high-class opal blue is more easily sulphonated than the common blues. The sulphonation takes place in progressive stages, one sulpho group being introduced after the other. It is difficult to introduce more than two sulpho groups by the use of ordinary sulphuric acid. Fuming sulphuric acid must be resorted to in order to produce the trisulpho derivative. As this, however, is hardly ever required, being much too soluble for the purposes of the dyer, common sulphuric acid is invariably used, but the 'extra-strong' quality of 95–97 p.c. H_2SO_4 is, as a rule, preferred.

If this acid be allowed to act upon an aniline blue, the reaction begins at about 30° and results at first in the formation of the mono-sulpho derivative. The following are its properties:

In the free state triphenylrosaniline mono-sulphonic acid forms blue flakes, which are quite insoluble in water, in a solution of sodium bicarbonate, or even in weak ammonia. Sodium carbonate dissolves it on boiling; caustic soda in the cold. The solutions are perfectly colourless. They contain, in fact, the sodium salt of monosulphotriphenyltriaminotriphenylcarbinol:

The dry sodium salt is jet black.

This compound has the curious property of combining with wool in an alkaline bath. The wool remains colourless, but after being washed with water it becomes brilliantly blue if immersed in weak sulphuric acid.

This curious property, discovered by Nicholson, has been made use of by wool dyers, who prefer the 'alkaline' or 'Nicholson' blues to all others for the production of bright and brilliant blues.

The alkaline blues originally manufactured by Nicholson and other makers were as nearly as possible the pure sodium salts of the mono-sulpho derivative. Owing to the difficulty of dissolving them even in boiling water, another kind of alkaline blues was produced later on; these new alkaline blues contain a proportion of the disulpho derivative. They form blue powders, easily soluble in water, giving a solution which is distinctly blue. The use of these new alkaline blues is exactly similar to that of the old quality.

If the sulphonation of the opal blue be carried farther by raising the temperature and allowing the reaction to continue for a longer period, the monosulpho acid gradually disappears and is replaced by the disulpho derivative. This is insoluble in weak sulphuric acid, but rather soluble in pure water, with an intensely blue colour. Its sodium salt forms bright coppery masses soluble in water with blue colour.

This salt contains probably the compound represented by the following formula :

The disulpho derivatives of the various classes of triphenyl-rosanilines are known under the names of *Cotton blue*, *Water blue*, *China blue*, *Navy blue*, *Guernsey blue*, and many others, which are again sub-divided by the use of the letters R and B. Thus a 6B cotton blue is the disulpho acid of a very high-class, crystallisable Opal blue, whilst a 4R Guernsey or Navy blue would be a reddish-tinted blue, manufactured from an opal prepared with acetic acid and a small excess of aniline in the melt.

The process of sulphonation, though very simple in theory, requires great care and attention on the part of the manufacturer. The sulphonation is carried on in cast-iron pots into which the necessary quantity of sulphuric acid is introduced. The opal blue, which should be finely powdered and perfectly dry, is then stirred in, and the temperature raised gradually. Samples should be drawn from time to time, and the precipitate produced by the addition of water must be examined as to its solubility in water, weak ammonia, sodium carbonate, and caustic soda. When the desired degree of solubility is obtained, the liquid is poured into water, and the blues filtered off and carefully washed. When quite free from acid, they are dissolved in the necessary quantity of caustic soda; the solution is then filtered, and evaporated to dryness in jacketed pans. Cotton blues should be freed from the excess of sulphuric acid by the addition of slaked lime. The solution of the calcium salt is filtered and converted into the sodium salt by double decomposition with sodium carbonate. After another filtration, the solution of the blue is evaporated to dryness. Certain artifices are required to produce porous masses, such as the brand known as *China blue*, which is manufactured for export, and is required to possess a given bulk for a given weight.

Appendix to basic triphenylmethane colouring matters.

Auramine. This dye-stuff, although a derivative of diphenylmethane, is so closely connected with the manufacture of crystallisable violet that it cannot be omitted from this article.

It has been shown that crystal violet, as well as *Victoria blue* and other dye-stuffs, are manufactured from dimethyl and diethyl diamino-benzophenone. Now, if these ketones be heated with ammonium chloride in the presence of zinc chloride, an interesting reaction takes

place at the temperature of 150°–160°. The oxygen of the ketone is replaced by the imino group NH, thus :

The imides thus obtained are yellow colouring matters, and have received the name of *auramines*. The auramine of commerce is imino-tetramethyl-di-*p*-amino-diphenylmethane hydrochloride, containing one molecule of water of crystallisation :

It forms a yellow powder easily soluble in water. It is exclusively used for dyeing and printing on cotton.

Substituted auramines may be obtained by using the hydrochlorides of primary bases instead of sal-ammoniac. Thus a phenylated auramine of orange colour may be produced by acting with aniline hydrochloride upon tetramethyldiaminobenzophenone.

The auramines were discovered by Caro and Kern in 1884. They form the subject of the Eng. Pats. 5512, 1884, and 5741, 1884, and the D. R. PP. 29060 and 31936. (See art. AURAMINE, vol. i. 431.)

II. THE AURIN GROUP.

The members of this group contain oxygen in the place of the pentavalent nitrogen of the preceding one. If magenta and its congeners may be considered as quinone-imides, the aurins are the corresponding quinones.

The generic relation between the fuchsin and the aurin groups will be best seen by showing how the typical representative of the former, parafuchsin, may be transformed into the first representative of the aurin group, aurin itself.

We know that parafuchsin, if treated with an excess of acid, is transformed into the triacid salt of triaminotriphenylcarbinol :

Now this salt, if treated with nitrous acid, is transformed into the corresponding diazonium compound.

This, on being boiled with water, loses

nitrogen and is transformed into trihydroxy-triphenylcarbinol

The latter loses, in *statu nascendi*, one molecule of water, being transformed into its inner anhydride, aurin:

Thus aurin is parafuchsin in which all nitrogen has been replaced by oxygen.

This mode of formation has long been known, not for aurin itself, but for its higher homologue, rosolic acid, which was prepared from the ordinary fuchsin or magenta by the process described. The many co-ordinate points of aurin and rosolic acid were recognised at an early period. On the other hand, chemists were aware of the distinct difference between aurin and rosolic acid, which is just as considerable as that existing between parafuchsin and its higher homologue.

When an insight into the nature of the fuchsin group had been obtained, the knowledge of the constitution of the aurin group followed as a natural consequence.

But even before this was the case, another connection was discovered between aurin and fuchsin.

It had long been known that aurin (the mode of formation of which will be given later on) may be modified by heating it with alcoholic ammonia. F. Persoz produced a red dye-stuff, which he called *Pæonine*, by this process. This had, in all probability, the following constitution:

In 1878, Dale and Schorlemmer, whose researches on aurin are of great importance, showed that aurin, by very prolonged heating with alcoholic ammonia, may be transformed into pararosaniline

Thus the connection of the two typical dye-stuffs was definitely established. At present we know that the aurin group contains the acid counterparts of the basic members of the fuchsin group. A considerable number of them are known and described in chemical literature. As, however, almost all of them are of no practical value it would be useless to enumerate them in this article. We will therefore describe only those substances of the aurin group which are of some practical interest. There are very few of them.

1. Aurin $\text{C}_{18}\text{H}_{14}\text{O}_3$. The discovery of this substance, or one very nearly related to it, dates as far back as 1834, when F. Runge, the pioneer of the chemistry of coal-tar, observed that crude carbolic acid (containing cresol) was transformed into an acid red dye-stuff by oxidation. Later on (1859), Kolbe and Schmitt and F. Persoz simultaneously observed that pure phenol, when treated with oxalic acid, or with oxalic acid and sulphuric acid, was transformed into a similar red substance. The manufacture of the new dye-stuff was first taken up in Lyons by the firm of Guinon and Marnas. Later on, it was carried out on a large scale by C. Calvert and by C. Lowe; also by Roberts, Dale & Co., in Manchester. The crude aurin thus obtained is a non-crystallisable, brittle, pitchy mass, of a brilliant green metallic aspect, insoluble in water, but soluble in caustic soda solution, with a magnificent red coloration. It dyes silk and wool from an acid bath, producing an orange shade on these fibres. It was much used on silk in former days, but its use has been abandoned since the introduction of the azo-colouring matters, which produce brighter and faster shades.

The researches of Dale and Schorlemmer, Zulkowski, and others have shown that common aurin consists of a mixture of a number of substances which, in a pure state, are well crystallised. Of these, aurin itself $\text{C}_{18}\text{H}_{14}\text{O}_3$, oxyaurin $\text{C}_{18}\text{H}_{12}\text{O}_4$, methylaurin $\text{C}_{20}\text{H}_{16}\text{O}_3$, and pseudorosolic acid $\text{C}_{20}\text{H}_{16}\text{O}_4$, may here be mentioned. All these substances are produced by the action of nascent formic acid (generated from the oxalic acid) upon phenol. This mode of formation of aurin itself may be represented by the following equation:

A large number of other reactions have been observed in which aurin is formed to a greater or lesser extent. Thus, for instance, it is obtained by acting with formaldehyde, with iodoform, with chloroform and caustic potash on phenol. These reactions have never attracted the attention of manufacturers, aurin having lost its practical interest.

The sodium salt of crude aurin is known in commerce under the name of *Yellow Corallin*.

2. *Pæonin*, *corallin red*, *aurin red* is the sodium salt of the reaction product of alcoholic ammonia upon aurin, which has already been mentioned and the constitution of which is given above.

3. *Azullin* is a similar product, of a dirty violet shade, obtained by heating aurin with aniline. It is probably phenylated pæonin:

4. *Rosolic acid* is the name which was originally given by Runge to the oxidation product of crude carbolic acid. For a long time it was considered to be identical with aurin. At

present this name is reserved for the product obtained from the ordinary fuchsin of commerce by the diazotising process. It forms magnificent blue needles, which, being homologous to true aurin, have the composition $C_{20}H_{16}O_2$:

It dyes silk and wool orange shades, similar to those obtained with aurin. It is of no practical interest.

5. **Chrome violet** $C_{22}H_{12}O_6Na_3$ is the only member of the aurin group which is of considerable practical value. It is the sodium salt of aurin tricarboxylic acid:

It was discovered in 1889 by Sandmeyer, and patented (D. R. P. 49970, J. R. Geigy). It is prepared by acting with formaldehyde, or with a mixture of methyl alcohol and sodium nitrite, upon a solution of salicylic acid in sulphuric acid. The carboxyl groups are in the *ortho*-position to the hydroxyl groups. The result of this arrangement is that the dye-stuff combines readily with metallic mordants of the iron group, and especially with chrome mordant, producing violet shades of considerable fastness on cotton. It is chiefly used for printing on cotton.

The process patented for the production of chrome violet is interesting, because it forms a general and excellent synthetical method for the production of the aurins. It is strictly analogous to the synthetical method adopted for the production of 'Neu-fuchsin' by the 'Farbwerke' of Höchst. Two stages may be distinguished in the process:

(a) In the first stage, formaldehyde (or methylal) acts upon two molecules of the phenol—in the case of chrome violet, salicylic acid—forming the diphenylmethane derivative (methylene salicylic acid):

This reaction may be facilitated by the addi-

tion of condensing agents, such as hydrochloric acid and others.

(b) In the second stage, the diphenylmethane derivative is simultaneously condensed and oxidised with another molecule of the phenol into the corresponding aurin by the mixture of sulphuric acid and sodium nitrite:

Any phenol, or substitution product of a phenol, may be substituted for the salicylic acid in the process.

Later on, N. Caro (Ber. 25, 940) prepared a large number of carboxylated aurins by this process, substituting resorcylic, gallic, and cresotinic acid for the salicylic acid in the patented process. The compounds obtained proved to be very similar to chrome violet.

6. Of the large number of aurins prepared, only one more need be mentioned here: **pittacal**, a curious substance discovered in 1835 by Reichenbach in certain portions of beechwood tar. Liebermann more closely investigated this substance, and gave to it the name of *eupittonic acid* (Ber. 1876, 9, 334; 1878, 11, 1104). Hofmann determined its constitution (*ibid.* 1878, 11, 1455; 1879, 12, 1371, 2261).

Pittacal is hexamethoxyaurin:

formed by the simultaneous oxidation of dimethylpyrogallol:

and dimethyl methylpyrogallol:

which are both contained in wood tar. The methyl group of the second compound yields the central carbon atom in the same way as occurred with cresol in the formation of the rosolic acid observed by Runge.

Pittacal is an orange substance, crystallising in beautiful crystals when pure. Its solution in caustic alkalis is of a beautiful blue colour.

By heating pittacal with ammonia, Grätzel

TRIPHENYLMETHANE COLOURING MATTERS.

obtained a violet colouring matter, which proved of no practical value (*v. EUPITTONIC ACID*, vol. ii. 689).

III. THE PHTHALEIN GROUP.

The phthaleins were discovered by Baeyer in his memorable researches on the condensation of phthalic acid with aromatic hydrocarbons and phenols. Their constitution was, however, at first misunderstood. In 1880, when the curious properties of phthalic anhydride became more definitely known, the error was corrected and the phthaleins were recognised as congeners of the triphenylmethane group.

It is a well-known fact that every *o*-dicarboxylic acid is capable of forming, by losing the elements of water, an inner anhydride. These anhydrides act very easily on phenols, in some cases without the addition of condensing agents. Water is again eliminated, and a dye-stuff formed in every instance. Of the many colouring matters thus obtained, only those prepared from phthalic anhydride have, with one exception, become of general and practical interest, and these will here be described.

The central carbon in these dye-stuffs is afforded by one of the carbonyl groups of the anhydride of an *o*-dicarboxylic acid. If we restrict our consideration to phthalic anhydride, the formula may be thus modified :

phthalic acid being benzene *o*-dicarboxylic acid.

Phthalic anhydride, although perfectly symmetrical in its constitution

acts, in condensations, like an asymmetrical compound, only one of the carbonyl groups being attacked and losing its oxygen. Thus, by being condensed with two molecules of benzene it yields diphenyl-phthalide or phthalophenone :

which is the parent substance of all the phthaleins, just as triphenylmethane is the parent substance of the fuchsin and aurin groups. Diphenyl-phthalide, however, is but the inner anhydride of triphenylcarbinol *o*-carboxylic acid

hence the near relation between the phthalein, fuchsin, and aurin groups.

Formerly it was considered as probable that the anhydride structure of phthalophenone was preserved in the dye-stuffs derived from it. At present, almost all chemists are of the opinion that such is not the case, that the carboxyl group becomes free after the condensation has taken place and that it simply serves as a salt-forming group of minor importance. The quinonoid structure is shifted to the pyrone ring which is always present in all the really useful members of this group. Phenolphthalein and diaminophthalophenone, which do not contain the pyrone ring, are of no value as dye-stuffs. The constitution of the more important members of this group will be seen from the structural formulae given for each of them.

1. Phenolphthalein $\text{C}_{20}\text{H}_{14}\text{O}_4$ was discovered by Baeyer in 1871 (*Ber.* 1871, 4, 658). Its constitution is

it may be considered as a substituted phthalophenone, but as in the free state it has no quinonoid structure, it is also colourless. It is easily prepared by heating phthalic anhydride with phenol in presence of sulphuric acid or stannic chloride. It forms pale-yellow crystals, which dissolve with a fine red colour in caustic alkalis. In the salt so formed the quinonoid structure is established and the substance thereby becomes a dye-stuff :

The practical importance of phenolphthalein is very small. Its only use is that of an indicator for alkalimetric purposes.

For observations on the colourless salts of phenolphthalein and on its value as a colorimetric standard, see Kober and Marshall, *J. Amer. Chem. Soc.* 1911, 33, 59. For the behaviour of phenolphthalein derivatives as indicators, see Rupp, *Arch. Pharm.* 1911, 249, 56.

2. *Tetranitrophenolphthalein* $\text{C}_{20}\text{H}_6\text{N}_4\text{O}_{12}$ has been proposed as an orange colouring matter for wool. Its sodium salt $\text{C}_{20}\text{H}_6\text{N}_4\text{O}_{12}\cdot\text{Na}_4$ is sold as an orange powder under the name of *Aurotine*. It was discovered by C. Dreyfus, H. Bull, and T. Hall, and patented in England under 3441 (1889), in Germany under 52211. In a pure state free tetranitrophenolphthalein forms orange crystals, melting at 344° .

It has long been known that phenolphthalein is not a good dye. The same applies to all the ordinary typical phthaleins. Phthalophenone (diphenylphthalide) is but a poor chromogen, but its properties are at once improved (as has already been shown above) if the two phenyl-radicles in its molecule be linked together by another group, preferably oxygen. We thus come to chromogens containing the pyrone ring

combined with the structure of triphenylmethane derivatives, which, by the introduction of auxochromic groups, give rise to some of the most beautiful dye-stuffs yet discovered. As in all cases, the auxochromic groups introduced may be either the hydroxyl or the amino group; and in the latter hydrogen may be replaced by organic radicles. We thus get phthalein colouring matters of either phenolic (acid) or aminic (basic) character. For a long time the former alone were known; we will therefore, consider them first.

A. Acid phthalein dye-stuffs.

The prototype of these is—

1. **Fluorescein** $C_{20}H_{12}O_6$. This beautiful substance is formed most easily if phthalic anhydride and resorcinol be mixed in molecular proportions and heated to 190° . In the factories this operation is carried out in enamelled cast-iron pots, heated in an oil bath. The ingredients melt, and large quantities of steam are given off. When the reaction is finished the mass solidifies into a cake of dark-brown colour, which consists of almost pure fluorescein.

In this reaction two molecules of resorcinol combine with one of phthalic anhydride. At the same time they interact upon one another, losing one molecule of water, and forming the pyrone ring:

Fluorescein in a free state has thus a constitution quite analogous to that of phenolphthalein, although the presence of the pyrone ring is indicated by the intense brick-red colour of the substance. It is quite insoluble in water, sparingly so in the majority of other solvents. It, however, we dissolve it in alkaline liquids, it assumes, like phenolphthalein, its quinonoid nature and this change is marked by the intensity of its colour. In caustic alkalis and in ammonia it dissolves with a brown colour. The solutions have, especially when dilute, a most brilliant and beautiful green fluorescence. Hence the name of the substance.

Concerning the nature of the changes which take place when fluorescein is treated with

alkali, see Baeyer, Annalen, 1910, 372, 80, part iii.

Sodium salt of Fluorescein, showing quinonoid structure combined with pyrone ring

The crude fluorescein obtained in the manufacture, as above described, seems to contain two modifications of the substance (which may be isomerides). By treating the crude cake with boiling spirit, a certain amount of a soluble, non-crystallisable fluorescein is extracted, whilst the greater proportion of it remains undissolved, and is obtained as a crystalline residue on filtering. This process of purification is invariably used in the manufacture of the dye-stuff. Both the soluble and the insoluble part are worked up in the manner to be described hereafter, the insoluble fluorescein giving the better and purer qualities of the dye-stuffs, whilst the low-class qualities are made from the soluble fluorescein obtained by evaporating the alcoholic extract.

A small quantity of the fluorescein manu-
factured is transformed into its sodium salt

which is sold, under the name *Uranin*, in the shape of a yellow powder, very soluble in water. It is used for dyeing pale yellows on silk.

If benzyl chloride and some sulphuric acid be added to the fluorescein melt a substance is obtained which is supposed to be benzyl-fluorescein :

Its sodium salt is sold as a yellow dye-stuff under the name *Chrysolin*. This substance, discovered by Reverdin in 1877, is not of much practical importance.

By far the greater part of the fluorescein produced is transformed into very beautiful red colouring matters by the introduction of halogen atoms into its molecule. The dye-stuffs so prepared are known by the generic name of *Eosins*.

If fluorescein be treated by substituting reagents, it is generally observed that four atoms of hydrogen are replaced by other groups. Further investigations have shown that this substitution takes place in the phenyl radicals, which entered the fluorescein in the shape of resorcinol, whilst the phenyl radicals derived from the phthalic anhydride is never attacked by these reagents.

The most important of the dye-stuffs so prepared is

2. Eosin $C_{20}H_{12}O_{10}Br_2K_2$, the potassium salt

of tetrabromofluorescein. The sodium salt is also occasionally met with, but it does not crystallise so well. The constitutional formula of eosin is :

Eosin is prepared by acting with four molecules of bromine upon one molecule of fluorescein. The crystallisable, modification of the latter is used for the manufacture of a good product. On the small scale a solution of the fluorescein in glacial acetic acid is prepared, and the bromine introduced gradually.

For manufacturing purposes glacial acetic acid is too expensive. The following process, which admits of operating in aqueous solutions, may be used instead.

The bromine is dissolved in exactly the necessary quantity of caustic soda, and the solution is evaporated to dryness. The resulting salt consists of a mixture of sodium bromide and sodium bromate. It is dissolved in water and mixed with a solution of the theoretical quantity of fluorescein in caustic soda. The mixture is then acidified with hydrochloric acid. The bromine generated acts at once upon the fluorescein, and the precipitate obtained is eosin, which need only be dissolved in a solution of potassium carbonate and evaporated to crystallisation.

The quantity of bromine used may be reduced to half (two molecules or four atoms) by using a mixture of potassium bromide and potassium or sodium chlorate, instead of the salt obtained by evaporating the solution of bromine in caustic soda.

This process, although cheap and simple, is not generally used, because the bromine is found to act too energetically. A certain amount of the eosin is destroyed, and the remainder is not so brilliant in colour as it might be.

The bromination proceeds much better in an alcoholic solution; alcohol is, therefore, frequently used for the purpose in the manufacture of eosin. The fluorescein is finely ground, and suspended in strong spirit. The necessary quantity of bromine is added. The bromination takes place slowly and gradually, and an excellent product is obtained. The spirit is recovered by distillation.

In order to reduce the bromine in this as in the aqueous process to two instead of four molecules, the addition of a chlorate is necessary. But a chlorate must be used which is soluble in spirit. Cupric chlorate is preferred to any other. It is prepared by mixing concentrated aqueous solutions of sodium chlorate and cupric chloride or sulphate. The solution obtained is added to the operation in progress.

Eosin forms either a dark-brown powder, or dark-brown crystals with a green metallic lustre. The potassium salt may also be obtained in flesh-coloured crystals by re-crystallisation from spirit. These crystals contain alcohol of crys-

tallisation. According to strength and purity of shade, the commercial eosins are distinguished by certain letters and additions, such as 'eosin B,' 'A,' 'GGF,' 'DH,' 'extra,' 'extra-fine,' 'soluble,' and others. All these brands dissolve easily in water, with a scarlet coloration. Dilute solutions show a marked greenish fluorescence.

Eosin is used for dyeing silk and other fibres, also for staining paper, and for preparing red inks of a very fine scarlet colour. Large quantities are used for the last-named purpose. Eosin is not a fast colour, but its brilliancy of shade secures a ready sale for the large quantities produced.

3. Eosin soluble in spirit (*Primrose, methyl eosin*). These names are applied to certain products, which are produced by boiling eosin, dissolved in spirit, with caustic soda and methyl iodide, or ethyl bromide. The carboxyl group is thus alkylated, whilst the hydroxyl group remains combined with alkali. The sodium salts thus obtained form glistening crystals, insoluble in water but soluble in spirit. They have the constitution :

in which R stands for either methyl or ethyl. Small quantities of these substances are prepared and employed as an addition to the vermilion used in cotton printing, in order to increase the brilliancy of its shade. Spirit eosin was formerly also used for silk dyeing, but for this purpose it has been replaced by the bluish eosins soluble in water, to be described later on.

If the hydroxyl group of eosin is also to be alkylated, this can only be effected by acting with alkyl iodide or bromide upon the silver salt of eosin. The dialkyl-ethers thus obtained are colourless.

4. Eosin scarlet (*Eosin B, BN, BW, scarlet, J, JJ, V, &c.*). Sodium salt of dinitrodibromofluorescein $C_{20}H_6N_2O_5Br_2Na$.

If fluorescein be treated with nitric acid, dinitrofluorescein is obtained, which has found no application as a colouring matter. But by subsequent bromination it yields a brilliant scarlet. The same product (or an isomeric very similar to it) may be prepared by first brominating the fluorescein and then treating it with nitric acid.

This dye-stuff was hailed with enthusiasm when it made its appearance in 1875, but its use was soon much restricted by the introduction of the scarlet azo-dyes which are quite as brilliant, and at the same time faster, cheaper, and more easy in their application.

5. Erythrosin (*Bluish Eosin, Dianthin, Primrose soluble, Pyrosin B, and other names*).

This is the sodium salt of tetraiodofluorescein $C_{20}H_4O_5I_4Na$. The potassium salt is also met with occasionally. It is prepared by iodinating fluorescein with iodine and oxidising agents, such as mercuric oxide, iodic acid, cupric chlorate,

&c. It may also be prepared by introducing iodine monochloride into an alcoholic suspension of fluorescein.

Erythrosin dissolves in water, with a fine red colour, and very slight fluorescence. It dyes silk in shades which are much more bluish than those obtained with eosin.

Erythrosin was introduced into the market in 1876 by Bindschedler and Busch. It was well received by the silk dyers. Owing to the high price of iodine, a mixture of eosin and Bengal red is now used for producing the same shades.

There is one application, however, for which pure erythrosin is still required—for producing orthochromatic dry plates for photographic purposes. As a sensitiser of silver bromide, erythrosin holds a prominent place amongst all the colouring matters hitherto tried.

Di-iodofluorescein was sold and used for a very short time as an orange dye-stuff, under the name '*Pyrosine J.*'

6. **Phloxin** (*Potassium salt of dichloro- or tetrachloro- tetrabromofluorescein*).

This colouring matter, discovered in 1876 by Nölting, together with the following ones, formed a new departure in the manufacture of the eosin dyes. The characteristic feature of these substances is the fact that they contain halogen atoms substituted for hydrogen, not only in the resorcinol groups, but also in the phenyl group derived from the phthalic anhydride. Now, it has already been said that a substitution of this kind cannot be effected in ready-made fluorescein. To prepare phloxin, therefore, or any of its congeners, a special fluorescein must be used, prepared not with ordinary phthalic anhydride, but with the anhydrides of dichloro- or tetrachloro- phthalic acid. Dichlorophthalic acid is best prepared by oxidising dichloronaphthalene, whilst tetrachlorophthalic acid may be obtained by chlorinating phthalic anhydride in the presence of finely divided iron. Both acids give colouring matters of very similar shades, the tetrachloro derivatives being but very little bluer than the dichloro derivatives. The process of manufacture of the dye-stuffs is identical with that described for eosin. The constitutional formula of phloxin is

if derived from tetrachlorophthalic acid. The phloxin derived from dichlorophthalic acid contains, of course, two atoms of chlorine less.

Commercial phloxin is a red powder, soluble in water, with a red colour and no fluorescence. It dyes beautiful bluish-red shades on silk, which resemble those obtained with erythrosin.

7. **Cyanosin** is the monomethyl ether of phloxin. It is soluble in spirit, and dyes shades still bluer than phloxin.

8. Bengal red (*Rose Bengale N*)

is the iodo derivative of this series. It is the bluest eosin dye-stuff obtained. It is very expensive, and was formerly used in large quantities to produce the most brilliant bluish-reds on silk. It has now, to a great extent, been replaced by the rhodamines. Its methyl ether, soluble in spirit, received the name of *Cyanosin B*. Its application never became important.

The phthalein derivatives of resorcinol are all very brilliant dyes. There are, however, some other acid phthaleins which, although important as colouring matters, are of much milder hues. They are derivatives of pyrogallol.

9. **Gallein** $\text{C}_{20}\text{H}_{12}\text{O}_7$. If phthalic anhydride be condensed with pyrogallol, the reaction takes place quite as easily as with resorcinol. The product obtained is, as might be expected, dihydroxyfluorescein. The constitutional formula now adopted for gallein is

For the manufacture of gallein it is not necessary to prepare pure pyrogallol. Gallic acid may be used instead, which, losing carbon dioxide, is at once transformed into gallein by the action of the phthalic anhydride.

Gallein is generally sold in the shape of a violet paste. It is sparingly soluble in water, easily soluble in caustic alkalis, with a bright-blue coloration. It dyes mordanted wool and cotton. Chrome mordants are used preferably, and dark-violet shades are obtained.

On account of the similarity of the application of gallein to that of alizarin, gallein is also sold under the name of *Alizarin violet* or *Anthracene purple*.

10. **Cerulein** (*Alizarin green, Anthracene green*) $\text{C}_{20}\text{H}_8\text{O}_6$. This is one of the most important dye-stuffs for wool and cotton, dyeing a beautiful and very fast olive green on chrome mordants. The cotton printer uses it constantly, both pure and mixed, with other dye-stuffs of the alizarin family.

It was discovered in 1871 by A. Baeyer, who obtained it by heating gallein with concentrated sulphuric acid to 200°. By the same process it is now prepared in immense quantities on the large scale.

In this process the substance loses one molecule of water and the carboxyl group forms a new hexagon ring by condensing with the neighbouring benzene ring, thus:

TRIPHENYLMETHANE COLOURING MATTERS.

Cœrulein forms a black paste, insoluble in water. It is soluble in caustic alkalis, with a greenish-blue coloration.

11. Cœrulein S (soluble cœrulein)

This is the product of the reaction of sodium bisulphite upon cœrulein; its manufacture is carried on by the Badische Anilin and Soda works at Ludwigshafen. It forms a black powder, soluble in water, with a brown coloration. It is easily decomposed by the addition of acids or by heat. It is used for the same purposes as cœrulein, and is very convenient, on account of its easy solubility. In dyeing with it, it is, of course, decomposed, the ordinary cœrulein being deposited on the fibre.

B. Basic phthalein dye-stuffs.

For a long time these were not known. The manner in which they might be obtained had, of course, suggested itself to the consideration of chemists, but the substances required for their synthesis seemed to be quite out of the reach of the manufacturer. In 1887, however, M. Ceresole, of the Badische Anilin- und Soda-Fabrik, successfully effected the synthesis of the first basic phthalein, which proved to be of such value that a thorough search for a good means of preparing the necessary ingredients was made, which led to complete success.

To obtain the basic substance analogous to fluorescein, it is merely necessary to replace one of the hydroxyl groups of resorcinol by an amino-group; or, in other words, to employ *m*-aminophenol instead of resorcinol:

Experience has shown that the compound thus obtained has no practical value. If, however, diethyl *m*-aminophenol is used instead of the *m*-aminophenol, a most beautiful colouring matter is obtained, known under the name of

1. Rhodamin B $\text{C}_{22}\text{H}_{21}\text{N}_2\text{O}_3\text{Cl}$. The commercial product is the monohydrochloride:

It forms beautiful needles of a metallic green appearance, easily soluble in both water and spirit. Weak solutions show a most mag-

nificent orange fluorescence, which disappears on heating, and reappears in the cold. This is the most beautiful red colouring matter ever prepared, dyeing silk, wool, and cotton a most brilliant pink of a bluish shade.

The process described for the production of rhodamin is patented by the Badische Anilin- und Soda-Fabrik, Eng. Pat. 15374, 1887; D. R. P. 44002. The diethyl-*m*-aminophenol is prepared from diethylaniline by heating it with fuming sulphuric acid to 60°, diethylaniline *m*-sulphonic acid is formed, which yields the phenol by fusion with caustic soda.

There is, however, another process for the manufacture of rhodamin, discovered by the Farbwerke of Höchst (D. R. P. 48367, 1888). It consists in treating free fluorescein with phosphorus pentachloride, when the fluorescein chloride

is formed. This is transformed into rhodamin if heated with diethylamine under pressure.

2. Rhodamin S $\text{C}_{20}\text{H}_{22}\text{N}_2\text{O}_3\text{Cl}$, and

These two colouring matters, which are identical in their practical properties and applications, are not, strictly speaking, triphenylmethane derivatives; nor are they derived from phthalic acid. They must, however, be mentioned here, because they are near congeners of rhodamin B. They are obtained by treating dimethyl- or diethyl-*m*-aminophenol, not with phthalic, but with succinic, anhydride. Succinic acid is the typical *o*-dicarboxylic acid of the fatty series. Like phthalic acid, it forms an anhydride, which condenses with resorcinol into fluorescein-like dye-stuffs; these, however, offer no practical interest. The succineins of dimethyl- and diethyl-*m*-aminophenol, however, show a sufficient difference from rhodamin to be manufactured and sold as a special brand. The constitution of the dimethyl compound may be represented by the following formula:

It is, therefore, not a triphenylmethane derivative. It is sold in the shape of its zinc double chloride.

Rhodamin S shows great affinity to unmordanted cotton. It is one of the few members of this group which may be considered to be what is now called a substantive colouring matter.

The properties of rhodamin S are very similar to those of rhodamin B. It forms crystals with a green metallic lustre, easily soluble in water, with a red coloration, and a marked

yellow fluorescence. The shades obtained with it are yellower than those produced with rhodamin B.

Rhodamin B and S remained for some time the only important members of this magnificent group of dye-stuffs. After a while, however, some new representatives of it made their appearance, of which the more important may be here shortly described.

Rhodamin G $C_{26}H_{27}N_3O_3Cl$ is obtained by heating rhodamin B with aniline hydrochloride. One of the ethyl groups is split off in the shape of ethyl chloride and the recovered dye-stuff is a tri-ethyl-rhodamin which dyes wool and silk in red shades of a much more yellowish tinge than the original rhodamin B.

The process of alkylation, which produced such remarkable results in the eosin group, proved equally applicable to the rhodamins. It was carried out at first by using alkyl chlorides, but later on it was discovered that a much cheaper and simpler way to the same end consists in saturating alcoholic solutions of rhodamins with hydrogen chloride. As this is a method which is exclusively applicable to the alkylation of organic acids, the possibility of using it for the rhodamins formed a proof of the presence of a free carboxyl group in the dye-stuffs and went a long way in establishing the modern views about their constitution.

Rhodamin 3B, *Aniline*, was the first of the alkylated rhodamins. It dyes a more bluish shade of red than rhodamin B, and is, if possible, even more brilliant and pure in its tinge, which strongly resembles that of certain flowers such as the 'Crimson Rambler' rose.

Rhodamin 6G was obtained by the same process from *sym*-diethylrhodamin (produced by the condensation of phthalic acid with two molecules of mono-ethyl-*m*-aminophenol), and has consequently the following constitution:

When once the constitution of the rhodamins was recognised, it was clearly seen that they may also be considered as derivatives of *o*-benzoyl-benzoic acid:

Suitable substitution products of this acid may therefore be used for the synthesis of rhodamins. This is important because it enables us to produce asymmetrical rhodamins, whilst the original process was applicable only to the production of symmetrical members of this important class of dye-stuffs. As an example of this method, *Rhodamin 12 GM* may be quoted,

which is prepared by acting with dimethyl-amino-hydroxybenzoylbenzoic acid:

upon monomethylresorcinol and subsequent esterification of the product obtained. This dye-stuff is consequently quite asymmetrical and has the constitution:

It dyes silk, wool, and cotton a beautiful yellowish red.

If in the process given for the production of rhodamin 12 GM the monomethylresorcinol be replaced by *m*-amino-*p*-cresol:

a new and exceedingly beautiful dye-stuff is obtained, which is sold under the name *Irisamin* or *Rhodin 3G*. It dyes silk, wool, and mordanted cotton a flaming, beautiful red.

Several other members of this group have been prepared by various methods, amongst which the reaction of formaldehyde upon ready formed rhodamins may be mentioned. All the rhodamins have also been found applicable not only to the regular dyeing of textile fabrics, but also to the staining processes so largely used for paper, wood and confectionery. Very large quantities of these dyes are used for such purposes.

Few groups of synthetical dye-stuffs have proved so prolific as that of which a short description has here been given. The triphenyl-methane group contains some of the oldest artificial colouring matters known, but for more than half a century it has continued to yield new additions to the vast number of such compounds which chemical science has placed at the disposal of our textile industries. O. N. W.

SUPPLEMENT.

Recent progress in this group of colours, which already contains dyes of almost every shade, and suitable for nearly all kinds of dyeing processes, has been mainly towards the production of colours having greater fastness than is possessed by many of the earlier members of the group. It is interesting to note that whilst work has been undertaken in very numerous directions, the most important practical results have thus far been obtained upon a few fairly well defined lines.

In addition to the extension of the group in new directions, some interesting conclusions in connection with the constitution of phenylated

fuchsin need to be noted, whilst the connection between colour and chemical constitution and other problems of a theoretical nature concerning the triphenylmethane compounds have not ceased to claim attention.

The application of Brilliant Green as an antiseptic and in connection with the detection of typhoid carriers, is of considerable interest, and our knowledge in this field has been greatly added to by the work of Fairbrother and Renshaw (J. Soc. Chem. Ind. 1922, 41, 134 T), whilst Casella (Eng. Pat. 14742, 1912) claims that compounds of the rosaniline group which have halogens in the 'ortho' position to the amino group are of value in medicine on account of their action on tripanosomes.

I. THE FUCHSIN GROUP.

(A) Diamino-triphenyl-methane derivatives.

In this group the extension of the 'Patent Blue' class calls for most notice. Substitution

derivatives such as *Patent Blue A*, (I), and *Cyanol FF* (Casella), (II), have been produced

By the use of such groups as NO_2 , COOMe , CN , or the halogens Cl and Br , in place of the sulphonic acid group in the ortho position, it has been possible to produce other products having similar properties. In this connection a further

by the use of ethyl-benzyl-aniline and mono-ethyl-*o*-toluidine respectively in place of dimethyl- or diethyl-aniline in the processes for the manufacture of 'Patent Blue.' When patent blue itself is oxidised (D. R. PP. 60961, 61478; Friedl. 3, 152, 153) a new dye, *Cyanin B* (M. L. B.), is produced, which is faster to light and washing than patent blue, and dyes similar shades. Concerning the structure of cyanin B, little is definitely known, but it is considered probable that during the oxidation an ethyl group is removed.

Very interesting and useful results have been obtained from investigations of the effect produced upon the tinctorial properties of compounds of the malachite green type

by substitution in the third phenyl group. Not a little of the work of this nature has resulted from the desire to explain the very bluish shade of patent blue and its fastness to alkalis in comparison with other closely related colours.

In the first instance it was considered that the hydroxy group present in the 'meta' position was responsible for these differences. Sandmeyer (J. Soc. Dyers and Cols. 1895, 154) and Suais (Bull. Soc. chim. 1897, 517) independently succeeded in showing that this was not the case, but that the effects mentioned were due to the sulphonic acid group in the 'ortho' position to the methane carbon atom. This conclusion was arrived at in two ways: (i) by condensation of benzaldehyde *o*-sulphonic acid (see Vol. I. p. 569) with dimethylaniline followed by oxidation of the leuco compound thus produced, and (ii) by condensation of tetramethyl-diamino-diphenyl-carbinol with metanilic acid, elimination of the amino group from the resulting leuco compound, then oxidation of the product. In either case the final product is the ortho-sulphonic acid of malachite green, and this resembles patent blue in that it gives dyeings fast to alkali and more blue to tone than malachite green. The two series of reactions may be represented thus:

observation of Suais (Bull. Soc. Ind. Mulhouse, 1912, 82, 703) is of interest. He concludes that the property of fastness to alkalis is not confined to the dyes containing an acid group in the 'ortho' position to the central carbon atom.

but is shared by the 'meta' diazo-sulphonates of this series. As instance of this class of compounds he mentions a green dye obtained by oxidation of the leuco base:

This latter is produced from the corresponding amine by treating its diazo compound with sulphite.

The following are some representative commercial products in which ortho substitution of the type mentioned above occurs:

Erioglaucine A

is obtained by condensation of benzaldehyde *o*-sulphonic acid with ethyl-benzyl-aniline sulphonic acid, oxidation of the leuco compound produced and conversion of the product into the acid ammonium salt (D. R. P. 89397; Frdl. 4, 184). It gives bright shades fast to alkali. *Eriochlorine* is said to be the above mixed with yellow and violet.

Benzyl Green B is a product in which the sulphonic acid group in the ortho position to the methane carbon atom of erioglaucine A is replaced by a chlorine atom.

Setoglaucine, obtained by condensation of *o*-chloro-benzaldehyde with dimethylaniline and oxidation of the leuco compound formed (D. R. P. 94126), is *o*-chloro-malachite green. When the same aldehyde is taken but condensed with ethyl-benzyl-aniline, or mono-ethyl-*o*-toluidine, the dyes produced are *Night Green 2B* and *Setocyanine* respectively. The introduction of further substituents in the benzaldehyde used is exemplified in *Glacier Blue*, which is made from 2:5-dichloro-benzaldehyde and mono-methyl-*o*-toluidine (D. R. P. 71370), and *Night Blue B*, made from 2-chloro-5-nitro-benzaldehyde and ethyl-benzyl-aniline sulphonic acid. An interesting extension of this series is found in the dye produced by the condensation of benzaldehyde 2:4-disulphonic acid with one molecule of diethyl-*m*-amino-phenol and one molecule of mono-ethyl-*m*-amino-*p*-cresol, closing the pyrone ring then oxidising the leuco compound thus formed. The dye gives red shades on silk, but does not colour cotton (U.S. Pat. 1006738).

The development of malachite green derivatives has not been entirely along these lines, and a number of 'para' compounds have been described (cf. Fr. Pat. 422843; Eng. Pat. 1913, 7757; and J. pr. Chem. 1915, 91, 341).

Azo Green

a 'meta' derivative, is an interesting colour

which is a member both of the triphenyl-met and of the azo group of dyes. It is formed by diazotisation of *m*-amino-malachite green and coupling with salicylic acid, and is a mordant colour giving yellowish-green shades on chrome mordanted wool. It is also used for calico printing (cf. also Eng. Pat. 234950).

Green dyes of considerable fastness are also produced by condensation of benzaldehyde (or homologues not containing an amino group in the para position) with alkyl, or aryl, derivatives of *m*-toluidine sulphonic acid and oxidation of the leuco compound formed. Alternately, the condensation product of benzaldehyde and *m*-toluidine may be sulphonated then oxidised (Bayer, Fr. Pat. 461810). The dyes are of the type:

A number of mordant colours derived from malachite green, chiefly by the introduction of hydroxyl and carboxylic acid groups into the third phenyl residue, are included in the series of chrome colours of the Bayer company, e.g. *Chrome violet* (I.) (D. R. P. 58483; Frdl. 3, 120). *Chrome bordeaux* (II.), and *Chrome green* (III.) (D. R. P. 60606; Friedl. 3, 25).

(I.)

(II.)

An interesting comparison of the properties of Malachite Green, with those of an analogous *furane* dye, has been made by Renshaw and Naylor (J. Amer. Chem. Soc. 1922, 44, 862), whilst Bogert and Nisson (Proc. Nat. Acad. Sci., 1924, 10, 421) have similarly compared a bis-triphenylmethane dye.

(B) *Triamino-triphenyl-methane derivatives.*

In this group considerable interest is attached to the work dealing with the phenylation products of rosaniline and *p*-rosaniline. Baeyer and Villiger (Ber. 1904, 37, 2870), Lambrecht (Ber. 1907, 40, 145), and Knecht (J. Soc. Dyers and Col., 1907, 119), have succeeded in showing that the phenylation of rosaniline proceeds rather differently from what has been generally assumed in the past. As the result of this work

it is concluded that whilst *p*-rosaniline may be converted into triphenyl-*p*-rosaniline by phenylation in the usual manner, in the case of rosaniline the reaction cannot be made to proceed beyond the formation of diphenyl-rosaniline. It is considered that this difference is due to steric hindrance, the methyl group in the ortho position to one of the amino groups in ordinary rosaniline preventing the entrance of the phenyl nucleus into the amino group of that aromatic residue, whereas in *p*-rosaniline this effect is not observed, as no methyl group is present in the ortho position to any of the amino groups. Baeyer and Villiger concluded from the examination of a sample of commercial aniline blue that it consisted of almost pure diphenyl-rosaniline. The production of *ppp*-triamino-triphenyl-methane colours from derivatives of *pp*-diamino-triphenyl-methane is of interest and forms a link between the products of this and of the preceding group of dyes. The Bayer company describes the preparation of triamino-triphenyl-methane colours, which give bluish shades, by treating *pp*-diamino-triphenyl-methane compounds containing a halogen or alkoxy group in the para position to the methane carbon, with amines or their salts (Fr. Pat. 474260), or by similar treatment of the corresponding para sulphonic acid derivatives (D. R. P. 287003). The latter process is exemplified by the formulæ:

and it is stated that this should prove to be a cheap technical method for the production of dyes of this type. In passing from (I.) to (II.), the shade of the dye changes from green to blue. For this type of process, see also D. R. PP. 292998, 293322 (M. L. B.).

Suiss (Bull. Soc. Ind. Mulhouse, 1912, 82, 691) describes the treatment of crystal violet (magenta, Paris violet, malachite green, and brilliant green react similarly) with *m*-toluylene-diamine at 160°–180°C., whereby a yellow fluorescent basic dye is produced and dimethylaniline liberated. It is probable that the products produced in this way are identical with the compounds obtained from the condensation of Michler's ketone with *m*-diamines (Eng. Pat. 1352, 1895).

In connection with the development of this group of dyes, the relationship that exists between *Eriocyanin A* (which may be prepared by condensation of tetra-methyl-diaminobenzhydrol monosulphonic acid with dibenzylaniline mono- or di-sulphonic acid and oxidation of the leuco compound produced (D. R. P. 88085; Frdl. 4, 219), and the much older colour *Benzyl Violet 7B* (1866), is perhaps worthy of

mention. This is clearly seen by comparison of their respective formulæ:

The important colour *Azo Green* (see above), is directly derived from *mpp*-tri-amino-triphenylmethane, and green azo-triphenylmethane dyes closely related to it are mentioned in D. R. PP. 175825, 175826 (M. L. B.).

According to Copisarow (Chem. Soc. Trans. 1920, 117, 1542) *Carbazol Blue* is a tricarbazyl-methane compound represented by $(C_6H_4NH)_3C = C_6H_4NHCOOH$. It is produced by fusing together carbazol and oxalic acid, and the linkage to the central carbon atom is presumed to be in the *para* position to the nitrogen atom in each carbazol nucleus.

Auramine.

In D. R. P. 287994, the Badische company indicate that very good yields of N substituted 4:4'-diamino-diaryl-thio-benzophenones are readily obtained from the corresponding hydrocarbons by treatment with polysulphides. The products are useful for the production of auramine derivatives (see article on AURAMINE, vol. i. p. 431).

II. AURIN GROUP.

In this group a considerable number of colours have been described which are related to the members of the diamino-triphenylmethane group in the same way as aurin is related to para-rosaniline.

Most of the colours of this sub-group contain carboxyl groups in the ortho position to the hydroxyls, and are of value as chrome colours. As in the case of the compounds of the Patent Blue group, increased fastness to alkalis is obtained by the introduction in the third benzene nucleus of a substituent (halogen, sulphonic acid, &c.) in the ortho position to the methane carbon atom. The following are typical commercial products of this class:

Eriochrome cyanin R is obtained by condensing benzaldehyde-*o*-sulphonic acid with *o*-cresotinic acid and oxidising the leuco compound produced (D. R. P. 189938; Frdl. 9, 200). This colour gives red dyeings on wool which change to violet-blue when after-chromed.

If *o*-cresotinic acid is condensed with an *o*-chloro-benzaldehyde, and the product oxidised, the resulting dye is *Eriochrome azurol B* (D. R. PP. 198909, 199943; Frdl. 9, 201, 204). For the preparation of *Chrome azurol S*, an *o*-chloro-benzaldehyde sulphonic acid is used in the condensation (D. R. P. 199943; Frdl. 9, 204). Members of the Chromoxan series of dyes (Bayer) are said to be produced in a similar manner from naphthalene aldehydes.

The use of penta- and tetra-chloro-benzalde-

hydes for the production of colours of this group has been described in D. R. P. 234519 (Bayer) and Eng. Pat. 13970, 1915 (Casella) respectively. The use of chlorination products of xylene—which are first converted to chloro-aldehyde-benzoic acid derivatives—for the production of dyes of this group has also been described by Casella (Eng. Pat. 16317, 1914).

When di-ortho-substitution products of benzaldehyde are used it is stated that colours of great depth and fastness result (D. R. PP. 199943, 213502).

In patent literature various chrome colours, belonging to this group, are also described, in which the non-hydroxylated benzene nucleus contains an amino, or substituted amino group (Eng. Pat. 12130, 1910; Fr. Pat. 417490; D. R. P. 252287 (M. L. B.); Fr. Pats. 424723, 425676 (Bayer); and Eng. Pat. 10335, 1911 (Geigy)), and these products give fast shades when chromed.

Azo colours which are members of this group have also been investigated, and the Bayer company (Fr. Pat. 413383; U.S. Pats. 1021364, 1021365, 1021366) describe the production of dyes which give yellow to red shades on wool from an acid bath, the colours passing to blue or black when after-chromed. These products are obtained by condensing amino-benzaldehyde (or its nuclear substitution products, e.g. *o*-chloro-*m*-amino-benzaldehyde) with 2 mols. of an aromatic hydroxy-carboxylic acid, diazotising and coupling the leuco compound produced, then oxidising the product. Green and Sen (Chem. Soc. Proc. 1912, 28, 137) have also examined azo dyes of somewhat similar type, but obtained by condensing azo-aldehydes with hydroxy-toluic or salicylic acids. The following formula represents a typical member of the series obtained by them:

The dyes are polygenetic, dyeing wool directly in red shades, and producing various shades with different metallic mordants. The final oxidation may, in the production of the chrome lakes (which are black), be carried out on the fibre by dyeing with the azo-methane derivative then treating with an acid solution of bichromate. A similar dyeing with a leuco compound, followed by simultaneous oxidation and formation of chrome lake on the fibre, is referred to in respect of other dyes of this sub-group in Eng. Pat. 25007, 1910; Fr. Pat. 421564 (A. G. F. A.).

In the true aurin group—that containing dyes derived from *ppp*-tri-hydroxy-triphenyl-carbinol—considerable attention has been paid to the production of chrome colours. A number of such products, belonging to the triphenylmethane or diphenyl-naphthyl-methane groups, have been described (cf. D. R. PP. 216924, 217571, 216686; Eng. Pat. 11083, 1911, &c.), most of them being prepared by condensation of hydroxy-

aldehydes (or their derivatives) with hydroxy-carboxylic acids (or derivatives), though use has also been made of the methylene-disalicyclic acid process. This work has resulted in the range of colour obtainable with this type of dye being considerably extended. In a large number of cases the after-chroming of material dyed with these products gives rise to a very marked change in shade.

Products have also been investigated in which the hydroxyl group in the third benzene nucleus is in the meta position to the methane carbon atom (Fr. Pat. 404800). In such cases the meta hydroxyl group may be introduced either by use of hydroxy- or amino-aldehydes; in the latter case the amino group is converted to hydroxyl by use of the diazo compounds either before or after the oxidation of the leuco triphenyl-methane derivative (D. R. P. 234805).

III. THE PHTHALEIN GROUP.

Here questions of structure and constitution have been responsible for a considerable amount of work. On the other hand, evidence is not lacking of attempts to extend the list of commercially useful products belonging to this group. The structure of the salts of the phthaleins has been discussed at length by Green (J. Soc. Chem. Ind. 1909, 638), whilst the production of isomeric forms of fluorescein and their salts has been described by H. v. Leibig and their probable constitution considered (J. pr. Chem. 1912, 86, 472). The effect of the introduction of additional auxochromes into compounds of the phthalein and benzein series of dyes has been studied by Watson (Chem. Soc. Trans. 1915, 107, 1579).

Various attempts have been made to obtain new dyes of this series, and the following are typical examples of these. By introduction of nitro groups, either by use of nitro derivatives of phthalic acid, or nitro-resorcinol and its derivatives (D. R. P. 245231), products have been obtained which give good dyeings on chrome mordanted wool. D. R. P. 290508 describes the condensation of pyrogallol (or other derivatives of resorcin having a para position to one of the OH groups free) with α -hydroxy-naphthoyl- α -benzoic acid, whereby chrome mordant dyes of the phthalein series are produced. Wool dyes have been prepared by treatment of eosin, or phloxin, with aniline, whereby the halogen is wholly or partially replaced by the amine residue, followed by sulphonation of the product (Chem. Zentr. 1913, 2, 2126). Colours of this group have been described by Lucius and Brüning (D. R. PP. 290540, 291883), in which selenium has been introduced into the molecule by treatment of phthalins—obtained by reduction of phthaleins—either with selenium halides or selenium oxy-chloride.

In the rhodamine group it is interesting to note the description by Block (Bull. Soc. Ind. Mulhouse, 1913, 83, 81) of the use of tetrachlorophthalic anhydride in the production of derivatives of rhodamine, as in the acid group it may be used for the preparation of phloxin. When condensed with dimethyl-*m*-amino-phenol it is stated that it yields a dye giving shades which are very fast to light and alkali.

Intermediates.

In conclusion, it should be noted that the extension of the triphenyl-methane group of dyes has given rise to a considerable amount of investigation of the derivatives of benzaldehyde and to the manufacture of quite a number of these, which were previously but rarely met with. For further details the article on BENZ-ALDEHYDE, vol. i. 565, should be consulted.

A. E. E.

TRIGEMININE. Pyramidone butyl chloral hydrate.

TRILITE. Syn. for trinitrotoluene, used as an explosive.

TRINOL. Syn. for trinitrotoluene.

TRIPHYLITE. A manganese lithium phosphate LiMnPO_4 , occurring naturally as large, rough (orthorhombic) crystals and coarsely cleavable masses. By the isomorphous replacement of manganous oxide by ferrous oxide it passes into the closely allied mineral lithiophyllite (LiFePO_4). The colour is grey or bluish, but, the mineral being readily weathered, the masses are usually dark brown on the surface. Triphylite occurs in pegmatite-veins, often in association with spodumene and other lithium-bearing minerals, and sometimes with tin ore. It is found at Bodenmais in Bavaria, Huréaux and Chanteloube in Haute-Vienne, Branchville in Connecticut, Pala in California, the Black Hills in South Dakota, and King's Mountain in North Carolina. Containing 8.1–9.4 p.c. of lithia, it has occasionally been collected when mining for other minerals, and used as a source of lithium salts.

L. J. S.

TRIPLASTITE. An explosive consisting of a mixture of di- and trinitrotoluene (70 pts.), gun-cotton (1.2 pts.), and lead nitrate (28.8 pts.).

TRIPLITE. Fluorophosphate of manganese and iron ($\text{Mn,Fe}[(\text{Mn,Fe})\text{F}]\text{PO}_4$, crystallised in the monoclinic system. Calcium and magnesium are also often present in small amount. The rough crystals and compact masses are dark-brown to black with a resinous lustre; the powder is yellowish-grey. Sp.gr. 3.6–3.8; H. 5–5½. The mineral is soluble in hydrochloric acid, and with sulphuric acid evolves hydrofluoric acid. It occurs in pegmatite-veins and in quartz-veins in the vicinity of granite masses; and is found at Limoges in France, Rabenstein in Bavaria, &c. In the Singar mica mines, in the Gaya district of Bengal, it occurs in considerable quantity as large masses with pitchblende. A variety containing very little iron and of a pale salmon-pink colour is found with wolframite and bismuth minerals in White Pine Co., Nevada.

L. J. S.

TRIPOLITE or **TRIPOLI** v. **DIATOMITE**.

TRITICUM. Couch grass or *Agropyrum* of the B.P. The dried rhizome of *Agropyron repens* (Beauv.).

TRITOL, TRITOLO. Syn. for trinitrotoluene.

TRITOPINE v. **OPPIUM**.

TRIXIDIN. Trade name for an emulsion of antimony trioxide.

TROCHOL. A neutral unsaponifiable crystalline substance obtained by the saponification of red Japanese bird-lime made from the bark of *Trochodendron aralioides*. After purification by precipitation from chloroform solution by light petroleum and recrystallisation from chloroform.

alcohol, trochol forms colourless needles or prisms $C_{22}H_{44}O_8$, $\frac{1}{2}(C_2H_5O + H_2O)$, m.p. 252° [$\alpha_D^{15} + 20^\circ$ (in chloroform alcohol)]. Yields a *diacetate*, colourless prisms, m.p. 217° ; *dibenzate*, colourless needles, m.p. 172° (sintering at 145°). Trochol occurs as the palmitic ester in the bird-lime; by heating the components together at 200° in a vacuum the ester is obtained as a colourless viscous substance (Hidekichi Yanagisawa, J. Pharm. Soc. Japan, 1921, No. 471, 405; 1922, 179). *Trochic acid* $C_{21}H_{40}O_8$, white powder, m.p. 225° , exists in the bird-lime in the free state (cf. Yushichi Nishizawa, J. Chem. Soc. Japan, 1922, 43, 154). Trochol yields a *diphenylcarbamate* $C_{28}H_{42}O_8(CO \cdot NPh)_2$, colourless prisms, m.p. 167° ; *formate*, nacreous scales, m.p. 306° , and *phthalate*, a white crystalline powder, m.p. 224° – 228° . On oxidation with hydrogen peroxide in glacial acetic acid the alcohol gave a dihydroxymonoketone, *trocholone* $C_{20}H_{40}O_8$, an amorphous powder, m.p. about 100° ; *trochol peroxide* $(C_{21}H_{42}O_8)_2$, colourless scales, m.p. 215° ; (*semicarbazone*, fine white needles, m.p. 290° ; *acetyl derivative*, fine white needles, m.p. 205° ; *oxime*, small white needles, m.p. 217°); and *trocholic acid* $C_{22}H_{42}O_8$, white granules, m.p. 282° (diacetate, white crystalline powder, m.p. 145°). The authors conclude that trochol is a secondary-tertiary, but not a primary alcohol. When a mixture of trochol and chromic anhydride is treated with water an odour of butyric acid is produced, and acetic acid can be isolated by the distillation of the mixture with steam (Hidekichi Yanagisawa and Norikazu Takashima, J. Pharm. Soc. Japan, 1923, No. 494, 251–258; Chem. Soc. Abstr. 1923, 124, i. 1008).

TROGERITE v. URANIUM.

TROILITE. A name applied by Haidinger to ferrous sulphide FeS , occurring in meteorites. V. PYRRHOTITE.

TRONA, URAO, or NATURAL SODA. The sodium carbonates occurring as minerals are: *thermonatrite* $Na_2CO_3 \cdot H_2O$ (orthorhombic); *natron* (q.v.) $Na_2CO_3 \cdot 10H_2O$ (monoclinic); *trona* $Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$ (monoclinic); and possibly the anhydrous salt. Of these, trona is by far the most important and constitutes the larger part of the deposits of natural soda. It forms beds of white, cavernous material with acicular or bladed crystals lining the cavities; and is usually intermixed with more or less earthy matter and sodium chloride and sulphate. It is deposited from the water of soda-lakes and forms an efflorescence on the surface in desert regions. The Natron Lakes of Lower Egypt are well known, and similar lakes and surface efflorescences of soda are met with in many parts of the Sahara and Sudan. Extensive deposits are found in the neighbourhood of Lake Chad, and a large deposit has been opened up at Lake Magadi in Kenya Colony, East Africa. The latter has an area of 324 sq. miles, and the reserves of over a hundred million tons of soda are being constantly increased by springs in the lake. The material contains 98.5 p.c. of soda crystals, with sodium chloride 0.2% and sodium sulphate 0.1 p.c. Soda-lakes also occur in the western states of North America, viz. in Arizona, California, and Nevada.

The name 'trona' is said to be of Arabic

origin; and 'urao' is a native name for the soda deposited at the bottom of a lake at Lagunilla in Venezuela.

TROOSTITE. A constituent of steel intermediate in characteristics between sorbite and martensite (q.v.). It is obtained by quenching highly heated steel in oil or by quenching from the transformation temperature in cold water, and is plentiful in tempered steels.

It acquires a deep brown or black tint when etched with picric acid, and can thus be distinguished under the microscope. Benedick regards it as a colloidal solution of carbon iron (J. Iron and Steel Inst. 1905, ii. 352; 18 ii. 217). The name troostite is also given to a variety of *Willemite* (q.v.).

TROPACOCAINE v. COCAINE AND SYNTHETIC DRUGS, TROPEINES.

TROPAEOLINE v. AZO-COLOURING MATTERS.

TROPEINES. The Solanaceous Alkaloids.

This group comprises the following members, and possibly others not yet fully examined:—

Atropine and hyoscyamine $C_{17}H_{23}O_3N$;
Noratropine and norhyoscyamine

$C_{16}H_{21}O_3N$

Apoatropine and belladonnine $C_{17}H_{21}O_3N$;

Tropacocaine $C_{18}H_{19}O_3N$ (see p. 221);

Hyosine (scopolamine) $C_{17}H_{21}O_4N$;

Meteloidine $C_{18}H_{21}O_4N$.

These are all tertiary bases except *nor-atropine* and *nor-hyoscyamine*, and on hydrolysis furnish an acid and an amino alcohol. Of the eight naturally occurring alkaloids only three are of importance in medicine, viz. atropine, hyoscyamine, and hyosine. Homatropine, a synthetically prepared tropeine, is also of importance in medicine. The best known sources of the three alkaloids are belladonna (*Atropa Belladonna* (Linn.)), henbane (*Hyoscyamus niger* (Linn.)), stramonium (*Datura Stramonium* (Linn.)), all of which are used in medicine. Other plants which contain them in important quantities, and either are or may be used commercially as sources of the alkaloids, are *Hyoscyamus muticus* (Linn.), *H. albus* (Linn.), and *H. reticulatus* (Linn.), *Datura Metel* (Linn.), *D. arborea* (Linn.), *D. quercifolia* (H. B. and K.), *Duboisia myoporoides* (R.Br.), *Duboisia Leichhardtii*, *Scopolia carniolica* (Jacq.), and *S. japonica* (Maxim.), *Mandragora officinarum* (Linn.), and *Solandra longifolia*. As a rule, at least two of the alkaloids are found together in each plant, but *H. muticus* is remarkable in containing only hyoscyamine. It is probable that atropine rarely, if ever, occurs preformed in plants, and the traces generally found in the extracted alkaloids are due to racemisation of hyoscyamine either during the drying of the plant or by the action of chemical agents used for extraction. In general, the alkaloids are present in the stem, leaves, root, and seed, and the amount of total alkaloid present in each of these parts shows great variation.

Preparation.—The method used for the extraction of these alkaloids varies to some extent with the material employed, but the

following general process gives good results as a rule. The finely-ground, air-dry drug is exhausted by percolation with cold 90-95 p.c. alcohol and the greater part of the solvent removed by distillation. The semi-solid extract is then treated with dilute (0.5 p.c.) hydrochloric or sulphuric acid, until no more alkaloid is removed. This acid liquid is filtered, shaken with small quantities of chloroform, if necessary, to remove traces of chlorophyll, oil, or other soluble non-basic matters, then made slightly alkaline with dilute ammonia, and the alkaloid extracted by means of chloroform. The latter is distilled off, leaving, as a rule, a clean gum-like residue. From this, by solution in chloroform and careful addition of light petroleum, hyoscyamine may be caused to separate in crystalline form. If hyosine be present it remains dissolved in the chloroform, and may be caused to separate by further addition of light petroleum. The salts of these alkaloids being more stable than the free alkaloids they are best purified by recrystallising their salts from water. Hyoscyamine may be finally purified by re-crystallisation from alcohol by addition of water. The best source of hyoscyamine is the Egyptian plant, *Hyoscyamus muticus*.

ESTIMATION OF TOTAL ALKALOIDS. Dunstan and Ransom have devised the following methods:

For the root.—Exhaust by hot percolation 20 grms. of the finely-powdered root with a mixture of equal parts of chloroform and absolute alcohol. Agitate the solution with two successive quantities of 25 c.c. of distilled water, adding a small quantity of dilute sulphuric acid. The salts pass into the aqueous layer, and the colouring matter remains dissolved in the chloroform. Wash the aqueous extract with a little pure chloroform to remove adhering impurity, then add ammonia in slight excess, and dissolve out the liberated alkaloids by agitation with chloroform in the usual way. The residue of alkaloid left on the evaporation of the chloroform is dried at 100° and weighed and finally titrated (Pharm. J. 1883-4, [iii.] 14, 623).

For the leaves.—20 grms. of the finely-powdered dry leaves are exhausted with absolute alcohol. The liquid is largely diluted with water, acidified with hydrochloric acid, and repeatedly extracted by agitation with chloroform until the whole of the chlorophyll, fat, &c., has been removed. The liquid is then made alkaline with ammonia, and extracted with chloroform, which, on evaporation, leaves a residue of alkaloid. This must be dried at 100° before being weighed. This process answers equally well for stems or fruit capsules, and for seeds, if the latter are first extracted with light petroleum to remove oil (Pharm. J. 1885-6, [iii.] 16, 237).

Extract of the leaves.—From 1 to 2 grms. of the extract are dissolved, as far as possible, in warm dilute hydrochloric acid, any residue being extracted with the dilute acid until all the alkaloid has been dissolved. The acid liquid is then extracted with chloroform until nothing further is removed, and, after this treatment, is made alkaline with ammonia, and the free alkaloid removed by agitating again with chloroform, which on evaporation leaves a residue of alkaloid that is dried at 100°C. and

weighed and finally titrated (*ibid.* 1885-6, [iii.] 16, 238).

Alcoholic extract of the root.—2 grms. of this extract are dissolved as far as possible in dilute hydrochloric acid. This solution is then treated as described under the leaf extract (*ibid.* 1885-6, [iii.] 16, 777).

No method is yet available for the quantitative separation and estimation in mixtures of the individual mydriatic alkaloids, but the approximate amounts of each present may sometimes be determined by careful fractionation with gold chloride.

Atropine $C_{17}H_{23}O_3N$ is the racemic form of hyoscyamine, from which it is readily formed by the action of alkalis. It was first obtained by Mein (Annalen, 1833, 6, 67) from the root of *Datura Stramonium* (Linn.), and called by him *daturine*. Geiger and Hesse obtained it independently (*ibid.* 1833, 5, 43; 6, 44; 7, 269) from belladonna root, and their material was analysed by Liebig, who assigned to it the empirical formula now in use. Atropine is stated to occur with hyoscyamine and a little hyosine in belladonna and stramonium and with more hyosine in *Scopolia japonica* (Maxim), but there is reason to believe that the alkaloid does not exist pre-formed in plants, although it may be produced in the course of preparation by the action of alkalis on hyoscyamine. In any case, the commercial alkaloid is now obtained invariably by conversion of hyoscyamine by the action of very dilute alcoholic alkali hydroxide (Will and Bredig, Ber. 1888, 21, 2797; cf. Gadamer, Arch. Pharm. 1901, 239, 294).

Properties.—Prismatic crystals, m.p. 118°. Readily soluble in alcohol or chloroform, less soluble in ether or hot water, sparingly soluble in cold water. The aqueous solution is alkaline to litmus, hæmatoxylin, and phenolphthalein. The fact that atropine is alkaline to phenolphthalein serves to distinguish it and its isomer from most other alkaloids. Atropine is optically inactive. One of the most remarkable properties of atropine is that of causing sustained dilatation of the pupil of the eye, a property which is often made use of in detecting it and other alkaloids of this group, several of which exert this mydriatic action. A drop or two of an aqueous solution, containing 1 part of atropine in 130,000 parts of water, when introduced into the eye of a cat is sufficient to produce this effect. When taken internally atropine is highly poisonous. It diminishes glandular secretions, causes paralysis of the vagus terminations, and acts as a sedative to involuntary muscles. Some of the alkaloid is apparently excreted unchanged in the urine.

The ordinary salts of atropine are crystalline and soluble in water. The sulphate

is commonly used in medicine; it forms colourless needles, m.p. 187°-188°, 194° (dry). The aurichloride $B \cdot HAuCl_4$ appears as an oily precipitate when produced in the ordinary manner. This soon solidifies to a crystalline mass, which may be re-crystallised from water acidified with hydrochloric acid. The crystals melt at 137°-139°. This salt and the picrate, m.p. 175°-176°, are useful for the identification of the alkaloid,

since the corresponding salts of the other alkaloids of this group melt at different temperatures.

Reactions and constitution.—Among the characteristic qualitative reactions of atropine may be mentioned one which has been modified by Labat (Bull. Soc. Pharm. Bord. April, 1914, 148), and consists in treating a particle of the alkaloid with 2 c.c. of a 10 p.c. solution of sulphuric acid and adding one drop of a saturated aqueous solution of potassium chromate, on warming, the characteristic hawthorn odour develops and changes to that of benzaldehyde. The latter odour is also produced when the alkaloid is boiled with a dilute solution of sodium hypobromite. This well-known test introduced by D. Vitali (Zeitsch. anal. Chem. 1881, 20, 563; Pharm. J. 1881, [iii.] 12, 459) has been modified by Arnold (Arch. Pharm. 1882, 20, 564), also by Flückiger (Pharm. J. 1886, [iii.] 16, 601), whilst E. Beckmann (Arch. Pharm. 1886, [iii.] 24, 481) points out that veratrine gives a somewhat similar reaction unless certain modifications are employed; and Droop Richmond (Analyst, 1918, xliii. 506) demonstrates other points which should be noted. Other characteristic colour reactions are described by Richard (Chem. Zeit. 1904, 28, 1048).

The reactions of atropine and other alkaloids with mercuric chloride were described by A. W. Gerrard (Pharm. J. 1884, [iii.] 14, 718), who in a later paper (Pharm. J. 1891, [iii.] 21, 898) modifies and more precisely defines the method of making the test, and gives details of the distinctive reactions observed with atropine, hyoscyamine, homatropine, and hyoscyne, under these conditions. The value of Gerrard's test has also been confirmed by Flückiger (Pharm. J. 1886, [iii.] 16, 601), who found cocaine gave a pure white precipitate which very soon turned red.

Amongst the more modern researches which may be mentioned are those of Eder in the Schweiz. Wchschr. f. Chem. u. Pharm. 1913, 51, 228; and Schweiz. Apoth. Zeit. 1917, 54; the latter of which contains a series of papers on the detection of atropine, whilst Wasicky (Zeitsch. anal. Chem. 1915, 54, 393) describes a colorimetric method of identifying atropine and allied alkaloids by means of *p*-dimethylamino-benzaldehyde.

In 1917, Rasmussen (Ber. Deut. pharm. Ges. 1917, 27, 193) described a method based on the precipitation of the sparingly soluble silicotungstate

as foreshadowed by O. Javillier (Bull. Sci. Pharm. 1910, 315); this salt is soluble in less than 1 part in 40,000 water.

Atropine readily undergoes hydrolysis with either acids or alkalis; in the latter case it yields tropic acid and tropine in accordance with the equation

When the hydrolysis is effected by an acid, especially concentrated hydrochloric acid, the tropic acid loses the elements of water, and

atropic acid $\text{C}_8\text{H}_7\text{O}_2$ results, whilst at a high temperature this latter compound is more or less changed into its polymers α and β -isatropic acid $\text{C}_{15}\text{H}_{19}\text{O}_2$.

The hydrolysis of atropine is preferably effected by heating the alkaloid with saturated barium hydroxide solution to 60° or 80° for a few hours. Dilute sulphuric acid is added until a drop ceases to give a pink coloration with phenolphthalein. The liquid is filtered, and the filtrate acidified with hydrochloric acid and twice shaken with ether, the ether is separated, and on evaporation yields the acid constituents of the hydrolysis; to obtain the basic product, the aqueous layer is shaken with an excess of alkali hydroxide and extracted with chloroform.

Atropine yields an anhydride (*apotropine*) (see below) when heated with dilute nitric acid (Pesci, Gazz. chim. ital. 1881, 11, 438; 1882, 12, 60), which Hesse subsequently isolated from belladonna root and named atropamine (Annalen, 1892, 271, 124; cf. Merck, Zeitsch. anal. Chem. 1892, 31, 229; and Hesse, Annalen, 1893, 277, 290). Apotropine is not mydriatic.

TROPINE $\text{C}_8\text{H}_{15}\text{ON}$ forms large, colourless tablets, m.p. 63° ; b.p. 229° ; sp.gr. 1.0392 at $76^\circ/4^\circ$, soluble in water, alcohol, or ether. It is a strong base, which forms crystalline salts. It is poisonous, but does not dilate the pupil of the eye. Tropine and tropic acid unite to form tropine tropate $\text{C}_8\text{H}_{15}\text{NO} \cdot \text{C}_8\text{H}_7\text{O}_2$, and this salt, when heated with dilute hydrochloric acid, loses water and furnishes atropine, identical with the natural alkaloid (Ladenburg, Annalen, 1883, 217, 74). Similarly, by heating other organic salts of tropine with dilute hydrochloric acid, dehydration occurs, with production of the acyl derivative of tropine. The bases thus formed have been called by Ladenburg *tropines*. In this way *l*-atropine (*l*-tropyltropine), *d*-atropine (*d*-tropyltropine), *pseudo*atropine (*atro*-*lactyltropine*), and atropamine (*apotropine*, *atropyltropine*) have been prepared (cf. Wolfenstein and Mamlock, Ber. 1908, 41, 723; and Wolfenstein and Rolle, *ibid.* 1908, 41, 733). Several of the tropines exert a mydriatic action. *Phenylglycolyltropine* or *mandelyltropine* $\text{C}_{16}\text{H}_{21}\text{O}_2\text{N}$ is used in medicine under the name *homatropine*. Its mydriatic effect is less persistent than that of atropine. As a result of Ladenburg's work it has been generally assumed that only those tropines produce a mydriatic effect which contain an alcoholic (not phenolic) hydroxyl in the aromatic acid residue, thus acetyl-, benzoyl-, and salicyltropines are not mydriatic, whilst mandelyltropine is mydriatic. Jowett and Pyman find that this is not strictly true, mydriasis being produced by terebyltropine (Chem. Soc. Trans. 1906, 89, 360), and only slightly by *o*-carboxyphenylglyceryltropine (*ibid.* 1906, 91, 93; 1909, 95, 1020; and Proc. Int. Cong. Appl. Chem. 1909) which should be very active. Certain tropines containing a lactone group become less active when the lactonic grouping is opened by the action of alkali.

Tropine has been the subject of numerous investigations especially by Ladenburg, Merling and Willstätter culminating in its synthesis by the last-named from suberone as a starting-point (Ber. 1901, 34, 3163; Annalen, 1903, 326, 23). On the basis of these results tropine and atropine

are now generally represented by the following formulae—

Tropine undergoes a series of interesting decompositions under the action of various reagents. The most interesting of these are as follows: When heated with dehydrating agents it furnishes *tropidine* $\text{C}_8\text{H}_{12}\text{N}$ (Ladenburg, Annalen, 1883, 217, 177), a strongly alkaline oil, b.p. $162^\circ\text{--}163^\circ$, sp.gr. 0.9467 at $19^\circ/4^\circ$, which has an odour recalling that of coniine. On oxidation with chromic acid tropine yields in turn *tropinone* $\text{C}_8\text{H}_{12}\text{ON}$ (Willstätter, Ber. 1896, 29, 396), m.p. $41^\circ\text{--}42^\circ$, b.p. $224^\circ\text{--}225^\circ$, *tropinic acid* $\text{C}_8\text{H}_{13}\text{O}_2\text{N}$ (Merling, Annalen, 1883, 216, 348; Willstätter, l.c.), and finally *ecgoninic acid* $\text{C}_8\text{H}_{11}\text{O}_2\text{N}$ (see under *Cocaine*), which was shown by Willstätter and Bode to be N-methylpyrrolidine-2-acetic acid (Ber. 1901, 34, 519), thus proving the presence of a pyrrolidine ring in tropine. For a detailed account of the important researches in the tropine series, Schmidt's Über die Erforschung der Konstitution und die Versuche zur Synthese wichtiger Pflanzenalkaloide, i. 1900; ii. 1904 (Enke, Stuttgart), should be consulted.

Atropamine (*Apo-atropine*) $\text{C}_{17}\text{H}_{21}\text{O}_2\text{N}$ is the anhydro derivative of atropine (Pesci, Gazz. chim. ital. 1881, 11, 538; 1882, 12, 60). It is reputed to occur naturally associated with atropine and hyoscyamine in the solanaceous plants (Hesse, Annalen, 1892, 271, 124; Merck, Zeitsch. anal. Chem. 1892, 31, 229; and Hesse, Annalen, 1893, 277, 290); but is best prepared from either of the two latter alkaloids by adding the substances gradually to strong nitric or sulphuric acid, or by heating them with acetic or phosphoric anhydrides.

Atropamine crystallises from ether in prisms, m.p. $60^\circ\text{--}62^\circ$, which are very slightly soluble in water and petroleum ether, readily in alcohol, chloroform, benzene, and carbon bisulphide. It forms salts which crystallise well from water. The sparing solubility of the hydrochloride and hydrobromide affords a ready means of separating atropamine from the other alkaloids of this group. The aurichloride crystallises from water in fine yellow needles, m.p. $110^\circ\text{--}112^\circ$.

On hydrolysis atropamine yields atropic acid and tropine

Atropamine is optically inactive, does not redden phenolphthalein (being thus unlike atropine and hyoscyamine), but colours red litmus blue. It has a bitter taste, does not possess mydriatic properties, but produces a burning sensation when dropped into the eye. The hydrochloride $\text{B}\cdot\text{HCl}$, m.p. $237^\circ\text{--}239^\circ$, forms leaflets, and the aurichloride $\text{B}\cdot\text{H}\cdot\text{AnCl}_2$, needles, m.p. $110^\circ\text{--}112^\circ$.

Belladonnine $\text{C}_{17}\text{H}_{21}\text{O}_2\text{N}$. This alkaloid is stated to occur in the leaves and root of *Atropa Belladonna* (Linn.) (Hübschmann, J. 1858, 376; Kraut, Ber. 1880, 13, 165; Dürkopff, *ibid.* 1889, 22, 3183; Hesse, Annalen, 1891, 282, 100); and is generally found in the mother-liquors of hyoscyamine and atropine. According to Merling (Ber. 1884, 17, 381) it has the formula $\text{C}_{17}\text{H}_{21}\text{O}_2\text{N}$, and is isomeric with anhydro-atropine (apoatropine), and this was confirmed by Hesse (l.c. 1892, 271, 123; 1893, 277, 295), who stated that it can be prepared by the action of (1) sulphuric acid on atropine or hyoscyamine, or (2) hydrochloric acid on atropamine (apoatropine). Belladonnine is a resinous, uncrystallisable base, which is hydrolysed with much greater difficulty than the other solanaceous alkaloids, yielding tropine $\text{C}_8\text{H}_{13}\text{ON}$ and atropic acid (Merling). It appears to be devoid of mydriatic power.

The salts are amorphous $\text{B}\cdot\text{H}_2\text{PtCl}_4$ and BHAuCl_4 , are yellow pulverulent precipitates quite insoluble in cold water.

Homatropine (*Mandelyltropine*)

is the chief artificial tropine used in medicine. It is a lower homologue of atropine, in which the CH_2OH group is replaced by OH, and is prepared by passing hydrogen chloride gas through a mixture of 7 parts of tropine, 10 parts of mandelic acid, and 2 parts of water; it crystallises from dry ether in prisms, m.p. $99^\circ\text{--}100^\circ$, it is also soluble in castor and olive oils, and such solutions are employed in ophthalmic surgery for instilling into the eye. Homatropine resembles atropine and hyoscyamine in its general physiological effects, but it is much less toxic and in small doses is a true hypnotic. It has a powerful mydriatic effect which is produced and passes off more rapidly than is the case with the natural tropeines. Homatropine hydrobromide crystallises in flat rhombic prisms or plates, m.p. $212^\circ\text{--}214^\circ$; the hydrochloride has m.p. $219^\circ\text{--}227^\circ$; the sulphate, m.p. $222^\circ\text{--}226^\circ$; the aurichloride forms yellow prisms slightly soluble in water, it is precipitated first as an oil, but subsequently becomes crystalline; homatropine methobromide has m.p. $192^\circ\text{--}196^\circ$.

Hyoscyamine $\text{C}_{17}\text{H}_{23}\text{O}_2\text{N}$. An isomeride of atropine. It is the most common of the solanaceous alkaloids, being the principal alkaloid in *Atropa Belladonna* (Linn.) (Schmidt, Arch. Pharm. 1905, 243, 303), and *Hyoscyamus niger* (Linn.), and *H. albus* (Linn.), the sole mydriatic alkaloid in *H. muticus* (Linn.) (Dunstan and Brown, Chem. Soc. Trans. 1899, 75, 74; 1901, 79, 72), and the chief alkaloid in *Datura Stramonium* (Linn.), *Duboisia myoporoides* (R. Br.), *Scopolia carniolica* (Jacq.) (Dunstan and Chaston, Pharm. J. 1889-1890, [iii.] 20, 461), and *S. japonica* (Maxim.) (Schmidt, Arch. Pharm. 1888, [iii.] 26, 185, 214), and in other similar plants; it exists in minute quantities in lettuce, *Lactuca viroea* (Linn.) and *L. Scariola* (Linn.) (Dymond, Chem. Soc. Trans. 1892, 61, 90).

Preparation.—Hyoscyamine may be extracted from the various plants containing it by means of the process described in the introduction to this section. The best source of the alkaloid is the stem and leaves of *Hyoscyamus*.

been partly racemised during its isolation, there being no method of purifying the amorphous base.

Hyoscyne hydrobromide $B \cdot HBr \cdot 3H_2O$ has m.p. 193° – 194° , $[\alpha]_D$ (in water) -25.9° ; it forms large rhombic tablets; the commercial salt generally contains 11–12 p.c. of water and is variable in its optical rotation, owing to the presence of *d*-*l*-hyoscyne. The picrate forms slender matted needles, m.p. 187° – 188° , the aurichloride, yellow prisms, m.p. 198° – 200° , and the auribromide, brown prisms, m.p. 210° . The aurichloride forms needles with serrated edges, m.p. 204° – 206° ; the auribromide forms red leaflets, m.p. 187° – 188° .

By the action of alkalis or by direct heat hyoscyne is racemised to *i*-scopolamine. Hyoscyne resembles atropine and hyoscyamine in its physiological action, producing more powerful but less lasting paralysing effect upon the peripheral nerve endings and depression of the motor area. It does not, however, stimulate the brain initially, and is consequently employed by preference for cerebral affections. It is of great use in acute mania.

When warmed with dilute alkalis or barium hydroxide *l*-hyoscyne is hydrolysed, yielding tropic acid and a new base, which has been variously called oscine, scopoline, or oxytropine. If hydrolysis be effected with dilute hydrochloric acid *l*-tropic acid and *d*-*l*-oscine result.

***d*-*l*-Hyoscyne** (*i*-Scopolamine, *Atroscine*) $C_{17}H_{21}O_4H$ is the optically inactive isomeride of hyoscyne. It forms 2 crystalline hydrates; with $2H_2O$, m.p. 37° – 38° , with $1H_2O$, m.p. 56° – 57° , the anhydrous base melts at 82° – 83° . It furnishes crystalline salts, the hydrobromide crystallises in rhombic tables, containing $3H_2O$, and has m.p. 181° , other salts are the hydriodide, m.p. 192° , the picrate, m.p. 173° – 174° , the aurichloride which forms needles with one edge serrated, m.p. 214° – 215° , and the methobromide, m.p. 216° – 217° .

Oscine (*Scopolone*) $C_8H_{13}O_2N$ results from the hydrolysis of hyoscyne (Hesse, Annalen, 1892, 271, 114; 1893, 276, 84; Luboldt, Arch. Pharm. 1898, 236, 11). It crystallises in prisms from light petroleum or chloroform, m.p. 109° – 110° , b.p. 241° – 243° . It is readily soluble in water and alcohol, and less readily in ether. Oscine is optically inactive, but unlike tropine it can be resolved into its *d*- and *l*-constituents (Tutin, Trans. Chem. Soc. 1910, 97, 1793).

Like tropine, oscine contains a hydroxy group and is readily esterified, forming a series of esters, the scopoleines. None of the scopoleines have been used in medicine.

i-Oscine yields a crystalline monoacetyl derivative, m.p. 53° , a benzoyl derivative, m.p. 68° – 70° , together with other crystalline salts. The hydrochloride forms (hydrated) tablets and (anhydrous) prisms, m.p. 273° – 274° , the picrate crystallises in flattened rhombs, m.p. 237° – 238° , the *d*-*l*-isomerides have the same melting-points.

Mandragorine $C_{15}H_{19}O_2N$ was obtained by Ahrens (Ber. 1889, 22, 2159) from *Mandragora officinarum* (Linn.), and from the same source by Hesse (J. pr. Chem. 1901, [iii.] 64, 274), along with hyoscyamine, hyoscyne, and norhyoscyamine. According to Thoms and Wentzel (Ber.

901, 34, 1023), Ahrens' mandragorine was merely a mixture of hyoscyamine with hyoscyne and possibly a third alkaloid (*v.* MANDRAGORA ROOT, vol. iv. p. 210).

Meteloidine $C_{15}H_{21}O_2N$ was obtained by Pyman and Reynolds (Chem. Soc. Trans. 1908, 93, 2077) from *Datura meteloides* (DC.) along with atropine, and hyoscyne (scopolamine) to the extent of 0.07 p.c. It crystallises in abular needles, m.p. 141° – 142° , and furnishes a crystalline, optically inactive hydrobromide $B \cdot HBr \cdot 2H_2O$, m.p. 250° (anhydrous), and an aurichloride, m.p. 149° – 150° . On hydrolysis by baryta water meteloidine furnishes tiglic acid $CHMe : CMe \cdot COOH$ and a new base *teloidine* $C_8H_{13}O_2N$, which crystallises with $1H_2O$ and has m.p. 168° – 169° (anhydrous); the aurichloride $B \cdot HAuCl_4 \cdot \frac{1}{2}H_2O$ has m.p. 225° , and crystallises in hexagonal plates.

Norhyoscyamine $C_{15}H_{21}O_2N$ occurs in *Scopolia japonica* (Maxim), *Datura Metel* (Linn.), *Datura meteloides*, *Duboisia Myoporoides*, *Duboisia Leichhardtii*, *Salandra longifolia*, and *Mandragora officinarum*. It is a white crystalline base, m.p. 140.5° , strongly basic in character (being alkaline to phenolphthalein). It forms beautifully crystalline salts, of which the following have been characterised: the hydrochloride, m.p. 207° , the sulphate, m.p. 249° , oxalate, m.p. 245° – 246° , aurichloride, m.p. 178° – 179° , platinichloride, m.p. 141° , picrate, m.p. 220° . A solution of the base in 50 p.c. ethyl alcohol gives $[\alpha]_D -23.0^\circ$. On treatment with methyl iodide it yields hyoscyamine (its nitrogen methyl derivative), and by the action of dilute alkalis gives rise to noratropine (Carr and Reynolds, Trans. Chem. Soc. 1912, 101, 946; Petrie, Proc. Linn. Soc. N.S.W. 1917, 815).

Noratropine $C_{16}H_{21}O_2N$ is a white crystalline base, m.p. 113° – 114° , which readily combines with water forming a monohydrate, m.p. 73° ; it is optically inactive, being the racemic modification of norhyoscyamine, it forms well-crystallised salts of which the following have been characterised: the hydrochloride, m.p. 193° , the sulphate, m.p. 257° , and the aurichloride ($B \cdot HAuCl_4$), which forms rosettes of leaflets which melt under hot water and crystallise on cooling, m.p. 157° .

Both norhyoscyamine and noratropine possess mydriatic properties, but are less active than hyoscyamine or atropine.

Pseudohyoscyamine was the name given to a compound isolated by Merck (Arch. Pharm. 231, 117) from the plant *Duboisia myoporoides*. The formula $C_{17}H_{23}O_2N$ was wrongly assigned to it; subsequent investigations, however, of the alkaloids of this plant (Carr and Reynolds, Trans. Chem. Soc. 1912, 101, 946) have shown that the so-called pseudohyoscyamine of Merck was impure nor-hyoscyamine contaminated with a little hyoscyamine.

Solandrone. Solandrone was the name given by Petrie to the alkaloid isolated from solandra leaves in 1908. When later it was characterised it was found to be identical with norhyoscyamine (*l.c.*).

Tropacocaine (*Benzoylpseudotropine*)

was first isolated by Giesel (Ber. 1891, 24, 2336), from Java coca leaves and subsequently by

TROPEINES.

Heese (J. pr. Chem. 1902, [ii.] 66, 401) from Peruvian coca. Hara and Sakamoto have described the preparation of trapacocaine from the petroleum extract of coca leaves produced in Java (J. Pharm. Soc. Japan, 1924, 503, 33; Chem. Soc. Abstr., 1924, 126, i. 870). It crystallises in needles, m.p. 49°, and its solubility in dilute ammonia affords a means by which it can be separated from the accompanying alkaloids. Its alcoholic solution is strongly alkaline and optically inactive. The hydrochloride has m.p. 283° (decomp.), and the aurichloride, m.p. 208°.

On warming with either mineral acids, or alkalis, the base undergoes hydrolysis and furnishes benzoic acid and pseudotropine (Liebermann, Ber. 1891, 24, 2338).

Pseudotropine $C_8H_{13}ON$ is isomeric with tropine, it forms colourless tablets or prisms, is optically inactive, and has m.p. 108°, and b.p. 240°; it readily esterifies with organic acids, furnishing a series of derivatives which from their analogy with the tropeines have been called pseudotropeines, but, unlike the former, exert no mydriatic action. F. H. C.

TROPILENE v. KETONES.

TROTYL. Syn. for trinitrotoluene, used as an explosive.

TRUFFLES, subterranean fungi, highly prized as food. Many species are known. König divides the edible truffles into two chief classes—

(1) **White truffles**, the best of which is the African truffle, *Tuber niveum* (Desf.) or *Terfezia Leonis* (Tul.), but also including the Italian truffle, *Tuber magnatum* (Pico.) or *Tuber album* (Balb.), with a garlic-like odour, and the German white truffle, *Tuber album* (Bull.) or *Chæromyces meandriiformis* (Vitt.), of much less value.

(2) **Black truffles**, which include the highly prized French truffle *Tuber melanospermum* (Vitt.), which is usually in size between a walnut and an apple, of dark brown or black colour, and covered with polygonal warts. It possesses a strong aromatic odour, resembling that of the strawberry; the winter truffle, *T. brumale* (Vitt.) occurs in France and Italy, resembles the French truffle, but has not such an aromatic smell and taste. The summer truffle, *T. aestivum* (Vitt.) is the one most usually found in England, generally in beech, oak, or birch woods, and in marly soils. It is gathered from July to September.

König gives, as the mean composition of truffles—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
77.1	7.6	0.5	6.6	6.4	1.9

Chatin (Compt. rend. 1890, 110, 376, and 435) found the dry matter in French truffles to vary from 20.8 to 25.0 p.c. of the original fresh material, and to contain from 4 to 9 p.c. of its weight of nitrogen, and from 5.6–11.2 p.c. of ash. The ash, in different samples, contained: silica 10–35 p.c., potash 17–28, soda 0.6–2.1, lime 6.0–9.4, magnesia 0.2–3.1, ferric oxide and traces of alumina 3.2–8.4, manganese oxide, traces to 0.05, phosphorus pentoxide 18.4–30.2, sulphur trioxide 2.1–4.6, chlorine with traces of iodine 0.2–0.4 p.c. Much larger proportions of potash and phosphorus pentoxide were found in the ash of truffles by Kohlrausch and Loewcke,

quoted by König. The amount of alumina is also apparently very variable, since Pizzi (quoted by König) found, in the ash of black truffles, 5.77 p.c. of alumina, in that of white truffles, 7.17 p.c.

As to the nature of the nitrogenous constituents of truffles, little appears to be known; probably a considerable proportion of it is in the non-proteid form.

In the non-nitrogenous extract, mannitol, trehalose and malic and citric acids have been found.

For an examination of the *tubulane* or Caucasian truffles, and of various species of *Terfezia*, known as 'terfas' and 'kames' in the north of Africa and in Western Asia v. Chatin (Compt. rend. 1893, 114, 46; and Revue intern. des falsific. 1893, 14).

Truffles are sold, either in the fresh condition, imbedded in lard, dried, or cooked and preserved in olive oil, or in hermetically sealed cases.

König gives, as the mean of 9 analyses of the air-dried product—

Water	Protein	Fat	N free extract	Crude fibre	Ash
4.4	33.9	2.0	24.9	27.1	7.7

H. I.

TRUXILLINES v. COCAINE AND THE COCA ALKALOIDS.

TRYEN, *p*-iodo-*o*-sulphooxy-cyclo-hexatriene pyridine.

TRYGASE v. SYNTHETIC DRUGS.

TRYPAFLAVIN (*Diaminomethylacridinium chloride*), a yellow dyestuff employed therapeutically in the form of a 0.1 p.c. solution as a bactericide. The solution is sensitive to sunlight and turns brown on exposure even to diffused daylight. Kept in the dark, or in dark-coloured bottles, especially in strong solutions, it may be preserved unchanged.

TRYPAN BLUE AND TRYPAN RED. Azodyes derived from benzidine having a strong trypanocidal action.

TRYPSIN v. FERMENTATION.

TRYPTOPHAN, β -indole- α -aminopropionic acid

It has been known since the researches of Gmelin, Barnard, and others of the earlier physiologists that on tryptic digestion a substance is formed from proteids that gives a reddish-violet coloration with chlorine or bromine. Other methods of decomposing proteids, such as putrefaction or alkali or acid hydrolysis, give rise to the same substance, for which the name *tryptophan* was suggested by Neumeister (Zeitach. Biol. 1890, 26, 234), and *proteinchromogen* by Stadelmann (*ibid.* 491). The compound itself was not known until 1901 when Hopkins and Cole (J. Physiol. 1901, 27, 418) isolated it from the products formed by the tryptic digestion of casein; they showed that it possessed the formula $C_{11}H_{13}O_2N_2$, yielded scatole and indole when heated, and adopting Neumeister's suggestion named it *tryptophan*.

Tryptophan occurs among the products of

Ellinger (Ber. 1905, 38, 2884) further showed that Nencki's scatoleacetic acid was identical with indole propionic acid obtained by a similar synthetic process from ethyl propionacetal-malonate

Constitution and synthesis.—The formation of indole (Kühne, Ber. 1875, 8, 206; Nencki, *ibid.* 336), of scatole (Brieger, *ibid.* 1877, 10, 1027), of scatole carboxylic acid (E. and H. Salkowski, *ibid.* 1880, 13, 2217) and of scatole-acetic acid (Nencki, Monath. 1889, 10, 506) on putrefaction of proteins was attributed by Nencki to the presence of a scatoleaminoacetic acid in the protein molecule; and when Hopkins and Cole found tryptophan to have the empirical formula $C_{11}H_{12}O_2N_2$, and to yield indole, scatole, scatole carboxylic acid and scatoleacetic acid on putrefactive decomposition, they regarded their substance as Nencki's hypothetical scatole-aminoacetic acid.

by oxidising tryptophan with ferric chloride (Hopkins and Cole, J. Physiol. 1903, 29, 451; Ellinger, Ber. 1906, 39, 2515), and can also be prepared by the action of chloroform and potassium hydroxide on indole; it condenses with hippuric acid to form an *azlactone*, or its 1-*acetyl* derivative (Ellinger and Matsuoka, Zeitsch. physiol. Chem. 1920, 109, 259), which on hydrolysis yields *α -benzoylaminoindolyl-acrylic acid*. This compound on reduction and subsequent hydrolysis yields *α -amino- β -indole-propionic acid*, identical with *dl*-tryptophan

[illegible]

Properties.—The tryptophan obtained from proteids is laevorotatory in aqueous solution. Hopkins and Cole (J. Physiol. 1901, 27, 418) found $[\alpha]_D -33^\circ$, H. Fischer (Zeitsch. physiol. Chem. 1908, 55, 74) found $[\alpha]_D -34.5^\circ$ for one specimen, whilst others gave values varying from -29.75° to -40.3° ; Abderhalden and Baumann (ibid. 412) found $[\alpha]_D^{20} -30.33^\circ$. In alkaline or acid solution, *L*-tryptophan is dextro-rotatory, having $[\alpha]_D^{20} +5.7$ to $+6.3^\circ$ in a 2-3 per cent. solution in *N*/2NaOH solution, or $+4.6^\circ$ in

+6.12° in 10-12 p.c. N/1NaOH solution (Abderhalden and Kempe, *ibid.* 1907, 52, 207; Abderhalden and Baumann, *l.c.*); lower values were found by Fischer (*l.c.*), $[\alpha]_D^{20} +5.56^\circ$ to 5.69° in a 2-3 p.c. solution of a N/1NaOH solution. This is probably due to partial racemisation as Abderhalden and Baumann (*l.c.*) found $[\alpha]_D^{20} +5.27^\circ$ for a specimen that had been repeatedly recrystallised; a 6 p.c. solution in N/1 hydrochloric acid gave $[\alpha]_D^{20} +1.31^\circ$ (Abderhalden and Kempe, *l.c.*). *l*-Tryptophan crystallises in six-sided and rhombic plates, is sparingly soluble in cold, readily so in hot water and has a slightly bitter taste; it darkens when heated at 240° and melts at 252° (Hopkins and Cole, *l.c.*), at 273° (Neuberg and Popowsky *l.c.*), at 289° (corr.) (Abderhalden and Kempe, *l.c.*). The brown pigment found in its solutions on standing is probably a condensation product (Abderhalden, *Zeitsch. physiol. Chem.* 1912, 78, 159).

dl-Tryptophan is prepared synthetically and also readily formed from *l*-tryptophan which racemises on crystallisation from pyridine, or by the action of ammonia or by heating at 170° with hydrochloric acid (Abderhalden and Baumann, *l.c.*; Allers, *Biochem. Zeitsch.* 1907, 6, 272; Neuberg, *ibid.* 276); the racemic compound differs from the natural compound only in being optically inactive and in having a sweet taste. For the dissociation constants, see Aristides Kanitz (*Biochem. Zeitsch.* 1910, 29, 126).

Reactions.—The Adamkiewicz or Liebermann reaction given by certain proteins—namely, the formation of a blue-violet ring at the junction of the two liquids when concentrated sulphuric acid is added to a mixture of the protein with acetic acid or ether—is due to the presence of tryptophan in the protein and of glyoxylic acid in the acetic acid or ether (Adamkiewicz, *Ber.* 1875, 8, 161; v. Liebermann, *Zentr. Med. Wissensch.* 1887, 321, 450; Hopkins and Cole, *Proc. Roy. Soc.* 1901, 68, 21; *J. Physiol.* 1901, 27, 418; Cole, *J. Physiol.* 1903, 30, 311; Osborne and Harris, *J. Amer. Chem. Soc.* 1903, 25, 855; Bardachzi, *Zeitsch. physiol. Chem.* 1906, 48, 145; Dakin, *J. Biol. Chem.* 1907, 2, 289). According to Homer (*Proc. Camb. Phil. Soc.* 1912, 16, 405), who has studied the behaviour of tryptophan towards certain aldehydes, it is formaldehyde rather than glyoxylic acid that is the substance essential to the formation of the characteristic violet colour in the Adamkiewicz reaction (see also Fearon, *Biochem. J.* 1920, 14, 548).

For other colour reactions of proteins due to the presence of tryptophan, see Cole (*l.c.*); Dakin (*l.c.*); Fleig (*Proc. Soc. Biol. med.* 1908, 65, 193); Rosenheim (*Biochem. J.* 1, 233); Granström (*Beitr. Chem. Physiol. Path.* 1908, 11, 132); Heimrod and Levene (*Biochem. Zeitsch.* 1910, 25, 18); Mörrner (*Zeitsch. physiol. Chem.* 1919, 107, 203).

The red-violet colour produced by chlorine or bromine water on tryptophan is only given by free tryptophan, not by its polypeptides. The coloration attains a maximum when the amount of halogen is equivalent to four atoms per gram-molecule of tryptophan, and when concentrated solutions are used red amorphous

precipitates of the monohalogen derivatives are obtained $C_{11}H_{11}O_2N_2Cl$ and $C_{11}H_{11}O_2N_2Br$. These compounds are soluble in amyl alcohol, ether, or ethyl acetate, and the use of these solvents has been suggested to render the reaction more intense. The addition of excess of halogen converts the red compounds into yellow perhaloids $C_{11}H_{11}O_2N_2Cl_2$ and $C_{11}H_{11}O_2N_2Br_2$, (Neuberg and Popowski, *Biochem. Zeitsch.* 1907, 2, 357; Neuberg, *ibid.* 1910, 24, 423; Abderhalden and Kempe, *l.c.*).

Detection and estimation.—According to Herzfeld (*Biochem. Zeitsch.* 1913, 56, 258) a distinct blue colour may be detected if there is 1 part of tryptophan in 1,000,000 by means of *p*-dimethylaminobenzaldehyde; 20 grms. of *p*-dimethylaminobenzaldehyde are dissolved in 500 c.c. concentrated hydrochloric acid a 500 c.c. water. To 50 c.c. of the solution to tested 10 c.c. of the reagent are added and mixture diluted to 100 c.c. with concentrated hydrochloric acid. The colour can be estimated against an ammoniacal copper sulphate solution; see also Fasal (*Biochem. Zeitsch.* 1912, 44, 392); Thomas (*Ann. Inst. Pasteur.* 1920, 34, 701); for a colorimetric method for the estimation of tryptophan, Levene and Rouiller (*J. Biol. Chem.* 1907, 2, 481); Fürth and Nobel (*Biochem. Zeitsch.* 1920, 109, 103, 124); Fürth and Lieben (*ibid.* 1921, 116, 224; 1921, 122, 58); Ide (*Z. expt. Med.* 1921, 24, 166); Lüscher (*Biochem. J.* 1922, 16, 556).

For the estimation of tryptophan in proteids, Homer (*J. Physiol.* 48, iv-v) recommends hydrolysing the proteid with baryta and estimating the tryptophan by means of bromine which has been standardised against a known solution of pure tryptophan. See also Folin and Looney (*J. Biol. Chem.* 1922, 51, 421).

For the microchemical detection of tryptophan in plants, see Kretz (*Biochem. Z.* 1922, 130, 86).

Tryptophan is decomposed on heating into carbon dioxide, indole and scatole; when fused with potassium hydroxide, scatole, to the extent of 65 p.c. of the calculated amount, is the chief product (Hopkins and Cole, *l.c.*).

Tryptophan is coloured yellow to orange by *Bacillus proteus vulgaris* only at P_H 8.9-9.4. The practical bearing of this is concerned with the manufacture of Stilton cheese (Mattick and Williams, *Biochem. J.* 1921, 15, 213). *l*-Tryptophan is converted by *B. proteus* into *l*-indole lactic acid (Sasaki and Otsuka, *Biochem. Z.* 1921, 121, 167).

In the animal economy, tryptophan undergoes bacterial decomposition with the formation chiefly of indole; in the case of dogs it is partially converted into *kynurenic acid* (4-hydroxyquinoline 3-carboxylic acid)

(*v.* QUINOLINE) and excreted as such. The administration of tryptophan causes an increased excretion of kynurenic acid (Kretschy, *Ber.* 1879, 12, 1873; Weiss, *Abd. Ber.* 1881, 33, 181, 171; Monastch, 1883, 4, 156; 5, 16; Solomon, *Zeitsch. physiol. Chem.* 1907, 33, 497; Capaldi,

1842, 1897, 23, 32; Mendel and Jackson, Amer. J. Physiol. 1898, 2, 1; Camps, Ber. 1901, 34, 2703; Mendel and Schneider, Proc. Amer. Physiol. Soc. 1900, ix-x; Amer. J. Physiol. 1901, 5, 427; Gies, *ibid.* 1901, 5, 191; Glaessner and Langstein, Beitr. chem. Physiol. Path. 1901, 1, 28; Ellinger, Ber. 1904, 37, 1801; Abderhalden, Löffler and Pinoussohn, Zeitsch. physiol. Chem. 1909, 62, 139; Homer, J. Biol. Chem. 1915, 22, 391; Matsuoka, J. Biol. Chem. 1918, 35, 333; Späth, Monatsh. 1921, 42, 89).

Ellinger and Matsuoka (Zeitsch. physiol. Chem. 1920, 109, 259) find that when indolepyruvic acid (I) is administered subcutaneously to a dog, it is possible to isolate from the urine kynurenic acid in amount rather less than one-half of that obtained when tryptophan is injected; and the conclusion is drawn that the conversion of tryptophan into kynurenic acid is best represented by the scheme

1-2-Methyltryptophan

crystallises with 1MeOH in colourless prisms, m.p. 263°-273°, according to the rate of heating; the picrate, $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\cdot\text{C}_6\text{H}_5\text{O}_2\text{N}_3$, crystallises in orange plates, m.p. 173° (Barger and Ewins, Bio-Chem. J. 1917, 11, 58).

Salts of 1-tryptophan.—1-Tryptophan has an acid reaction towards litmus, and forms salts both with acids and bases; the *copper salt* ($\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3$)₂Cu, sparingly soluble grey-blue precipitate (Abderhalden and Kempe, Zeitsch. physiol. Chem. 1907, 52, 207); the *silver salt* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\text{Ag}$; the *sodium salt* has $[\alpha]_D + 2.50^\circ$ in 2 p.c. solution (H. Fischer, l.c.). The *hydrochloride* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\cdot\text{HCl}$ has m.p. 251° and $[\alpha]_D - 13.44^\circ$ in 2 p.c. aqueous solution (H. Fischer); the *picrate* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\cdot\text{C}_6\text{H}_5\text{O}_2\text{N}_3$, forms bright red lustrous needles or plates, m.p. 195°-196° (decomp.); the *picrolonate*

forms orange red needles, m.p. 203°-204° (Mayeda, Zeitsch. physiol. Chem. 1907, 51, 261).

Esters and acyl derivatives.—The *methyl ester* $\text{C}_{11}\text{H}_{11}\text{N}_3\cdot\text{COOMe}$ forms crystalline plates, m.p. 89.5° (corr.); the *hydrochloride*

crystallises in microscopic needles, melts with decomposition at 214° (corr.); the *hydrochloride of 1-tryptophan* $\text{C}_{11}\text{H}_{11}\text{N}_3\cdot\text{COCl}\cdot\text{HCl}$ melts and decomposes at 238° (corr.) (Abderhalden and Kempe, l.c.). The *phenylcarbamide derivative* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3$ crystallises in

needles, m.p. 166°; the *carbamide* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\cdot\text{CONH}\cdot\text{C}_6\text{H}_5$, m.p. 159°-160°; the *benzenesulphonic derivative* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\cdot\text{SO}_3\text{Ph}$ melts and decomposes at 185° and forms a sparingly soluble sodium salt; the *β-naphthalenesulphonic derivative* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\cdot\text{SO}_3\cdot\text{C}_{10}\text{H}_7$ melts at 180°, the *sodium salt* at 304° (corr.) (Abderhalden and Kempe, l.c.; Ellinger and Flamand, Ber. 1907, 40, 3029).

d-Tryptophan-anhydride, m.p. 230°-245° (decomp.), has $[\alpha]_D + 20.59^\circ$ in water (Fränkel and Feldsberg, Biochem. Zeitsch. 1921, 120, 218).

Other derivatives of tryptophan are *monochlorotryptophan* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\text{Cl}$, an amorphous red precipitate, m.p. 280°, converted by excess of chlorine into the *perchloride* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\text{Cl}_4$, a yellow precipitate decomposing at about 100°; *monobromotryptophan* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\text{Br}$, an amorphous red precipitate with a black reflex, m.p. 270°-280°; the *perbromide* $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_3\text{Br}_3$ is yellow and decomposes at 75° (Neuberg and Popowsky, Biochem. Zeitsch. 1906, 2, 357).

The *betaine* of tryptophan is identical with the alkaloid *hypaphorine*, discovered by Greshoff (Mededeelingen uit's Lands Plantentuin, 1890, 7, 29) in the seeds of *Erythrina hypaphorus* (Boerl.), and is of considerable biochemical interest as it is the only naturally occurring simple derivative of tryptophan. The alkaloid can be synthesised from tryptophan by the action of methyl iodide, sodium hydroxide and methyl alcohol, which yields the *iodide of methyl α-trimethylamino-β-indolepropionate*

m.p. 197°, and this on hydrolysis gives *hypaphorine* or *α-trimethylamino-β-indolepropionbetaine*

of which the *nitrate* has m.p. 215°-220° and $[\alpha]_D + 94.7^\circ$. Greshoff found $[\alpha]_D 91^\circ-93^\circ$ for the natural base (van Romburgh and Barger, Chem. Soc. Trans. 1911, 2068).

M. A. W.

TSCHIEFFKINITE.* A titano-silicate of cerium earths (Ce_2O_3 , &c., 23-47 p.c.) of doubtful composition, and probably only an alteration product lacking in homogeneity. Two analyses (R. Hermann, 1866) show ThO_2 20.9 and 14.4 p.c. The mineral is black, opaque, and pitted, with a brown weathered crust on the exterior. Sp.gr. 4.2-4.5. It is found in pegmatite in the Ilmen Mtns., Urals; Kanjamalai Hill, near Salem in Madras; Nelson and Bedford counties in Virginia, here as masses up to 20 lb.; and in Madagascar.

L. J. S.

TSCHEN or CHEN. Chinese coins of a brass or bronze-yellow colour, containing 55-64 p.c. copper, 26-35 p.c. zinc, and from 1-2 p.c. tin, 2-4 p.c. iron and 1-6 p.c. lead; and occasion-

* This is the usually-accepted spelling, but the transliteration from the Russian (тешкины) is partly German and partly French. The original is Tschewkins (G. Rose, 1869); and equivalent would be Chevkinite.

ally small quantities of antimony, arsenic, and nickel (Pöpplein, Chem. Zentr. 1859, 494).

TSCHERMIGITE. The mineralogical name for ammonium-alum $(\text{NH}_4)_2\text{SO}_4 \cdot \text{Al}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$. In nature it is found as crystalline crusts on lignite containing streaks of pyrites at Tschermig, Brüx, and Dux in Bohemia. The white, fibrous, platy masses somewhat resemble fibrous gypsum; but distinct cubo-octahedral crystals are also found. In some quantity it has been found in bituminous shale near Wamsutter in Wyoming (E. T. Erickson, J. Wash. Acad. Sci. 1922, 12, 49). It is also recorded as a volcanic product from the solfatara of Pozzuoli near Naples.

L. J. S.

TSCHEWKINITE v. TSCHEFFKINITE.

TSE-HONG. A mixture of white lead, alumina, ferric oxide, and silica, used by the Chinese for painting on porcelain.

TSING-LIEN. A red pigment used in porcelain painting. Consists of a mixture of stannic and lead silicates with copper oxide or cobalt and gold.

TUBA. The Malay name for *Derris elliptica* (Benth.), used in Java to kill fish. Contains tubatocin $\text{C}_{12}\text{H}_{11}\text{O}_8$, white crystals from alcohol, m.p. $163^\circ\text{--}165^\circ$, soluble in most organic solvents, insoluble in water, acids, and alkalis. Reduces ammoniacal silver and alkaline copper solutions. Produces in fish, frogs, and mammals general motor paralysis. Lethal dose for rabbit (intravenous) 0.009 grm. per kilo (Ishikawa, Jap. Med. Lit. 1917, 1, 7; Chem. Abstr. 1917, 11, 2371; cf. Greshoff, Ber. 23, 3537; van Sillevoldt, Arch. Pharm. 1899, 237, 595; Power, Arch. Pharm. 1903, 6, 1).

TUFA v. TRAVERTINE.

TUFF or VOLCANIC TUFF (from Ital. *Tufo*).

A pyroclastic rock consisting of more or less compacted dust and fragmentary material ('ashes,' *lapilli*, *scoriae*), produced by volcanic explosions. The composition varies between wide limits, depending on the kind of lava or rock from which the material has been derived; logists distinguish rhyolite-tuff, trachyte-tuff, andesite-tuff, basalt-tuff, palagonite-tuff, and ultrabasic-tuff. Further, there may be an intermixture of fragments of sedimentary rocks and other foreign material; and if deposited in water they are stratified, and may shade off into shale, limestone, sandstone, &c. They also vary much in texture and physical characters, from loose and earthy to hard and compact. Those interbedded with the older sedimentary strata may have their characters so obliterated that they are difficult to recognise as tuffs. For instance, the green roofing slates of the English Lake District were deposited as tuffs in Ordovician times; and other silicified tuffs are now used for road-stones.

The *pozzolana** of the Phlegrean Fields, the island of Ischia, and elsewhere near Naples, is an incoherent trachyte-tuff which has been extensively used, mixed with lime, for making hydraulic mortar, cement (pozzolanic cement), concrete, and artificial stone. The colour varies from yellow to grey (*tufo giallo* and *tufo bigio*). A similar sandy tuff which has been used for the same purpose (Roman cement) since the time of the Romans also occurs in the extinct

* Also spell *pozzolana*, *pozzuolana*, *puzzolana*; from *pozzuoli* near Naples.

volcanic district around Rome. Here also there is a more compact, though soft and easily worked, granular tuff, in which the ostacombs are excavated; and a harder stony tuff (*tufo liscio*) employed as a building stone. Another compact tuff, which has been much used as a building stone in ancient and modern Rome, is the *peperino*† (*lapis Albanus*) of the Alban Hills. This is a leucite-basalt-tuff, showing black grains suggestive of peppercorns embedded in a grey ground. Sandy volcanic tuffs similar in character to pozzolana occur at many other localities, from some of which it is exported for the manufacture of cement, e.g. Santerin, Auvergne, Hungary, Canary Islands (here known as 'tosca'), Crimea, Eifel. In the Eifel it is known locally as *trass* (or *duckstein*), and is extensively quarried in the Brohl and Nette valleys, between Andernach on the Rhine the Laacher See. This also is a trachyte-tuff, composed largely of glassy fragments of pumice with fragments of *grauwacke* and clay-slate. It is dull and earthy with a yellowish, grey, brown colour; 40–70 p.c. is soluble in hydrochloric acid. The looser material is used for manufacture of hydraulic cement, whilst some of the more compact is employed as a building stone, and as a fire-stone in ovens. The latter is very porous (weight per cubic foot, 85½ lbs.; porosity, 29–45 p.c.), is easily worked, and it hardens on exposure; on account of its lightness it is especially adapted for vaults and arches.

Analysis I is of yellow pozzolana (poasil tuff) from Cape Posilipo, Naples (also CO_2 3.16; Mn_2O_3 0.54; 90 p.c. of the material is soluble in hydrochloric acid; sp.gr. 2.46); II pozzolana from near Naples (ignited material; also NaCl 2.56); III red pozzolana from near Rome; IV, trass from Brohl valley, Rhine; V, trass from Andernach; VI, blue trass (*duckstein*) from Plaidt, Nette valley, Rhine (also MnO 0.58).

L. I. S.

TULA METAL. An alloy of silver, copper, and lead made at Tula in Russia.

TUNG OIL is obtained from the seeds of *Aleurites cordata* (Muell. Arg.) *Elaeagnus cordata* [Bl.]; *Elaeagnus vernicea* [Juss.]; *E. sinensis* (*Dryandra vernicea* [Cox.]), and *A. fordii*, trees indigenous to China and Japan. Trees belonging to the same species also grow abundantly in Indo-China, Tonkin, Annam, and Cambodia.

The fruits form a nut, in which three seeds, having a hard shell and an oleaginous kernel, are enclosed; in China the oil is frequently termed 'nut oil,' and in America is known as China wood oil.

Three kinds of seeds are distinguished—

† Not to be confused with 'tung' (= *Trachypithecus*).

yellow, drab, and white. The seed of the Japanese tung tree is smaller than that of the Chinese variety (*Alseurites fordii*), and yields an oil which gelatinises less readily on heating. A Japanese oil had the following characters: iodine value, (Wij's) 150.2, (Häbl.) 154.4; saponif. value, 193.2; acid value, 0.9; sp.gr. at 15°/15°, 0.9342; $n_D^{25} = 1.4982$. Two samples had n_D^{40} , 1.5078 and 1.5116 respectively, and showed a decrease in refractive index of 0.000395 for each 1°C. rise in temperature (H. E. Goldsmith, Ind. Eng. Chem. 1923, 15, 786; J. Soc. Chem. Ind. 1923, 938 A).

The viscosity is intermediate between that of Chinese tung oil and raw linseed oil (Gardner and Ratliff, Chm. 138, U.S. Paint Manufacturers Assoc. Nov. 1921). There are four species of tung oil trees in Japan, viz. (a) Japanese tung oil tree, *Alseurites cordata*, (b) Chinese tung oil tree, *A. fordii*, (c) Kangtung tung oil tree, *A. montana*, and (d) Bakoly (or tropical) tung oil tree, *A. moluccana* (better known as candlenut oil). Of these (a) is grown all over the interior of the country and the others in Formosa.

Other analyses are as follows:—

Oil contents.	(a)	(b)	(c)	(d)
In seeds, p.c.	37.77	44.11	37.43	23.61
In endosperm, p.c.	59.15	66.29	59.78	70.66
Time for drying at 95°C. (min.)	65	55	60	270
Sp.gr. (15°C.)	0.9340	0.9488	0.9372	0.9267
Acid value	0.47	1.52	0.59	0.80
Saponif. value	194.79	196.76	194.31	195.13
Iodine value (Wij's)	151.37	157.17	154.85	146.31
Refract. index (25°C.)	1.5065	1.5210	1.5147	1.4785
Reichert-Meißl value	0.39	1.10	0.35	0.71
Unsaponif. matter, p.c.	0.41	0.59	0.99	0.97

(I. Miura, Kōgyō-Kwagaku Zasshi, J. Chem. Ind. Japan, 1923, 26, 316-321; J. Soc. Chem. Ind. 1923, 42, 786 A.)

Analyses of the oil from *A. montana* and

Japanese *A. fordii*, and a comparison with the proposed American standard, based on the examination of oils from the Chinese *A. fordii*, are as follows:—

	<i>A. montana</i> .	<i>A. fordii</i> (Japanese).	American specification, for China wood oil.
Specific gravity at 15°/15°C.	0.9467	0.9439	0.938-0.943
Refractive index n_D^{15}	1.494	1.4917	$n_D^{25} 1.515-1.520$
Acid value	3.4	Nil	7.0 max.
Saponification value	203	204	190-195
Unsaponifiable matter, p.c.	0.6	—	0.75
Iodine value	141.4	157.7	163
Heat test	16"	19.5"	12"
Iodine jelly test	45"	35"	—
"Titre test"	54-54.5	—	—

The heat test is considered the most satisfactory criterion (Rau, Robertson, and Simonsen, Indian Forest Rec. 1924, 10, 1; Analyst. 1924, 49, 399).

In China the seeds are roasted, crushed between stones, and expressed in wooden presses. The kernels contain about 53 p.c. of oil, but yield only 40-41 p.c. The cold-drawn oil is pale yellow (*white tung oil*), and is the variety chiefly imported into Europe as China wood oil. The oil obtained by hot pressing is dark brown (*black tung oil*), and is consumed at home; it has an unpleasant taste, and its odour is more pronounced than that of the white tung oil, which is also somewhat unpleasant. This odour, attributed to damaged kernels, precludes its use for many purposes. Tung oil is also expressed in Madagascar, where the oil is known under the name 'Bakoly oil,' probably a corruption of 'bancoulier' (*Alseurites moluccana*; candlenut oil). The Chinese and Japanese oils differ in specific gravity, iodine value, and gelatinising power (see *Characteristics* under *Oils, Fats, and Waxes*). The chief shipments of oil are made from Hankow and Wuchow in

China; comparatively smaller quantities are exported from Japan (Hokkaido).

Tung (China wood) oil contains little, if any, saturated fatty acid and relatively little oleic acid, elaeostearic acid, $C_{11}H_{21}O_2$, being the characteristic acid. Both the glyceride and the fatty acid (α -acid) derived from it change to isomeric forms (β) of higher melting-point by exposure to light or under the influence of catalysis (Bauer and Herberts, Chem. Umschau, 1922, 29, 220; cf. Morrell, J. Soc. Chem. Ind. 1918, 181 T). It does not yield any ether-insoluble bromide. In the 'elaidin test' an oily layer is obtained resting on the lower, nearly solid product; when stirred up, the whole mass flows.

Tung oil contains from 75 to 85 p.c. of glyceryl α -elaostearate, which changes under the influence of light into the solid geometrical isomeric, glyceryl β -elaostearate. Both the α - and the β -triglycerides increase in weight at about the same rate when exposed to the air in thin films. After standing for 10 months in a closed brown glass bottle, β -elaostearin became insoluble in acetone and no longer melted, but charred at about 265°. Both α - and β -elaostearic acids

m.p. 46° and 72° respectively, were prepared from tung oil which had stood for some time, by extracting it with ethyl alcohol and fractionally crystallising the extract from this solvent at about 0°. Another acid (m.p. 106.5°), presumably a cleavage product, was obtained from the residue insoluble in cold alcohol. After 8-10 days a thin layer of the α -acid was transformed into a clear yellow syrup, whilst the β -acid was only transformed into a clear yellow, viscous syrup after 4 weeks' exposure. Only two of the three possible geometrical isomerides of elaeostearic acid have been obtained. It is considered that the α -acid is probably the *cis-cis* form and the β -acid the *cis-trans* form. Bromination of both α - and β -acids yields the same tetrabromide (m.p. 114°). The transformation of the α - into the β -geometrical isomeride, on treatment with bromine, is considered to be a peculiarity confined to compounds containing two double linkings separated by two methylene groups, a constitution which explains the high reactivity of elaeostearic acid. Evidence is adduced in favour of the view that the conversion of the α - into the β -acid plays very little part in the mechanism of the drying of tung oil, which appears to be a colloidal phenomenon involving transformation from the sol to the gel form rather than a case of molecular polymerisation (A. Eibner, O. Merz, and H. Munzert, Chem. Umschau. 1924, 31, 69; Chem. Soc. Abstr. 1924, 126, i. 609). Boeseken and Ravensway (Rec. trav. Chim. 1925, 44, 241) conclude from refractometric determinations that elaeostearic acid has three double bonds and belongs to the linolenic series. This is confirmed by Kaufmann (Ber. 1926, 59, 1390), who finds that thiocyanogen is absorbed at only two of the double bonds, but that the third double bond can be saturated with bromine when the oil is exposed to the rays of a mercury vapour lamp. Kaufmann thus found two specimens of tung oil to have the following composition: I. elaeostearin, 78.5; olein, 22.8 p.c.; II. elaeostearin, 87.1; olein, 13 p.c.

Thomas and Yu (J. Amer. Chem. Soc. 1923, 45, 120) have devised a qualitative test for elaeomargaric acid, which consists in treating the insoluble magnesium salts from tung oil with 90 p.c. alcohol, and then liberating the fatty acid in the absence of air. A yield of about 20 p.c. (m.p. about 44°) is obtained.

The oil may be identified by its strong characteristic smell, and also by the manner in which it dries. Although it forms a skin more rapidly than does linseed oil, the skin it yields, e.g. on a glass plate, when dry, is opaque, wax-like, and has no elasticity. Therefore, tung oil cannot replace linseed oil, but is nevertheless largely used as a substitute for it. A number of patents have been taken out for the manufacture of boiled oils, varnishes, rubber substitutes, and linoleums, in which larger or smaller quantities of tung oil are used in place of linseed oil. V. VARNISH.

Drying of Tung Oil.—Tung oil appears to dry in about two days in moist air, but the resulting film is always wrinkled or cracked and uneven. In dry air a smooth coherent film is obtained, but the time required is about 14-21 days. In either case, however, the full gain in (129-133 p.c.) requires about

21-30 days, and it is concluded that tung oil is really a slow-drying oil, and that the rapid apparent rate of drying in moist air is not 'drying' in the usual sense (i.e. oxidation and polymerisation), but is a colloidal coagulation in which moisture acts as the coagulant (W. Schmidt, Farben-Zeit. 1924, 29, 1261; J. Soc. Chem. Ind. 1924, 43 B, 604).

A characteristic property of tung oil is that it forms a jelly on being heated to 250° for a short time, or even when kept at 180° for an hour or two. Tung oil gelatinised by heating to 200°-250°C. and extracted with ether yields an extract which can be divided into two fractions by treatment with acetone, viz. 12 p.c. of a thick insoluble oil, a bimolecular triglyceride of elaeostearic acid, and 88 p.c. of oil soluble in acetone. The former fraction (thick oil) is soluble in benzene, ether, and chloroform, and is converted by heating or exposure to air into a solid insoluble mass having about the same iodine value as the acids from the thick oil and as the acids isolated from the solid product insoluble in ether obtained by heating tung oil. Coagulated tung oil contains, in addition to unchanged oil, oily and solid polymerisation products both in the sol and gel form. Substances such as naphthenic acid, linseed oil, and colophony, which prevent the coagulation of tung oil, merely reduce the tendency of the sol to pass into the gel form. The formation of the gel is favoured by exposure to the air, rise of temperature, and by the addition of a little gelatinised oil. It is also caused by the action of light, with the initial formation of α -elaeostearin (*cis* form) and β -elaeostearin (*trans* form), which are respectively soluble and insoluble in acetone. The β -glyceride easily polymerises to a substance insoluble in the usual organic solvents. Tung oil dries, with the formation of crystalline masses of β -elaeostearin, but heated (i.e. polymerised) tung oil, on the contrary, dries evenly, as β -elaeostearin is in this case not present (J. Marcusson, Z. Deuts. Oel. u. Fettind. 1923, 43, 162-163; Chem. Zentr. 1923, 94 [iv.] 297; J. Soc. Chem. Ind. 1923, 42, 938 A). On exposure to the light the oil also becomes solid. The jelly-like mass so obtained possesses some elasticity, is insoluble in the ordinary solvents for oils, and shows no tendency to melt again on being heated to 250°. The gelatinisation is not due to oxygen absorption, since it takes place when air is excluded. Chapman (Analyst, 1912, 37, 543) has made a critical examination of various polymerisation tests, and has shown that greater importance should be attached to the hardness of the jelly obtained under standard conditions than to the time required to effect the polymerisation. The time, however, is the basis of the so-called Browne method, which is commonly employed by varnish chemists, and is officially adopted by the American Society for Testing Materials (Analyst, 1912, 37, 410). It consists in heating 5 c.c. of the oil at 282° and noting the time required for complete solidification. This should not take more than 12 minutes for a pure oil. Jameson (Analyst, 1920, 45, 328) has shown that the time is increased by the presence of free fatty acid, which frequently occurs to the extent of from 1.9 to 4.6 p.c. When tung oil is heated with lead oxide or red lead, the oil

gelatinises within 15 mins. to a light brown mass.

If a saturated solution of iodine in chloroform or any other solvent be dropped on to the oil it is immediately solidified; and if the oil has been previously dissolved in chloroform, a jelly is obtained. Bromine has no such action on the oil.

When a solution of 1 grm. of the oil in 5 c.c. of chloroform, is stirred with 5 c.c. of a saturated solution of iodine in chloroform, the whole is converted into a stiff jelly after about 2 mins. With 2 grms. of the oil the jelly is so stiff that it can be granulated.

Investigation of the effect of glycerol, oleic acid, resin, 'ester gum,' paracoumarone resin, and linseed oil on the rate of gelatinisation of tung oil shows that their efficiency in preventing this change falls in the order given. Tung oil containing 6 p.c. of glycerol can be 'bodied,' e.g. at 280°C., without difficulty. Tung oil containing lead linoleate equivalent to 0.02 p.c. of lead, when treated in this way and dissolved in turpentine, dried rapidly to a smooth tough, transparent film (F. H. Rhodes and T. J. Potts, Chem. and Met. Eng. 1923, 29, 533; J. Soc. Chem. Ind. 42, 1923, 1081 A).

In China and Japan tung oil is used chiefly as a natural varnish for wood, for caulking junks and boats, as a common adulterant of lacquer, and also for lighting. Large quantities are also consumed for water-proofing paper and all kinds of tissues. The oil is further employed in admixture with powdered lime as a mortar. The lamplack of the best kinds of Chinese ink are obtained by burning the oil with a regulated amount of air. The cold-drawn oil is stated to be used in medicine as an emetic and also as a purgative. It should be noted that the raw oil is poisonous. J. L.

TUNGSTEN. Sym. W. At.w. 184.1. Although found in most of the tin deposits throughout the world, the mineral *wolfram* which furnishes the bulk of the tungsten of commerce and its products, appears to have been regarded, until the middle of the eighteenth century, rather as a constituent of *cassiterite* than as an associated mineral. The term 'wolfram' was, in fact, apparently applied to it on account of its causing loss of tin in smelting, in the same sense that antimony was called 'the wolf' by the alchemist because it devoured the base metals when employed in the refining of gold.

The word 'tungsten' is of Scandinavian origin and signifies 'heavy stone,' in allusion to the high specific gravity of wolfram.

In 1781, Scheele obtained a yellow powder (which he termed tungstic acid) by acid treatment of the aqueous extract from the fusion of a certain heavy lime mineral with potassium carbonate. The production of a yellow colouring matter by direct acid treatment of this mineral (afterwards termed *scheelite*) had been previously noted by Woulfe, who did not, however, explain its nature. Scheele's work was confirmed and amplified by Bergman in 1782, and the following year, his former pupils, the brothers D'Elhuyart, are stated to have shown the presence of tungstic acid in wolfram and to have produced metallic tungsten from it.

Scheelite CaWO_4

80.55 p.c. of WO_3) is also an important tungsten mineral, but its common association with rare metals (molybdenum, &c.) and base metals (antimony, &c.), from which it is difficult to effect a separation, has resulted in a smaller output and a lower price as compared with wolfram. Among other minerals may be mentioned *reinite*, a variety of ferberite, FeWO_4 , *cupro-scheelite* $\text{CaWO}_4 \cdot \text{CuWO}_4$, *stolzite* or *raspite* PbWO_4 , and *tungstite* (*tungsten ochre*) $\text{WO}_3 \cdot \text{H}_2\text{O}$ and *ferritungstite* $\text{Fe}_2\text{O}_3 \cdot \text{WO}_3 \cdot 6\text{H}_2\text{O}$. The last-named minerals are commonly found as an incrustation produced by the weathering of tungsten minerals, but occasionally occur massive, and the author has an interesting piece of the former which was sent to England as *scheelite*, but is almost pure tungstic acid, apparently of colloidal origin.

The principal countries where tungsten minerals are found are (in order of importance) United States (chiefly west of the Rocky Mountains), Burma (mainly from Tavoy, south of Rangoon), Bolivia, Portugal, Australia, Japan, South China, Spain, South Africa (including Rhodesia), Austria, Germany, France, and England (Cornwall). The world's production (mostly wolfram, although notable quantities of *scheelite* are mined in United States, Australia, New Zealand, and South Africa) is estimated at nearly 20,000 tons in 1917 against about 8,000 tons in 1913. The largest producers are United States (about 4,700) followed by Burma and Bolivia with about 3,000 and nearly 4,000 respectively. The British Empire produces about 30 p.c. of the total world's production. For a useful summary of the occurrence of tungsten ores, see S. J. Johnstone, J. Soc. Chem. Ind. 1918, 37, 29 R. and later.

Although their value mainly depends on the amount of tungsten which they contain, almost the whole of the output being absorbed in the manufacture of the metal and its alloys, the minerals are invariably sold on their tungstic acid content. The best concentrated or hand-picked material contains up to 74 p.c. WO_3 , but the usual value of that sold in bulk varies between 65 and 72 p.c., the latter being considered high grade. The sale of the ores was, before the war, more often a matter of private treaty, although schedules, covering ores of various percentages and showing limits for P, S, and other impurities, were published by several firms in the United States. The home consumption of ores of tungsten was comparatively small before the war, when most of the ore produced within the Empire was bought and smelted by the Germans, who separated it and exported to this country the manufactured tungsten metal. At the outbreak of war, the then existing makers of the commercial metal ('tungsten powder') and ferro-tungsten in England very largely increased their output, and other concerns commenced the manufacture, notably one organised by an association of the large steel interests. The price of wolfram and *scheelite* rapidly rose to more than double that obtaining before the war, until all ores of tungsten produced within the Empire were commandeered, by agreement between the Imperial and Colonial governments, and a maximum price fixed. The basis price fixed

was 55s. (afterwards raised to 60s.) for each unit WO_3 (i.e. for each 1 p.c. per ton of ore) at 65 p.c. or over, 3d. deduction being made by the buyer for each unit or part of a unit below 60 p.c., and 6d. per unit below 60 p.c. down to 55 p.c. Ore containing lower percentages is saleable at approximately the same rate of penalisation, and, if the impurity is chiefly tinstone, the tin is paid for if over 4 p.c., as it then usually pays for electro-magnetic separation and recovery of the tin. A large proportion of the wolfram ore imported into this country is 'concentrated' at the mine by hand-picking, but in some centres it is separated from the gangue by finer crushing and wet dressing. In the case of the Burmese and Bolivian production, the wolfram is more frequently associated with tinstone. Below 2 p.c. tin (metal) the concentrate is sold direct to the smelters; above that amount (and the ores or concentrates sometimes contain as much as 30 p.c. Sn and over) it is separated. For methods of analysis of ores and concentrates, see Hutchin, *Analyst*, 1911, 36, 398, and *Inst. Min. and Met.* 1918; also Frantmann, *Zeitsch. angew. Chem.* 1911, 24, 2142.

The treatment of the mined ore varies according to its nature and the associated impurities. In Cornwall, where the ores are frequently arsenical and the recovery of the wolfram is chiefly subsidiary to the tin, the treatment consists usually in wet-dressing the crushed ore on tables, roasting the first rough concentrates, re-grinding and concentrating, and finally dry-dressing by means of electro-magnetic separators. The last-named operation, which depends upon the fact that wolfram is weakly magnetic to an electro-magnet, provides the only available means of mechanically separating wolfram from tinstone and other heavy minerals which accumulate during the concentration. Three or four products are commonly produced, viz. fairly clean wolfram (from 60 to 65 p.c. WO_3), an intermediate or tinny wolfram, which is returned to the plant for re-treatment, a strongly magnetic iron oxide, which is valueless, although commonly containing 3 or 4 p.c. WO_3 , and a fairly clean tin concentrate containing usually less than 2 p.c. WO_3 . Much of the imported ore or concentrate from Burma or Bolivia contains wolfram in a less fine state of division, and electro-magnetic separation is carried out on the material with no preliminary treatment other than crushing and grading into various sizes. In this case, only two final products are obtained, viz. wolfram containing from 65 to 73 p.c. or even 74 p.c. WO_3 , and a non-magnetic 'reject' containing from $\frac{1}{2}$ to 2 p.c. WO_3 and from 60 to 70 p.c. tin (metal), according to the concentration of the original material. In the United States most of the wolfram occurs free from tin and in a gangue of a comparatively low specific gravity composed chiefly of silicious matter. In this case a simple concentrating plant consisting of crusher, jigs, and shaking table is sufficient. Wolfram, is, however, extremely friable and liable to slime on crushing, and great care must be exercised to minimise the losses which are in any case considerable. No satisfactory method has yet been devised for the mechanical separation of an ore contain-

ing both wolfram and scheelite with tinstone, such as is found in the Shan States (Burma) and elsewhere. Scheelite is heavy and non-magnetic, and remains with the tinstone when either wet-dressing or electro-magnetic separation is employed. It is invariably present in wolfram ores, although frequently in more traces.

For the estimation of tin in wolfram, see O. F. Lubatti (*Chem. Soc. Trans.* 1923, 123, 1409-1411).

For estimation of molybdenum in tungsten, see W. J. King (*J. Ind. Eng. Chem.* 1923, 15, 350).

The composition of selected specimens of the principal tungsten minerals of the nature of wolfram is shown in the following table, compiled from published and private sources, including Dr. W. F. Hillebrand of the United States Geological Survey, and H. E. Wood of the Colorado Scientific Society, etc. :—

	Wolfram.		Ferberite.		Hübnerite.	
	Colo-rado	Burma	Slam	Corn-wall	Spo-ken	Colo-rado
	P.c.	P.c.	P.c.	P.c.	P.c.	P.c.
WO_3	74.10	75.41	75.00	73.16	75.0	75.9
FeO	11.07	17.33	15.05	22.78	18.0	23.0
MnO	14.35	7.13	8.26	3.06	3.0	0.6

The above analyses are all those of picked specimens, any silica, lime, alumina and other gangue matter being ignored. Traces of columbium, tantalum and other rare metals, as well as of tin, copper, and bismuth, are commonly present in actual combination, even in selected crystals.

Estimation of tungsten in low-grade ores.—

Two grms. of ore are fused with 4 parts of sodium peroxide in a nickel crucible. The fused mass is leached with 100 c.c. of water, the liquid filtered, and the precipitate well washed. The filtrate is heated, acidified with nitric acid, and made alkaline with ammonia; the precipitate is left to settle and filtered off. The hot filtrate, faintly acidified with nitric acid, is treated with excess of mercurous nitrate solution followed by ammonia until the precipitate gets black; the liquid, however, should remain faintly acid and contain mercurous nitrate. The precipitate is filtered off, washed with boiling water and dried, and the paper ashed separately. The precipitate is ignited to constant weight in a platinum crucible and fused with potassium bisulphate, and the cold mass is treated with hot water and a fragment of ammonium carbonate; if the resulting solution is not perfectly clear, the flocculent precipitate (silica or alumina) is filtered off, ignited, and weighed, and the weight subtracted from the first, tungstic acid being obtained by difference (*E. Jünger, Zeitsch. anal. Chem.* 1923, 63, 438; *Analyst*, 1924, 49, 298).

Estimation of tungsten in tungsten-steels.—

Two to three grms. of the steel are dissolved in 80-100 c.c. of 1:1 hydrochloric acid and the solution is evaporated to 40 c.c. Nitric acid is added drop by drop until all the iron is oxidised and the insoluble material assumes a yellow colour. The solution is cooled below 40°, then gently evaporated to 15 c.c., and boiled with 5 c.c. of strong hydrochloric acid and 4 or 6 drops of strong hydrofluoric acid. 80 c.c. of cold water are added and the solution is boiled for 3 min. and filtered through a pulp filter.

The precipitate is washed with hot dilute hydrochloric acid till free from iron, ignited, and weighed as tungsten trioxide (K. Swoboda, *Oesterr. Chem. Ztg.* 1924, 27, 53; *J. Soc. Chem. Ind.* 1924, 43 B. 435).

Manufacture of tungsten.—The manufacture of tungsten (by the soda fusion method) and ferro-tungsten (by the thermit or electric furnace method) demands an ore or concentrate as free from impurities as possible, and, while makers' requirements differ in normal times, this is only because those whose requirements are less stringent are themselves prepared to carry out the necessary purification. Objectionable impurities, inasmuch as they affect either or both the quality of the resultant product and the yield, are Sb, As, Bi, Cu, Sn, P, S, and Si, and they should be removed, so far as possible, before the chemical or metallurgical treatment. In the sodium carbonate fusion method, arsenic, phosphorus, and silica are highly objectionable, owing to the formation of soluble tungstates; freedom from tin, copper, and bismuth is not so important as it is in the thermit process, when these metals, if present, appear in large proportion in the ferro-alloy. In the electric furnace method of reduction these metals are objectionable, but are to some extent volatilised in the process. Wolfram is preferred to scheelite by the users of the soda fusion method, but a mixture of the two minerals is an advantage in the thermit and electric furnace treatment. Some users object to hübnerite, or wolfram containing an excess of manganese over iron, but no discrimination is made in the market; wolfram, ferberite, hübnerite, and scheelite, all fetching the same price per unit of WO_3 .

The treatment of tungsten ores for the manufacture of metallic tungsten ('tungsten powder' or of its oxides or salts) comprises a series of operations which, although chemically and metallurgically simple, require extreme care and experience, and result in heavy losses even under the best conditions. The first step is the production of sodium tungstate by the 'Oxland process', patented in 1847 and still used with practically no modification. It consists in heating, in a reverberatory furnace, the finely powdered ore with from 5 to 10 p.c. more than the theoretical amount of sodium carbonate (sometimes with the addition of about 5 p.c. sodium nitrate). The charge is maintained at a bright red heat for from two to three hours and rabbled occasionally by hand. The mass is not allowed to fuse beyond a pasty condition, in which state it is withdrawn when the reaction is completed. Sodium sulphate in place of the carbonate was proposed by Oxland, but its necessities a higher temperature and results in irregularity in the furnace and in the nature of the product, and has met with no general application. The fritted charge or 'melt' is broken up when cold, reduced to powder and dissolved by means of live steam in a boiler provided with stirrers. The tungstate solution and residual mud (consisting mainly of oxides of iron and manganese) is pumped through a filter press and the liquor concentrated to the required strength. For the preparation of pure tungstate the solution is crystallised and re-crystallised in vats.

For the manufacture of tungstic acid, the second step in the production of metallic tung-

sten, the hot concentrated solution of sodium tungstate is run direct from the evaporator into boiling hydrochloric acid (strongest commercial HCl, sp.gr. about 37°Tw.), the granular, yellow tungstic acid being washed by decantation, pressed and calcined. The strength of the solution of both tungstate and acid and the method of admixture and washing, require the most careful supervision. Under the best conditions, both temporary and permanent, losses are heavy, partly from the production of a soluble acid tungstate and partly from the formation of colloidal tungstic acid. The production of both is minimised by the use of pure ores, by precipitation with a large excess of acid at the highest possible temperature, and by washing rapidly with dilute acid. Any arseno- or phospho-tungstates which may have been formed are not decomposed by HCl, and silico-tungstates also result in loss of WO_3 , by remaining partly in solution or, if decomposed, hinder settlement and introduce SiO_2 into the precipitated WO_3 . In order to recover any tungstate or tungstic acid in solution, it is usual to treat all filtrates and wash waters with lime, the precipitated calcium tungstate being either mixed with a fresh furnace charge or put aside for special treatment.

The third and final step in the manufacture of tungsten consists in the reduction of the calcined tungstic acid with carbon, which is usually carried out in crucibles, either in coke wind furnaces or regenerative gas furnaces of the Siemens type. The calcined tungstic acid is finely ground and intimately mixed with the purest anthracite, in the proportion of slightly less carbon than is theoretically required for the reduction of the metal with production of carbon monoxide. The temperature is raised slowly until it reaches about 1100°C. at which it is maintained for some hours, when the crucible is cooled in a reducing atmosphere. The partly sintered mass is removed from the crucible, finely ground in a ball mill, washed free from undecomposed oxide, free carbon and particles of crucible, heated with a weak solution of sodium carbonate to remove remaining traces of oxide, and finally dried as a fine-grained but distinctly granular powder. Proposals have been made from time to time to carry out the reduction by means of producer gas, while hydrogen is always used when the pure carbon-free metal is required.

Metallic tungsten may also be prepared by the direct reduction of sodium tungstate with carbon at a heat sufficient to volatilise the sodium which is simultaneously produced, or by similarly reducing calcium tungstate and dissolving out the lime which remains with the resultant powdered metal, or by reducing tungstic acid with metallic zinc. The metal obtained thus and by many other apparently simple processes is, however, always impure, and the only commercial methods known consist in the reduction of tungstic acid by the processes already referred to.

The melting-points of tungsten-molybdenum alloys lie on a straight line connecting the melting-points of the elements, and the microstructures are all homogeneous. The two form a continuous series of mixed crystals. The electrical conductivity temperature coefficients

TUNGSTEN.

confirm this; this coefficient may be used to determine small proportions of molybdenum in tungsten (W. Geiss and J. A. M. van Liempt, *Zeitsch. anorg. Chem.* 1923, 128, 355-360; *J. Soc. Chem. Ind.* 1923, 42, 1227 A).

The accepted standard specification for tungsten powder in England is as follows:—

	p.c.
Tungsten	96-99
Carbon	0.6
Silicon	0.3
Manganese	0.3
Sulphur	0.06
Phosphorus	0.02
Arsenic	Trace
Tin	0.05
Copper	Trace
Calcium	0.1

	1 P.c.	2 P.c.	3 P.c.	4 P.c.	5 P.c.	6 P.c.	7 P.c.
Tungsten	83.36	84.82	80.74	85.72	81.79	98.51	96.45
Carbon	0.54	0.027	0.04	0.75	0.53	0.109	0.129

Nos. 1, 2, and 3. Ferro-tungsten produced by the aluminium or 'thermit' process. Balance, metallic iron.

Nos. 4 and 5. Ferro-tungsten produced by the electric furnace.

Nos. 5 and 6. Tungsten powder produced by reduction of WO_3 by carbon. Iron is usually about 0.5 or 0.6 p.c. (For analytical methods, see Arnold, *Zeitsch. anorg. Chem.* 1914, 88, 748, and R. Fieber, *Chem. Zeit.* 1912, 36, 334.)

Ferro-tungsten is an alloy usually containing from 80 to 85 p.c. W. It is made on a large scale by the 'thermit' process (*q.v.*) and in the electric furnace. By the former method two qualities are made by at least one English firm, viz. one very low in carbon and containing about 2 p.c. silicon, for the manufacture of magnet and other steel, and the other containing about 0.5 p.c. carbon and about 1 p.c. silicon for high-speed tool steels. In the electric furnace the ore is commonly smelted with carbon as a reducing agent, and the resulting alloy decarburised and refined. It is stated that one American firm smelts scheelite with iron sulphide and carbon in the electric furnace producing an alloy low in carbon.

The loss of tungsten is high in all methods of reduction. It is estimated that yields of 91½, 87, and 88½ p.c. respectively are obtained in the thermit, electric furnace, and soda fusion processes, but these figures vary considerably in different works and are probably not on the low side. In the case of ferro-tungsten, losses in the slags may be partly recovered by re-treatment. In the electric furnace there is also loss by volatilisation.

With the exception of a very small amount (probably under 1 p.c.), the whole of the world's output of tungsten is used in the manufacture of alloy steels; chiefly in those known as 'high-

and for ferro-tungsten:—

Tungsten	75-80
Carbon	1.0
Manganese	1.5
Silicon	1.5
Calcium	0.5

In the event of manganese and silicon not exceeding 1 p.c. each, calcium may be 1 p.c.

Copper	0.35
Tin	0.35
Sulphur	0.07
Arsenic	0.06
Phosphorus	0.06

The following table shows the composition of a number of typical varieties of tungsten powder and ferro-tungsten as made in England at the present time (iron omitted):—

speed' tool steels. The original 'self hardening' steel of Mushet, first made in 1857, contained about 6 p.c. W. The modern high-speed steels contain between 16 and 20 p.c. W. and from 2 to 4 p.c. Cr., and have the property of red-hardness, i.e. ability to retain their temper at the dull red heat which is reached when cutting metal at a high speed. Arnold and Read (*Proc. Inst. Mech. Engs.* March, 1914) attributed this property to the presence of tungsten carbide. They showed that with about 11½ p.c. W present in the steels they examined the whole was present as WC displacing Fe_3C . With less tungsten the two carbides Fe_3C and WC were present, and with more tungsten the excess was present as a tungstide (Fe_2W). Tungsten may be introduced into steel in the form of metallic powder or ferro-tungsten alloy. The prejudice against ferro-tungsten, which formerly existed among high-speed steel makers, due in some measure to the impurities present (high carbon, &c.) and irregularity of the tungsten content, appears to be largely disappearing under the influence of the excellent products which are now being manufactured in this country, and the scarcity of the powder in the early days of the war certainly helped the manufacturer of the ferro-alloy. Tungsten powder is preferred by a number of the English steel makers, and to-day probably the use is equally divided between the two. There is considerable loss by oxidation in the case of both, but users of the ferro-tungsten claim there is less danger of loss than with tungsten powder, and that it is cheaper. For particulars concerning alloys and the effect of tungsten upon the hardening and tempering of high-speed tool steel, see R. A. Hadfield, *Iron & Steel Inst.* 1903, 64, 14; Edwards & Kikkawa, *ibid.* Sept. 1915; and C. A. Edwards, *The Physico-Chemical Properties of Steel*, 1916,

Pure metallic tungsten, such as is used for the production of ductile tungsten, &c., is produced on a relatively small scale but has some highly important uses. A very high degree of purity is required, and the usual method of manufacture is by reduction with hydrogen, in electric resistance furnaces, of tungstic acid, purified by solution in ammonia, crystallisation of the ammonium tungstate, and re-precipitation by hydrochloric acid. The reduction is carried out at a temperature between 1000° and 1100°C. The metal powder is pressed in a hydraulic press into the form of rods, which are then sintered at a temperature of 1300°C in a current of hydrogen. The metal bar, which is still extremely brittle, is worked by hammering and rolling at a temperature of 1500°C. in a special machine through which hydrogen is flowing. Owing to the ease with which tungsten oxidises at a high temperature, cooling must take place in hydrogen. In the case of wire, the bar is worked down to about 30 mils ($\frac{3}{16}$ in.), when it becomes ductile at the ordinary temperature. The finer sizes are drawn while red hot through diamond dies. For a description of the methods for preparing ductile tungsten and filaments, see R. E. Myers, *Trans. Amer. Inst. Chem. Eng.* 1911, 3, 172; R. W. Moore, *Mot. & Chem. Eng.* 1914, 3, 186; also *Electrical Rev.* 1914, 74, 595.

Tungsten as ordinarily obtained is a powdered or semi-fused, crystalline, brittle metal, harder than glass, and having a sp.gr. of between 16.5 and 17. That obtained by Moissan in the electric furnace had a sp.gr. of 18.7 and was softer than glass. A method for causing small crystals of tungsten to grow into large single crystals by taking advantage of the thermal dissociation of tungsten hexachloride is described by van Arkel (*Physica*, 1923, 3, 76; *J. Soc. Chem. Ind.* 1924, 43, B. 427). The properties of pure wrought tungsten are entirely different from those of the powdered or ordinary cast metal. It is grey-white, lustrous, tough, and non-magnetic, and can be rolled into thin sheet, welded at a yellow heat, and drawn into wire considerably thinner than one-thousandth of an inch. It melts at $3100^{\circ} \pm 60^{\circ}$. Pifani and Meyer (*Ber. Deut. Phys. Ges.* 1912, 14, 326), $3540 \pm 30^{\circ}$. Langmuir (*J. Franklin Inst.*, 1915, 490), 3645° – 3665° , Worthing (*Zeitsch. Physik.* 1924, 22, 9; *Chem. Soc. Abstr.* 1924, 126, ii, 289). Its tensile strength increases as the drawing proceeds. Wire of 5 mils diameter has a tensile strength of 460,000 lb. per sq. in., that of 1.2 mils rises to 580,000; hard drawn piano wire having a tensile strength of 507,000 lb. The sp.gr. of the pure wrought metal is from 19 up to about 19.5 in the finest wire. Tungsten has the lowest coefficient of expansion of any known element except the diamond within the range of ordinary temperatures (Worthing, *Phys. Rev.* 1917, 638). The hard drawn wire has an electric resistance of 6.2 microhms per cubic centimetre at 25°, the temperature coefficient for 0° to 170° being 0.0051. The corresponding figure for annealed wire is 5.0. The spectrum of tungsten has been investigated, among others, by W. S. Gorton (*Phys. Rev.* 1916, 7, 203); Bayen (*Compt. rend.* 1924, 180, 57); Bloch (*ibid.* 133); and Lemon (*Nature*, 1925, 215, 802). The radiation of

heat and light from tungsten at high temperatures has been studied by Zwicker (*Proc. K. Akad. Wetensch. Amsterdam*, 1925, 28, 409; *Chem. Soc. Abstr.* 1925, 128, ii, 1041; see also Worthing, *Zeitsch. Physik.* 1924, 22, 9; *Sci. Abstr.* 1924, 27, 528).

Emission of positive ions from hot tungsten.—Tungsten at temperatures approaching the melting-point emits positively charged ions. The positive ions are not due to the presence of residual traces of gas; they only appear at temperatures above 2500°, and they are very heavy or very slow-moving particles, little affected by a magnetic field of 400 gauss, and probably consist of charged atoms or molecules of tungsten. The positive emission is much smaller than the electron emission at the same temperature and, like the electron emission, increases rapidly as the temperature is raised. At the highest temperatures the positive emission decreases rapidly with time. A tungsten spiral which has been made to give a large electron emission gives a larger initial positive emission when the potential tube is reversed (W. A. Jenkins, *Phil. Mag.* 1924 [vi], 47, 1025–1047; *Chem. Soc. Abstr.* 1924, ii, 443).

Tungsten is unaffected by water or air at ordinary temperatures, but when heated in air above 300°C. it oxidises rapidly and burns at a bright red heat. Molten sulphur or phosphorus attacks it slowly, while at a red heat their vapours rapidly convert it into the sulphide or phosphide. It is attacked by fluorine at ordinary temperatures with incandescence, and by chlorine at 250° to 300°C. It dissolves very little hydrogen and shows no tendency to react with nitrogen at temperatures up to 1500° (Sieverts and Bergner, *Ber.* 1911, 44, 2394). Tungsten is readily attacked by fused oxidising salts, such as alkaline nitrates and peroxides. Fused bi-sulphates and alkalis or alkaline carbonate also attack it, but their solutions have no action. It is readily oxidised when heated with oxidising agents such as lead peroxide, potassium chlorate, &c. At ordinary temperatures it is unaffected by bromine, iodine, and sulphuretted hydrogen. Sodium hypochlorite has a considerable solvent action on the fine powder, which is also soluble in an ammoniacal solution of hydrogen peroxide. Strong or weak hydrochloric acid has no action upon it at ordinary temperatures, but the strong acid slowly attacks it at the boiling-point and produces a coating of black sub-oxide. Boiling dilute sulphuric acid has no action, but the hot strong acid attacks it slowly. Concentrated nitric acid has but little action, but the dilute acid produces a yellow coating of tungstic acid which, as is also the case with *aqua regia*, appears practically to prevent further action. Hydrofluoric acid does not affect the metal even when hot, but dissolves it readily when mixed with nitric acid.

Tungsten combines directly with silicon and boron at or near the melting-point. It has been alloyed with many metals such as aluminium, copper, manganese, and nickel, but the alloys are not yet in extensive use. It enters into the composition of 'steelite,' the new cobalt-chromium alloy used in cutting steel. Irman (*Metall. und Erz.* 1915, 12, 358) investigated nickel-tungsten alloys and found

that with 18 p.c. W the alloy was very ductile and very resistant to dilute sulphuric acid. An alloy of tungsten with 1 p.c. thorium and 0.2 p.c. platinum is said to produce a tough, ductile alloy (U.S. Pat. 1167827, 1916). Schirmeister (Stahl und Eisen, 1915, 996) finds tungsten increases the tensile strength of aluminium, and that the hardness of the hot-rolled alloys increases at first but becomes constant at 1 p.c., the ductility falling slowly. For properties of tungsten at high temperatures, see Langmuir, Phys. Rev. 1916, 7, 302.

As a winder for electric furnaces tungsten wire is cheaper and said to be superior to platinum. Owing to its high melting-point, heat conductivity and hardness, tungsten appears to be eminently suitable for electrical contact devices, and is superior to platinum as a material for the targets in Röntgen (X-ray) tubes. Owing to its high melting-point (over 3000° as compared with 1755° for platinum) it can be placed directly at the focus of the cathode rays, and radiographs of sharper definitions can be obtained with much shorter exposure than with platinum (Coolidge, J. Ind. Eng. Chem. 1912, 4, 2). Tungsten has been suggested as a catalyst for the production of ammonia from atmospheric nitrogen (Eng. Pat. 1161, Jan. 15, 1912, and U.S. Pat. 1916, 175693), and has also been used for valves of aeroplane engines and ultra-violet ray electrodes, and valves for wireless telegraphy. There is reason to think that a considerable future use for this metal lies in the manufacture of laboratory and other utensils, as, although not so resistant to certain reagents as platinum or tantalum, there are many purposes for which its special resistance to such reagents, coupled with its greater cheapness, will render it of special value.

It is now generally recognised that tungsten is one of the most important metals other than those commonly spoken of as commercial metals. The saving which has been introduced by its employment in the manufacture of high-speed steel and in the form of fine-drawn wire in the electric light industry shows very remarkable figures. A recent bulletin issued by the United States Geological Survey (F. L. Hess, Bull. 652), states that one man and one lathe can do as much work with high-speed tungsten steels as five men and five lathes could formerly do with simple carbon steels, and that hundreds of millions of dollars' worth of labour is saved annually by this means. The 'Mineral Resources,' 1910, estimated that, assuming the present lamp consumption to require 80 million 25-watt tungsten lamps per annum, the saving in current effected by employing tungsten lamps in place of the old carbon lamps would result in an annual saving of between £40,000,000 and £50,000,000. Since that time lamps filled with nitrogen have been placed on the market, and other improvements have been added which have made the incandescent electric lamp more efficient and the saving very largely increased. It is stated that in 1916 about 200,000,000 lamps were manufactured in the United States alone. For a description of the manufacture of filament lamps, see Coolidge, U.S. Pat. 6028933, 1913; also Elec. Rev. 1914, 74, 595, and J. Soc. Chem. Ind. 1914, 1083.

G. T. H.

COMPOUNDS OF TUNGSTEN.

Oxides.—Tungsten is said to form a number of oxides the separate existence of which is not definitely settled. Thus, when sulphuric acid acts on metallic tungsten under varying conditions, the blue oxides, WO , W_2O_3 , W_4O_9 , W_5O_{11} , are formed; sulphurous acid acts on tungsten forming the oxide W_2O_4 , and a beautiful purple oxide with a yellow metallic lustre, W_2O_5 , is obtained by heating ammonium metatungstate to a bright red heat or by fusing tungstic acid with potassium iodide (Desi, J. Amer. Chem. Soc. 1897, 19, 213). On heating tungstic oxide with carbon a blue or purple oxide is produced at 650° to 850°, a chocolate-brown mixture of oxides at 900° to 1050°, and metallic tungsten above 1050° (Davis, J. Ind. Eng. Chem. 1919 11, 201).

The hydroxide $W_5O_{11} \cdot H_2O$, a dark blue powder with a purple lustre, is formed when tungstic acid is reduced with stannous chloride and hydrochloric acid, or by heating the acid with hydrogen iodide in a sealed tube at 200°. With ammonia it yields ammonium tungtate and the hydroxide $W_2O_3 \cdot H_2O$ (Allen and Gottschalk, Amer. Chem. J. 1902, 27, 323).

The only oxides which are definitely known are WO_2 , W_2O_3 , WO_3 .

Tungsten dioxide WO_2 may be prepared by the reduction of the trioxide or an alkaline metatungstate with zinc and hydrochloric acid (Pfordten, Ber. 1883, 16, 508) or by heating the trioxide to a dull redness in hydrogen (Riche, Ann. Chim. 1857, [iii.] 50, 29; Greenwood, Chem. Soc. Trans. 1908, 1493). It may be obtained crystalline by reducing lithium paratungstate with hydrogen (Hallopeau, Compt. rend. 1898, 127, 512).

Tungsten dioxide may be formed by heating an intimate mixture of tungsten trioxide and $\frac{1}{10}$ its weight of glycerol, ethylene glycol or similar hydroxyl compound, to a bright red heat for some hours (Eng. Pat. 18922, 1907; J. Soc. Chem. Ind. 1908, 22; see also Van Liempt, Zeitsch. anorg. Chem. 1923, 126, 133).

Tungsten dioxide, prepared in the wet way is of a copper red colour, prepared in the dry way it is a brown powder. It is readily oxidised to the trioxide; heated in chlorine it yields a yellow oxychloride WO_2Cl_2 . When amorphous it is soluble in hydrochloric and in sulphuric acid, but is quite unacted on when crystalline.

Blue tungstic oxide W_2O_5 , formed when tungsten trioxide is reduced with hydrogen at 250°–300° (Malaguti, Compt. rend. 1835, 1, 292) or by electrolysis fused sodium tungstate (Smith, Ber. 1880, 13, 753), is readily oxidised to the trioxide.

Tungsten trioxide (tungstic oxide or anhydride) WO_3 occurs naturally as wolframite and as tungstite or meymacite (Walker, Amer. J. Sci. 1908, [iv.] 25, 305), also in the form of tungstates in wolfram and scheelite. It may be prepared by calcining in contact with air, the lower oxides, the metal, a sulphide or its hydrate (tungstic acid), v. below.

Tungsten trioxide forms large bright yellow needles which may be obtained by heating the amorphous metal to a very high temperature in air or by fusion of tungstic acid with borax in a porcelain vessel (Nordenfjeld, Pogg. Ann.

1861, 114, 612); or by passing hydrogen chloride over tungstic acid or a mixture of sodium tungstate and sodium carbonate at a white heat (Debray, *Compt. rend.* 1862, 55, 287). The green or blue colour which it occasionally exhibits is probably due to reduction at ordinary temperatures by traces of organic matter. The yellow colour may be restored by heating in oxygen. Its sp.gr., when amorphous, varies between 5.27–7.13, when crystalline between 6.30–6.38. It melts at 1473° and is insoluble in water. According to Matignon, tungstic oxide does not melt at 2130° (*Compt. rend.* 1923, 177, 1290; *Chem. Soc. Abstr.* 1924, 126, ii. 48). When heated in hydrogen it gives the blue oxide at 250°, the dioxide at a red heat, and the metal if the latter action is prolonged. It is also reduced when heated with zinc and certain other metals (Delépine, *Bull. Soc. chim.* 1900, [iii.] 23, 675). When heated with chlorine or sulphur monochloride, it is converted into a volatile oxychloride and in the former case also into the hexachloride (Smith and Fleck, *J. Amer. Chem. Soc.* 1899, 21, 1008; Bourion, *Compt. rend.* 1908, 146, 1102; Defacqz, *ibid.* 1319).

The oxide is soluble in hydrofluoric acid, but not in hydrochloric or nitric acids or in *aqua regia*. See also Ehrenfeld, *J. Amer. Chem. Soc.* 1895, 17, 381.

Plastic masses of tungsten oxide for incandescent lamp filaments may be prepared by treating the oxide or hydrated tungstic acid with ammonia at -20° or below, or when in alcoholic suspension with gaseous ammonia (*Eng. Pat.* 14850; *J. Soc. Chem. Ind.* 1908, 1198, 1104). According to J. A. M. van Liempt (*Zeitsch. anorg. Chem.* 1923, 127, 215–220), temperature has little effect on the precipitation of tungsten trioxide by mineral acid, but concentration of the acid has considerable influence. The oxide is precipitated as a mixture of the white and yellow forms, together with an absorption compound with water, and in order to obtain the precipitate in an easily manipulated form, it is advisable to use hydrochloric or nitric acid in high concentration and in excess (*J. Chem. Soc. Ind.* 1923, 42, 1174 A).

Tungstic acids.—Tungsten trioxide forms two well characterised acids, $\text{WO}_3 \cdot \text{H}_2\text{O}$ or H_2WO_4 and $(\text{WO}_3)_2 \cdot \text{H}_2\text{O}$ or $\text{H}_2\text{W}_2\text{O}_{13}$. In addition the salts of a number of polytungstic acids are known (Schaefer, *Zeitsch. anorg. Chem.* 1903, 38, 142).

For the hydrosols of tungstic acid, see Lottermoser (*Verh. Ges. deut. Naturforsch. Aerzte*, 1910, ii. 70); Müller (*Zeitsch. Chem. Ind. Kolloide*, 1911, 8, 93). For the hydrates of tungsten trioxide, see Hüttig and Kurre (*Zeitsch. anorg. Chem.* 1922, 122, 44).

Tungstic acid H_2WO_4 may be obtained by precipitating a solution of a tungstate with excess of hot acid. If cold acid is used, the white hydrate $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$ is formed, from which the acid may be obtained by boiling. The comparative rates of precipitation of tungstic acid from sodium tungstate by different acids has been investigated by van Liempt (*Rec. trav. chim.* 1924, 43, 30; *Chem. Soc. Abstr.* 1924, 126, ii. 194). It is prepared by digesting a tungsten mineral with hydrochloric acid, then with *aqua regia* until the brown powder has

become yellow, when the iron and manganese have been dissolved out. The residue is well washed and then shaken with ammonia which dissolves the free tungstic acid. On filtration and evaporation the tungstic acid crystallises out. The finely powdered mineral may be fused with calcium chloride or with alkali carbonates or sodium chloride. The mass is lixiviated and the calcium or other metallic tungstate residue is then decomposed with nitric or hydrochloric acid.

Tungstic acid may be prepared from wolfram or other mineral containing tungsten, by heating the mineral under pressure with a concentrated solution of potassium hydroxide, lime or baryta being added to form insoluble compounds with some of the impurities.

The tungstic acid is then separated from the solution either by fractional precipitation with acid, the impurities separating first, or the whole of the precipitate formed by adding sufficient acid is fractionally redissolved by alkali. The process is said to be economical, convenient, and to give very pure acid (*Fr. Pat.* 359040, 1908; *J. Soc. Chem. Ind.* 1908, 939).

A continuous process for the manufacture of sodium tungstate and tungstic acid from wolframite ore by fusion with soda-ash and sodium nitrate is described by Gordon and Spring (*J. Ind. Eng. Chem.* 1924, 16, 555; *J. Soc. Chem. Ind.* 1924, 43, B. 631).

Tungstic acid may be purified by treating tungsten trioxide with carbon tetrachloride vapour at a red heat. The resulting volatile chlorine compound is sublimed, condensed and treated with *aqua regia*; the tungstic acid formed is then further purified by solution in ammonia and reprecipitation with dilute nitric acid (*U.S. Pat.* 926084; *J. Soc. Chem. Ind.* 1909, 794).

Tungstic acid is a yellow powder insoluble in water and almost so in all acids except hydrofluoric acid, in which it dissolves to the extent of 44.7 p.c. at 25° , 55.3 at 50° , using 50 p.c. hydrofluoric acid (Rosenheim and Bernhardt-Grisson, 7th Inter. Congr. Appl. Chem., 1909, Sect. x. 120). It is readily soluble in alkalis.

A colourless alcoholic hydrochloric acid solution of tungstic acid when electrolysed by a graphite anode, first becomes deep blue (containing sexa- and quinquevalent tungsten), then green (containing only quinquevalent tungsten), which on further reduction changes to olive green (mixture of quinque- and quadrivalent), then to brown (quadrivalent). When polished platinum is used as cathodes only green solutions are produced; with mercury cathodes of 0.025 amp. per sq. cm. of cathode surface, quinquevalent tungsten is formed, whilst with 0.07 amp. and over, trivalent tungsten was produced. With lead cathodes the results were similar to those with mercury, except that the tervalent tungsten formed violet-red solutions. Zinc cathodes also give rise readily to the tervalent form (see also Collenberg and Racker, *Zeitsch. Elektrochem.* 30, 230; *Sci. Abstr.* 1924, 27, 775).

Freshly prepared tungstic acid dissolves in aqueous solutions of most aliphatic amines forming substituted ammonium tungstates such as $(\text{NMeH}_2)_2\text{W}_2\text{O}_{13} \cdot 6\text{H}_2\text{O}$, which crystallise on evaporation. When heated they are de-

composed forming the amine, tungstic acid and the blue oxide of tungsten (Ekeley, J. Amer. Chem. Soc. 1909, 31, 664). It also gives crystalline precipitates with pyridine and quinoline (Rosenheim and Bernhardt-Grissom, *l.c.*).

Colloidal tungstic acid may be prepared by adding hydrochloric acid to concentrated sodium tungstate solution until it has an acid reaction. The white gelatinous precipitate formed, protected from currents of air, is washed by decantation several times at 0° to 5°: 15 parts of the acid are then dissolved in 1 part of concentrated oxalic acid by gently warming, and the liquid is subjected to dialysis. If the outer water is changed frequently, the oxalic acid may be completely removed (Pappadà, Gazz. chim. ital. 1902, 32, ii. 22; see Sabanéeff, Zeitsch. anorg. Chem. 1897, 14, 354).

Colloidal tungstic acid may be obtained by dissolving 5 grms. of tungsten tetrachloride in about 50 c.c. of a mixture containing equal volumes of ethyl alcohol and ether; the filtered solution is diluted to 250 c.c. with alcohol and then mixed with an equal volume of water. The colloidal solution thus obtained behaves as a positive colloid; it may be kept for some days without appreciable opalescence being observed, but coagulation occurs more quickly by adding a larger quantity of water, and immediately when small quantities of neutral salts, hydroxides, or strong acids are added. Weak organic acids or rise in temperature exert no effect. If an electric current is passed through, a deep blue precipitate separates at the cathode (Müller, Zeitsch. Chem. Ind. Kolloide, 1911, 8, 93; Lottermoser, Verh. Ges. deut. Naturforsch. Aertze, 1910, 11, 70; Wöhler and Engels, Koll. Chem. Beihefte, 1910, 1, 454; Zeitsch. Elektrochem. 1910, 16, 693).

The colloidal acid is also prepared by dialysing a 5 p.c. solution of sodium tungstate to which sufficient hydrochloric acid has been added to combine with the sodium. Colloidal tungstic acid forms a gum-like mass which may be heated at 200° without becoming insoluble and which at a red heat is converted into the trioxide. The colloidal acid has, probably, the constitution of the *meta* acid.

Tungstic acid and sodium tungstate are used in the production of colour resists for aniline black. 200 grms. sodium tungstate dissolved in 1 litre of gum tragacanth paste constitutes a white resist which may be rendered more lustrous and opaque by passing the printed tissue, after steaming, through a solution of barium chloride. The compound thus formed may be coloured by pigments, such as vermilion, ultramarine blue and chrome green, a series of pale resist colours being formed, along with which the usual albumin and tannic acid colour mixtures may be printed (Scheurer, Bull. Soc. Ind. Mulhouse, 1900, 138; *ibid.* 1898, 122).

Tungstic acid may also be employed in the production of resist effects upon *p*-nitraniline red and of discharge effects upon indigo-dyed tissues. In the latter case, the tissue dyed with the indigo is padded in a solution of sodium tungstate, dried and printed with a steam discharge mixture containing barium chlorate, potassium ferrocyanide and a basic dyestuff able to withstand the oxidising action, such as methamine 6 G, ultramarine, or chrome yellow.

The colours are rendered faster by the addition of albumin together with an alkali citrate or tartrate.

Metatungstic acid $H_2W_6O_{13} \cdot 7H_2O$, first isolated by Scheibler (J. pr. Chem. 1861, [i.] 83, 310), may be prepared by decomposing the lead salt with hydrogen sulphide or the barium salt with dilute sulphuric acid. It crystallises in small yellow octahedra, very soluble in water, giving a bitter solution, and loses its water of crystallisation at 100°. (*Cf.* Rosenheim and Kohn, Zeitsch. anorg. Chem. 1911, 69, 247; *ibid.* 1916, 96, 139). For its photochemical properties, see Vasilieva (J. Russ. Phys. Chem. Soc. 1912, 44, 819). For its behaviour on electrolysis, see Leiser (Zeitsch. Elektrochem. 1907, 13, 690).

Paratungstic acid, the acid corresponding to the salts of the formula $12WO_3 \cdot 5M_2O \cdot Aq$, has been prepared in dilute solution by mixing barium paratungstate with a quantity of dilute sulphuric acid not quite sufficient for complete decomposition. The solution cannot be concentrated even *in vacuo* without decomposition, and when boiled it yields tungstic acid (Hallopeau, Compt. rend. 1895, 121, 61).

Tungstates.—Tungstic acid forms three series of salts: normal tungstates $R_2WO_4 \cdot xH_2O$; paratungstates $3R_2O \cdot 7WO_3 \cdot xH_2O$, or $5R_2O \cdot 12WO_3 \cdot xH_2O$

and metatungstates $R_2O \cdot 4WO_3 \cdot xH_2O$. Copaux (Compt. rend. 1913, 156, 1771) regards the paratungstates as hydrotungstates and represents them by $M_3[H(W_2O_7)_3]$. They may also be considered as compounds of 1 mol. of the tritungstate with 4 mols. of the hydrogen tungstate. Their derivation from normal tungstates may be expressed thus:

and

If, from analogy to the vanadates and molybdates, the action of hydrogen ions proceeds still further, hexatungstates should result, thus:

and the so-called metatungstates are in reality the hexatungstates (Prandtl, Ber. 1915, 48, 692). The alkaline tungstates $M_2WO_4 \cdot Aq$ are prepared by fusing a naturally occurring tungstate with sodium or potassium hydroxide or carbonate, preferably with the addition of a silicious or other flux. The alkali tungstate falls to the bottom and may be tapped off, or, after cooling, the slag may be removed (J. Soc. Chem. Ind. 1885, 116; *ibid.* 1900, 542; *ibid.* 1899, 171; Eng. Pats. 30053, 1897; 6045, 1900).

The *sodium salt* crystallises in thin prisms, soluble in 4 parts of cold, in 2 parts of hot water, the solution having a bitter taste and an alkaline reaction. It has m.p. 698° (Parravano, Gazz. chim. ital. 1909, 39, ii. 55).

The *potassium salt* forms large prismatic crystals, m.p. 894°. The ammonium salt is very unstable.

Calcium tungstate $CaWO_4$ occurs native as *scheelite* and may be prepared artificially by the interaction of calcium chloride and a normal tungstate. If the amorphous white precipitate so obtained is mixed with lime and heated in a current of hydrogen chloride, it is obtained

crystalline. The corresponding *barium tungstate* was prepared by Rousseau for use instead of white lead (Schoen, J. Soc. Chem. Ind. 1900, 740).

The so-called di- and tri-tungstates of sodium, barium, and calcium do not appear to exist.

Lead tungstate occurs native as *stolzite* and crystallises in red tetragonal pyramids.

Ferrous tungstate occurs as *wolfram*

forming dark grey or brownish-black prisms.

Manganese tungstate is found as *hübnerite*. Granger (Compt. rend. 1898, 127, 106; *ibid.* 1905, 140, 935) has proposed the employment of the tungstates in the ceramic industry.

Ammonio copper tungstate $\text{CuWO}_4 \cdot 4\text{NH}_3$, deep blue crystals, readily decomposed. A similar zinc salt is also known (Briggs, Chem. Soc. Trans. 1904, 675).

The copper compound

has been obtained by the interaction of an ammoniacal solution of copper sulphate and ammonium tungstate. It forms small blue needles (Briggs, *l.c.*).

Sodium paratungstate $\text{Na}_{10}\text{W}_{12}\text{O}_{41} \cdot \text{Aq}$ is known commercially as tungstate of soda and may be prepared on a large scale by roasting wolfram with soda ash and lixiviating the fused mass. The boiling solution is then nearly neutralised with hydrochloric acid and allowed to crystallise when large triclinic crystals of the salt separate. It is sometimes used as a mordant instead of sodium stannate in dyeing and calico printing. It also renders cotton, linen, &c., non-inflammable. The corresponding potassium salt is formed in glistening scales when normal potassium tungstate is boiled with a little water.

Sodium tungstate is much used both by itself and in conjunction with other fire-retarding compounds. In some experiments on its protective action recorded by Sibley (J. Ind. Eng. Chem., No. 8, 1921), impregnation of cotton fabrics with a 3 p.c. solution was found to be equally as efficacious as treatment with a more concentrated solution. For the protection of tulle, muslin, and other delicate fabrics impregnation with a solution containing 10 grms. tungstate, 125 grms. ammonium phosphate, and 7 grms. boric acid per litre has been proposed. This solution is added to the finishing medium (gum, starch, or dextrin) in the proportion 1 : 4. Ammonium chloride, ammonium sulphate, and aluminium acetate may also be combined with sodium tungstate. A medium particularly recommended for artificial silk can be prepared by diluting a mixture of the following solutions: 100 parts aluminium acetate (sp.gr. 1.13), 10 parts acetic acid (sp.gr. 1.06), and 200 parts sodium tungstate (sp.gr. 1.40). Water-resistance can be imparted by using an excess of the acetate (Eng. Pat. 175746 of 1920). According to Mond (Eng. Pat. 4457 of 1915) zirconium hydroxide may be applied to fabrics as a hydrogel, prepared by steeping in a solution of the aceto-nitrate containing magnesium sulphate, draining, heating to 65°C., and finally washing. One litre of the steeping medium

should contain 200 grms. magnesium sulphate and 20 grms. of the aceto-nitrate, prepared by evaporating zirconium nitrate with acetic acid. To enhance the fire-retarding effect, the treated fabric may be allowed to absorb phosphoric acid. Another method is to impregnate the material with a solution of precipitated zirconium phosphate in concentrated oxalic acid (Pharm. J. 1924, 691).

For various paratungstates, see Hallopeau, Ann. Chim. 1900, vii. 19, 19, 92; Taylor, J. Amer. Chem. Soc. 1902, 24, 629.

Metatungstates $\text{M}_2\text{W}_2\text{O}_{11} \cdot \text{Aq}$ were discovered by Marguerite (Ann. Chim. 1846, [iii.] 17, 475). The alkali salts are readily formed when the normal tungstates are boiled with tungstic acid until the filtrate no longer gives a precipitate on addition of hydrochloric acid. The other metatungstates are best prepared by double decomposition of the barium salt with the required sulphate or carbonate. The metatungstates have a bitter taste, are generally readily soluble in water and deposit tungstic acid on prolonged boiling. A large number of them are known but there is considerable difference of opinion as to their constitution (Copaux, Compt. rend. 1909, 148, 633; Zeitsch. anorg. Chem. 1911, 70, 297; Rosenheim, *ibid.* 418; *ibid.* 1911, 69, 247; 1912, 75, 141; Just, Ber. 1903, 36, 3619).

Pertungstates $\text{M}'\text{WO}_4 \cdot \text{Aq}$ are formed by boiling a paratungstate with hydrogen peroxide (Péchar, Compt. rend. 1891, 112, 1060); or by electrolysis of a slightly acid solution of sodium tungstate (Thomas, J. Amer. Chem. Soc. 1899, 21, 373). More highly oxidised compounds are formed by treating the pertungstates with hydrogen peroxide (Melikoff and Pissarjewsky, Ber. 1898, 31, 632; Pissarjewsky, J. Russ. Phys. Chem. Soc. 1902, 34, 472).

Tungsten bronzes are compounds of the alkali metals with tungsten and oxygen, which, owing to their colour and insolubility in acids and alkalis have been employed as substitutes for bronze powders. Their exact constitution is not known, although they are generally regarded as compounds of the tungstates with tungsten dioxide. They may be obtained by the reduction of the tungstates heated to redness with hydrogen, coal gas, zinc, iron or tin.

Tungsten bronzes may be prepared electrolytically by fusing tungstic acid with the calculated amount of metallic carbonate and electrolysis of the mass. A series of brightly coloured mixed alkali and alkaline earth tungsten bronzes of various compositions are described by Engels (Zeitsch. anorg. Chem. 1903, 37, 125) and Schäffer (*ibid.* 1904, 38, 148).

Four *tungsten sodium bronzes* are known. $\text{Na}_3\text{W}_2\text{O}_{11}$ of a golden yellow colour, $\text{Na}_2\text{W}_2\text{O}_{11}$ of a blue colour, $\text{Na}_3\text{W}_3\text{O}_{15}$ of a purple red colour, and $\text{Na}_4\text{W}_5\text{O}_{15}$ which forms red-yellow cubes and yields a brown-yellow powder (Philipp, Ber. 1882, 15, 499).

Potassium forms one bronze, $\text{K}_2\text{W}_2\text{O}_{11}$ (Knorre and Schäffer, *ibid.* 1902, 35, 3407).

Blue lithium bronzes are described by Hallopeau (Compt. rend. 1898, 127, 512).

Tungstates of the rare earths are described by Hitchcock (J. Amer. Chem. Soc. 1895, 17, 453).

TUNGSTEN AND THE HALOGENS.

Tungsten hexachloride WCl_6 is prepared by heating metallic tungsten in excess of pure dry chlorine, particular care being taken to exclude all traces of air and moisture in order to avoid the formation of the oxychloride (Roscoe, *Annalen*, 1872, 162, 349). A small quantity of the latter is formed at the beginning of the reaction, however, in spite of all precautions. It should be driven off beyond the portion of the tube where the chloride is to be collected. Tungsten hexachloride forms dark violet opaque crystals, which are very stable when pure but are readily decomposed by moist air or water, if the slightest trace of the oxychloride is present. It has m.p. 275° , b.p. $346.7^\circ/759.5$ mm.

On heating the hexachloride in a stream of nitrogen with powdered aluminium and quartz, extracting the product with hydrochloric acid, concentrating the reddish-yellow extract and saturating it with hydrogen chloride, it yields $HWCl_4 \cdot 4H_2O$ in slender yellow needles, which rapidly lose hydrogen chloride on exposure to air (Lindner, *Ber.* 1922, 55 [B], 1458).

The salt $K_2W_2Cl_8$ and a number of corresponding salts of tervalent tungsten form green solutions and are powerful reducing agents (Collenberg and Sandved, *Zeitsch. anorg. Chem.* 1923, 130, 1; *Chem. Soc. Abstr.* 1924, 126, ii, 51).

Tungsten pentachloride WCl_5 is formed by the incomplete reduction of the hexachloride in a current of hydrogen. It is volatile and when redistilled forms long, pure black shining crystals, m.p. 248° , b.p. 275.6° . It is hygroscopic and dissolves in water forming an olive-green solution, but most of it decomposes into the blue oxide and hydrochloric acid (Roscoe, *l.c.*).

Tungsten tetrachloride WCl_4 forms the non-volatile residue in the production of the pentachloride. It may also be prepared by the distillation of the latter or of the hexachloride, or better, a mixture of the two chlorides in a current of hydrogen. It forms a greyish-brown crystalline powder (Roscoe, *l.c.*). It is hygroscopic, infusible, is partially decomposed by water and is reduced by hydrogen to the metal.

Tungsten dichloride WCl_2 is best prepared by heating the tetrachloride in a current of carbon dioxide at the temperature of a moderately hot zinc bath. It is a grey non-volatile powder partly decomposed and partly dissolved by water forming a brown solution (Roscoe, *l.c.*).

Tungsten dioxydichloride WO_2Cl_2 , obtained by passing chlorine over the dioxide, forms light lemon-yellow scales. Heated with ammonia it forms the compound $W_2O_4N_2H_2$ (Smith and Shinn, *Zeitsch. anorg. Chem.* 1893, 4, 381).

Tungsten oxytetrachloride $WOCl_4$, beautiful red needle-shaped crystals, m.p. 210.4° , b.p. 227.5° , is formed by the interaction of the trioxide and phosphorus pentachloride (Schiff, *Annalen*, 1879, 197, 185); or by passing the vapour of the hexachloride over the heated trioxide.

Tungsten hexabromide WBr_6 , obtained by heating tungsten with dry bromine vapour in an atmosphere of nitrogen, forms blue-black needles which decompose when heated to a high temperature, give a colourless solution in aqueous ammonia, fume in air and give a royal

blue oxide when treated with water (Schaeffer and Smith, *J. Amer. Chem. Soc.* 1897, 18, 1098).

Tungsten pentabromide, prepared by passing dry hydrogen bromide over tungsten hexachloride at 300° , or better by the action of excess of bromine on tungsten, forms fern-like aggregates of dark needles with green reflex, m.p. 276° , b.p. 333° . It is very hygroscopic, yields the blue oxide when treated with water and dilute acids and is decomposed by alkalis, alkali nitrates, carbonates and bisulphates (Defacqz, *Ann. Chim.* 1901, [vii.] 22, 247).

Tungsten oxybromides WO_2Br_2 , $WOBBr_4$ and the compounds WCl_2Br_2 , $WCl_4 \cdot 3WBr_6$ are also known (Defacqz, *Compt. rend.* 1899, 129, 515).

Tungsten tetriodide WI_4 , obtained by the action of an excess of liquid hydrogen iodide on tungsten hexachloride at 110° , is a black crystalline substance of sp.gr. 5.2 at 18° , decomposed by water, alkali-hydroxides and carbonates. Soluble in absolute alcohol (Defacqz, *Compt. rend.* 1898, 127, 510).

Tungsten diiodide WI_2 , obtained by the action of hydrogen iodide on tungsten hexachloride at 400° , is an amorphous, insoluble, infusible, non-volatile brown powder of sp.gr. 6.9 at 18° (Defacqz, *ibid.* 1898, 126, 962).

Tungsten hexafluoride WF_6 may be obtained by the interaction of tungsten hexachloride with anhydrous hydrofluoric acid or with arsenic trifluoride, or, best of all, antimony pentafluoride. It has m.p. 2.5° and b.p. 19.5° . Is readily soluble in alkalis, attacks glass and most metals and forms double salts with alkali fluorides. When acted on by water it yields tungstic acid (Ruff, *Zeitsch. anorg. Chem.* 1907, 52, 256).

Tungsten oxytetrafluoride WOF_4 , obtained by the interaction of the oxytetrachloride and anhydrous hydrogen fluoride, forms small colourless hygroscopic plates, m.p. 110° , b.p. $185-190^\circ$, is decomposed by water forming tungstic acid and absorbs large quantities of ammonia in the cold (Ruff, *l.c.*).

Tungsten dioxydifluoride is known in an impure state. For various double fluorides, see Maignat (*Ann. Chim.* 1863, [iii.] 69, 63); Marchetti (*Zeitsch. anorg. Chem.* 1895, 10, 66); Miolati and Rossi (*Real. Accad. Lincei*, 1896, [v.] 5, ii, 223); Ephraim and Heymann (*Ber.* 1909, 42, 4456).

TUNGSTEN AND SULPHUR.

Tungsten disulphide WS_2 may be prepared by passing hydrogen sulphide over tungsten hexachloride at $375-550^\circ$, or by fusing an intimate mixture of pure dry potassium carbonate, flowers of sulphur and tungsten trioxide. It is a grey-black crystalline powder, insoluble in water, fairly stable, and has sp.gr. 7.5 (Defacqz, *Compt. rend.* 1899, 128, 609).

Tungsten trisulphide WS_3 , best obtained by treating a sulphotungstate with excess of sulphur, is a brown powder which becomes black when dried, is slightly soluble in cold water, more so in hot water, and readily in alkali hydroxides and carbonates (Corleis, *Annalen*, 1893, 232, 344). It has been obtained in the colloidal state by Winsinger (*Bull. Assoc. Sci. Belg.* 1893, 16, 390).

The compounds, $WCl_2 \cdot 3WS_2$ (*Ann. Chim.* 1901, [vii.] 22, 238) and $WO_2 \cdot S$ (Winsinger,

(*l.c.*) and a number of metallic sulpho- or thio-tungstates, M_2WS_4 (Coriols, *l.c.*), have been described. A *di-* and *tri-selenide* (Uelsmann, J. 1860, 92) and a *trithuride* are also known.

Tungsten nitrides W_2N_3 , W_3N_4 , a number of oxynitrides, nitretamido and oxynitretamido compounds, and also a hydroxylamine tungstate have been obtained (Wöhler, Annalen, 1850, 73, 190; *ibid.* 1858, 105, 258; Rideal, Chem. Soc. Trans. 1889, 41; Wöhler, *ibid.* 1851, 3, 171; Desi, *l.c.*; Allen and Gottschalk, *l.c.*).

Tungsten cyanides have also been prepared by Rosenheim and Dehn (Ber. 1914, 47, 392; Olsson, Ber. 1914, 47, 912).

TUNGSTEN AND PHOSPHORUS.

Tungsten combines directly with phosphorus when heated to redness, forming a dark green phosphide W_2P_4 .

Tungsten diphosphide WP_2 , produced by heating tungsten hexachloride at 450° in a current of hydrogen phosphide forms a black crystalline mass insoluble in water, sp.gr. 5.8. The phosphorus is readily displaced by the halogens and by sulphur and nitrogen at high temperatures. It may be reduced by heating with hydrogen, zinc or copper (Defacqz, Compt. rend. 1900, 130, 915).

If tungsten diphosphide is heated with a large excess of copper phosphide in a graphite crucible in a wind furnace and the product treated with dilute nitric acid, it yields the *monophosphide* WP , grey lustrous prismatic crystals, sp.gr. 8.5 (Defacqz, *ibid.* 1901, 132, 32).

Another phosphide W_2P is formed by reducing a mixture of phosphorus pentoxide (2 mols.) and tungsten trioxide (1 mol.) in a charcoal crucible at a high temperature (Wöhler, Chem. Soc. Trans. 1853, 5, 94).

Phosphotungstic acid.—Tungstic acid combines with phosphoric and also with arsenic, antimonie and vanadic acids to form complex compounds of varying composition, $M_2O_5 : WO_3 = 1:7$ to $1:24$ analogous to the molybdates. Phosphotungstic acid is used as a reagent for the precipitation of alkaloids, proteins and some of their products of hydrolysis, also for the detection of potassium and ammonium salts with which it gives insoluble precipitates. It may be prepared by acidifying a solution of 4 parts of sodium tungstate and 1 part of sodium phosphate with sulphuric acid and extracting the phosphotungstic acid with ether (Winterstein, Chem. Zeit. 1898, 22, 539).

Some new series of phosphotungstates are iber by F. Kehrman and R. Mellet (Helv. Acta, 1922, 5, 942), including the simple $3M_2O_3.P_2O_5.6WO_3.aq.$, of which the potassium, and ammonium salts have been prepared in the pure state.

Literature on phosphotungstic acids and the phosphotungstates: Kehrman, Zeitsch. anorg. Chem. 1891, 1, 428; Soboleff, *ibid.* 1896, 12, 16; Rogers, J. Amer. Chem. Soc. 1903, 25, 298.

Arsenotungstovanadates

$18(NH_4)_2O.As_2O_5.21WO_3.4V_2O_5.13H_2O$;

$6Ti_2O_3.As_2O_5.21WO_3.5V_2O_5.13aq.$; and

$6BaO.As_2O_5.17WO_3.5V_2O_5.4aq.$

are described as red crystals by Cannevi (Gazz.

chim. ital. 1923, 53, 773; Chem. Soc. Abstr. 1924, 126, ii. 117).

Tungsten arsenide WAs_3 , prepared by heating tungsten hexachloride in a current of hydrogen arsenide at 150° – 360° , is a black crystalline insoluble powder of sp.gr. 6.9 at 18° .

Tungsten chloroarsenide W_2AsCl_4 , obtained by heating the above substances in a sealed tube at 60° – 70° , forms hygroscopic bluish-black crystals, decomposed by water and acids (Defacqz, Compt. rend. 1901, 132, 138).

For *arseniotungstic acids and tungstates*, see Kehrman and Rüttimann (Zeitsch. anorg. Chem. 1899, 22, 285). *Vanadotungstates* Friedheim, *ibid.* 1894, 6, 11; Rogers, *l.c.*; Friedheim and Henderson, Ber. 1902, 35, 3242). *Antimoniotungstates* (Hallopeau, Compt. rend. 1896, 123, 1065). *Zirconotungstates* (*ibid.* 1896, 122, 1419). *Alumino- and alumino-phospho- and arseno-tungstates* (Daniels, J. Amer. Chem. Soc. 1908, 30, 1846).

Tungsten boride WB_2 , prepared by fusing the two elements together in an electric furnace, crystallises in hard octahedra, sp.gr. 9.6 (Tucker and Moody, Chem. Soc. Trans. 1902, 16).

TUNGSTEN AND CARBON.

When tungsten trioxide is fused with calcium carbide in an electric furnace, it forms an iron-grey carbide, CW_2 , which is harder than corundum and has sp.gr. 16.06 at 18° . In the presence of a large excess of iron, the carbide W , an iron-grey crystalline powder of sp.gr. 15.7 at 18° , is formed (Moissan, Compt. rend. 1897, 125, 839; Williams, *ibid.* 1898, 126, 1722).

Tungsten carbides are formed when the finely divided metal or its oxides are heated in carbon monoxide, or in a mixture of methane and hydrogen. At 1000° W_2C_4 is formed in carbon monoxide, and WC in a mixture of methane and hydrogen (1:1) at 80° (Hilpert and Ornstein, Ber. 1915, 46, 1669).

W_2C has been formed by heating tungsten in a carbon electric furnace; it melts above 2700° and solidifies as a homogeneous substance (Ruff and Wunsch, Zeitsch. anorg. Chem. 1914, 85, 292). Voigtländer and Lohmann (D. R. P. 286184, 1914) claim tungsten carbide to have a hardness of 9.8 compared with the diamond at 10.

Two carbides of tungsten, W_2C and WC , are formed when naphthalene vapour acts on incandescent tungsten filaments. These compounds at temperatures from $2400^\circ K.$ to $2790^\circ K.$ lose all their carbon, the tungsten filament regaining the same conductivity as before carbonisation. Incandescent tungsten may be carbonised by almost any hydrocarbon vapour. Alcohol will also carbonise the filament, but at only $\frac{1}{2}$ the rate at which acetylene effects the carbonisation. The electrical resistivity of cold W_2C is about 15 times that of tungsten, but the temperature coefficient of resistance is very much less. The conductivity of a partially carbonised filament at any temperature is in agreement with that calculated from the amounts of tungsten and W_2C present (M. R. Andrews, J. Phys. Chem. 1923, 27, 270).

Chromium tungsten carbide $OW_2.3Cr_2O_3$, is formed by heating a mixture of chromic oxide, tungstic acid and carbon in a carbon crucible in

an electric furnace for five minutes with a current of 400 amperes at 75 volts and treating the product with warm hydrochloric acid, then with concentrated ammonia solution. It forms small hard stable crystalline grains of sp.gr. 8.41 at 22°. By the addition of tungsten to chromium steels, the formation of this stable hard carbide might give rise to the production of new steels with special qualities (Moissan and Kouznetzow, *Compt. rend.* 1903, 137, 292).

Iron tungsten carbide $3W_2C \cdot 2Fe_3C$, a magnetic substance, sp.gr. 13.4 at 18°, has also been prepared (Williams, *ibid.* 1898, 127, 410; Carnot and Goutal, *ibid.* 1899, 128, 207).

TUNGSTEN AND SILICON.

Tungsten silicide WSi_2 has been prepared by heating copper silicide with amorphous tungsten in an electric furnace, using a current of 800–900 amperes and 50 volts, the resulting product is then washed successively with nitric acid, caustic potash, warm hydrofluoric acid and water. It may also be prepared by reducing a mixture of silica and tungstic anhydride with sulphur and alumina. It forms brilliant, grey crystals, of sp.gr. 9.4, which are not magnetic and are very stable (Dofacqz, *Cefmpt. rend.* 1907, 144, 848; Hönigschmidt, *Monatsh.* 1907, 28, 1017).

The silicide WSi_2 is obtained by heating the trioxide with silicon in the electric furnace, after which the mass is suspended in dilute hydrochloric acid (1 in 10) and electrolysed. The excess of metal dissolves and the silicide is removed, washed with *aqua regia*, then with ammonia, and is finally separated from carbon silicide gravimetrically by suspension in methyl iodide (Vigouroux, *Compt. rend.* 1898, 127, 393). It forms beautiful steel grey crystals with a metallic lustre, sp.gr. 10.9. See also Frilley, *Rev. de Metallurgie*, 1911, 8, 457; *J. Soc. Chem. Ind.* 1911, 1018.

Tungsten aluminium silicide forms black hexagonal crystals (Manchot and Kieser, *Annalen*, 1904, 337, 360).

Silicotungstic acids of the formulæ,

$H_8W_{12}SiO_{42} \cdot 20H_2O$, $H_8W_{12}SiO_{42} \cdot 29H_2O$, &c., were discovered by Marignac (*Ann. Chim.* 1864, [iv.] 3, 5). The acid corresponding to the last formula is formed by precipitating its salts with mercurous nitrate and decomposing the mercury salt with hot hydrochloric acid. It crystallises in large tetragonal prisms, is readily soluble in water, alcohol, and ether, and forms a valuable reagent for alkaloids. The salts, most of which are soluble in water, are prepared by boiling gelatinous silicic acid with metallic polytungstates (Wyrouboff, *Bull. Soc. franc. Min.* 1896, 19, 219; Friedheim and Henderson, *l.c.*).

ORGANIC SALTS OF TUNGSTEN.

of tungstic acid are described by Smith and Dugan (*J. Amer. Chem. Soc.* 1899, 21, 1016); *alkali tungsten tartrates* by Henderson and Barr (*Chem. Soc. Trans.* 1896, 1456); *citrates* by Henderson, Orr and Whitehead (*ibid.* 1899, 547); *tungsten oxalates* by Rosenheim (*Ber.* 1893, 26, 1191); *tungsten cyanides* by Rosenheim and Dehn (*Ber.* 1914, 47, 392; *ibid.*

1915, 48, 1167; Olsson, *Ber.* 1914, 47, 917; *Zeitsch. anorg. Chem.* 1914, 88, 49).

Tungsten forms ozosalts which are readily soluble and difficult to obtain free from the normal salts used in their preparation. The following have been described:—

Sodium ozotungsten oxalate

and also the corresponding ammonium and calcium salts which have only 1 mol. of water of crystallisation (Mazzucchelli and Inghilleri, *Atti. R. Accad. Lincei*, 1908, [v.] 17, ii. 30).

Complex compounds of the tungstic acids with organic acids have been obtained by Grossmann and Kramer (*Zeitsch. anorg. Chem.* 1904, 41, 43); and by Mazzucchelli and Bonghi (*Gazz. chim. ital.* 1910, 40, ii. 241); and additive compounds of the tetra-, penta-, and hexachloride with organic esters by Rosenheim and Loewenstamm (*Ber.* 1902, 35, 1115).

Oxalotungstites, *Chlorotungstites* and other derivatives of quinquevalent tungsten have been obtained by Collenburg (*Zeitsch. anorg. Chem.* 1918, 103, 247).

Gerber (*Mon. Scient.* 1917 [v.] 7, 73–219) finds evidence for the existence of a new element, *netungsten*, at wt. 187, associated with tungsten, and which, as it is spectroscopically indistinguishable from tungsten, he suggested may be an isotope of that metal (*cf.* Barbe, *Mon. Sci.* 1919, [v.] 9, i. 73).

TUNGSTENITE. Tungsten sulphide WS_2 , corresponding with molybdenite (MoS_2), which it closely resembles in physical characters. It occurs in some quantity intimately intermixed with pyrites, fahlore, and galena in a compact ore at the Emma mine in the Little Cottonwood district, Salt Lake Co., Utah. Under the microscope it is seen in this ore as feathery flakes resembling graphite in appearance. It is lead-grey and opaque with a metallic lustre, and soft enough to mark paper; sp.gr. about 7.4. The mineral is not oxidised by roasting in air, and is not attacked by hydrochloric or nitric acids, but is decomposed by *aqua regia* (R. C. Wells and B. S. Butler, *J. Washington Acad. Sci.* 1917, 7, 596). L. J. S.

TUNGSTITE or **TUNGSTIC-OGHRE**. A yellow, earthy mineral frequently observed in small amounts as an alteration product of wolframite and scheelite, and long supposed to be anhydrous tungsten trioxide WO_3 . The original tungstic-oghre of B. Silliman (1822) and the 'wolframine' from Cornwall were, however, never analysed, and in the text-books the characters of the artificial orthorhombic crystals of the anhydrous oxide have been assumed for the natural mineral. A mineral of similar appearance has been described under the name meymacite (A. Carnot, 1874) with the composition $WO_3 \cdot 2H_2O$. T. L. Walker (*Amer. J. Sci.* 1908, 25, 305) suggests that these are really identical and that the correct formula is $WO_3 \cdot H_2O$. He describes a golden-yellow mineral occurring with wolframite in veins of gold-quartz near Salmo in British Columbia. Minute crystals from cavities possess a perfect cleavage in one direction and are optically biaxial; sp.gr. 5.517; soluble in ammonia or sodium hydroxide, but not in acids.

Another 'tungstic ochre' occurring with

wolframite in the Germania tungsten mine, Deer Trail mining district in the State of Washington, was found by W. F. Schaller (Amer. J. Sci. 1911, 32, 161) to be a hydrated ferric tungstate, $\text{Fe}_2\text{O}_3 \cdot \text{WO}_3 \cdot 6\text{H}_2\text{O}$, for which the new name *ferritungstite* was proposed. This is pale-yellow to brownish-yellow and crystallised in minute hexagonal scales. L. J. S.

TURANITE. Hydrated copper vanadate, $5\text{CuO} \cdot \text{V}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, forming compact, spongy, or radially fibrous aggregates and reniform crusts of an olive-green colour. It is found with alaite (*q.v.*), ferganite (*q.v.*), tyuyamunite

malachite, &c., in the oxidation zone of the uranium and vanadium deposits which occur in limestone at Tyuya-Muyun in Fergana, Russian Central Asia. L. J. S.

TURANOSE. A sugar $\text{C}_{12}\text{H}_{22}\text{O}_{11}$, obtained by heating melezitose with acetic acid. Is not hydrolysed by any of the ordinary enzymes and is consumed very slowly by yeast. Rotatory power $[\alpha]_D = +71.8$ shows no birotation (Tanret, Compt. rend. 1906, 1424) (*v.* CARBOHYDRATES).

TURBIDIMETRY. See NEPHELOMETRY.

TURF. *v.* FUEL.

TURGITE *v.* TURITE.

TURICINE *v.* BETAINES.

TURITE, TURGITE or HYDROHÆMATITE.

A hydrated ferric oxide, $2\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, containing, according to the formula Fe_2O_3 , 94.7, (Fe 66.2), H_2O 5.3 p.c. It is sometimes soft and earthy with a bright red colour, being then included (together with earthy hæmatite) under red-ochre. It may also be massive and compact; with sometimes a radially fibrous structure and a smooth and brilliant mamillated or botryoidal surface, being then very similar to the kidney-iron-ore (more strictly the *Ger. Rother Glaskopf*) variety of hæmatite. Such material is dark red to black with a sub-metallic lustre. Sp.gr. 4.29–4.49; H. 6½ (harder than limonite). A characteristic feature is the dark cherry-red streak, which is of a lighter shade than that of hæmatite. Crystals are not known, but the fibrous material is birefringent with straight optical extinction. Few analyses show exactly the theoretical amount of water; there seems rather to be a gradual passage on one side to hæmatite (Fe_2O_3) and on the other to limonite ($2\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, with 14.5 p.c. H_2O). Compact or earthy red hæmatite often contains 1–2 p.c. H_2O . The existence of turite as a distinct mineral species has therefore been doubted, and it has been regarded as a colloidal material forming a stage in the hydration of hæmatite to limonite, or of the dehydration of limonite. Turite, however, when heated in a bulb-tube decrepitates with surprising violence, and in this respect it differs from both hæmatite and limonite. Its dehydration curve is quite distinct from those of limonite and goethite. Occurrences of fibrous mamillated turite and limonite at Salisbury in Connecticut and Bridgeville in Nova Scotia show a sharp line of demarcation between the two minerals. Turite was first described from the Turinaky¹ copper mines near Bogdolovak in the Urals, and it has since

been recorded with iron ores from many other Russian localities. It is no doubt a mineral of common occurrence elsewhere with hæmatite and limonite ores (L. J. Spencer, Min. Mag. 1919, 18, 339). L. J. S.

TURKEY-RED OILS *v.* OILS, FIXED, and FATS.

TURMERIC (*Indian saffron*; *Terra merita*). The so-called turmeric root of commerce is the underground stem or rhizome of *Curcuma longa* (Linn.), or of various species of *Curcuma*—e.g. *C. tinctoria*, *C. viridiflora* (Roxb.), &c. These plants, belonging to the *Scitamineæ*, are indigenous to Southern Asia, and are there largely cultivated, being exported from China, Madras, Bengal, Java, Malabar, Batavia and Barbadoes. Those varieties which are derived from the central rhizomes are more or less round (*Curcuma rotunda*, Linn.), while the lateral rhizomes are long and finger-shaped (*C. longa*). When of good quality these commercial varieties are hard, and possess a dull, waxy, resinous fracture, the external colour being yellowish-grey, and internally orange-brown, but producing, when ground, a somewhat bright yellow powder, having a strong characteristic odour and a peppery bitter taste.

The rhizome of *Canna speciosa*, a West African plant, is said to be exactly similar to East Indian turmeric in taste, smell, and chemical reactions (Daniell, Pharm. J. 19, 258). It is cultivated in Sierra Leone, and furnishes the so-called 'African turmeric.'

According to Pelletier and Vogel (Annalen, 44, 297), turmeric contains cellulose, gum, starch, mineral matter, a strong-smelling volatile oil, a brown colouring matter, and a characteristic yellow colouring matter named by them *Curcumin*. Pectin and pectic acid are also present (Schützenberger). Kachler (Ber. 3, 713) found a notable quantity of potassium binoxalate.

Pelletier and Vogel's method of isolating the curcumin consisted in first removing the fatty, resinous, and other impurities by extracting pulverised turmeric with water and carbon disulphide, then dissolving out the colouring matter with boiling alcohol, and purifying it by successive solution in ether and alcohol, precipitation with lead acetate, subsequent treatment with hydrogen sulphide and extraction of the product with ether. It was thus obtained as an amorphous yellow powder.

Lepage adopted a similar method, but after extraction with carbon disulphide the colouring matter was dissolved in alkali, precipitated with acid, and finally purified by means of ether.

Daube was the first to obtain curcumin in the crystalline state. He removed essential oil by passing a strong current of steam over the coarsely-ground turmeric, then thoroughly extracted it with hot water, and finally treated the dried residue with boiling benzene. On cooling the solution thus obtained, crude curcumin separated as bright orange-red crystalline crusts, which were pressed between blotting-paper, and dissolved in cold alcohol. After filtering off some yellow flocculent substance, the solution was precipitated with an alcoholic solution of neutral lead acetate, adding finally a little basic lead acetate in order to neutralise

¹ Hence the name, from the adjacent Tura river. The German spellings *turgite* and *turjit* are mistranslations of the Russian *тырма*, turite.

almost entirely the liberated acetic acid and prevent thereby any solution of the colour-lake. The brick-red precipitate was washed with alcohol, suspended in water, and decomposed with hydrogen sulphide. The liberated curcumin was extracted from the precipitate with boiling alcohol, from which it crystallised on slow evaporation.

Benzene is very suitable for the isolation of pure curcumin, for although it is very little soluble in this liquid, the resinous impurities are not dissolved thereby.

Gajewsky (Ber. 3, 265) obtained crystalline curcumin by first extracting turmeric root with carbon disulphide, then dissolving out the colouring matter with ether, and purifying it by fractional crystallisation from ether or benzene. He detected the presence of another colouring matter and also traces of an alkaloid. This chemist obtained an increased yield of colouring matter by washing the dry ethereal extract with dilute ammonia to remove resin, then dissolving the brittle residue in boiling concentrated ammonia solution and precipitating with carbon dioxide; 250 grms. ethereal extract gave 100 grms. flocculent curcumin, m.p. 140°. Jackson (Ber. 14, 485) also obtained crystallised curcumin by first removing the oil by long extraction with carbon disulphide (sixty hours), then thoroughly extracting (sixty hours) with ether, and after washing the orange-coloured product thus obtained with cold alcohol or ether, crystallising from hot alcohol.

Perkin (Chem. Soc. Trans. 1904, 85, 63) precipitates an alcoholic turmeric extract with lead acetate, washes the lead compound first with alcohol then with water, and decomposes it with dilute sulphuric acid. From the mixture of lead sulphate and curcumin the latter is removed with boiling alcohol and the extract evaporated and poured into ether, which causes the separation of tarry impurities. The ethereal solution, after evaporation to a small bulk, is treated with carbon disulphide and allowed to stand, the crystals which separate from time to time being removed. 0.56 p.c. of curcumin was thus obtained from turmeric.

Curcumin crystallises from alcohol in orange-coloured prisms, m.p. 165° (Daube), 172° (Gajewsky), 178° (Jackson), and 183° (Ciamician and Silber, Ber. 30, 192), and is soluble in ether, forming a green fluorescent liquid. Alkaline solutions dissolve it with a reddish-brown colour, which when neutralised passes to yellow, and on this account it is useful in the form of 'turmeric paper' as a reagent for alkalis. Whereas Daube assigned to curcumin the formula $C_{18}H_{16}O_8$, Gajewsky ($C_{18}H_{16}O_8$), probably

Jackson considered that $C_{18}H_{14}O_8$ or $C_{18}H_{12}O_8$ were more reasonable expressions, and of these Jackson and Menke (Amer. Chem. J. 6, 78) preferred the former, and prepared the following derivatives harmonising with this view:—

Dihydrocurcumin $C_{18}H_{18}O_8$, brownish-white powder, m.p. 100° ca.; *dihydrocurcumin anhydride* $C_{18}H_{16}O_7$, dirty white powder, m.p. 120° ca.; *disilylcurcumin* $C_{18}H_{20}O_8$, brownish tar; *p-bromobenzylcurcumin* $C_{18}H_{17}BrO_8$, pale yellow crystals, m.p. 76°–78°; *acetylcurcumin* $C_{19}H_{18}O_8$, brownish mass; *diacetylcurcumin* $C_{21}H_{20}O_8$,

yellow rhombic crystals, m.p. 154°; *curcumin-tetrabromide* $C_{18}H_{14}O_8Br_4$, powder, m.p. 185° ca.; *tetrabromocurcumin* $C_{18}H_{12}O_8Br_4$, red powder; *pentabromocurcumin dibromide* $C_{18}H_{10}O_8Br_5$, red powder, m.p. 120° ca.; *potassium curcumin* $KC_{18}H_{12}O_8$, red powder, and *dipotassium curcumin* $K_2C_{18}H_{10}O_8$, red needles. By fusion with alkali curcumin gives *protocatechuic acid*, when oxidised with permanganate *vanillin*, and the diethyl ether by similar treatment yields *vanillic acid ethyl ether*. Jackson and Menke represented curcumin by the following formula:—

Heller (Ber. 1914, 47, 2998) has obtained *dihydrocurcumin*, now shown to possess the formula $C_{22}H_{24}O_8$, by catalytic reduction, as colourless needles, m.p. 95°–96°.

Ciamician and Silber (Ber. 30, 192), as the result of methoxy determinations, assigned the formula $C_{22}H_{20}O_8$ or $C_{19}H_{14}O_8(OCH_3)_2$ to curcumin, and prepared *diacetylcurcumin*

needles, m.p. 170°–171°; and *curcumin dimethyl ether* $C_{18}H_{16}O_8(OCH_3)_2$, yellow needles, m.p. 135°. Digested with hydroxylamine hydrochloride in alcoholic solution curcumin gave the compound $C_{22}H_{22}NO_8$ (i.e. $C_{22}H_{20}O_8NOH-H_2O$), needles, m.p. 178°, whereas phenylhydrazine gave a substance crystallising in colourless needles.

Perkin (Chem. Soc. Trans. 1903, 83, 140; 1905, 85, 63), by means of alcoholic potassium acetate, obtained from curcumin the monopotassium salt $C_{22}H_{19}O_8K$, fine orange-red needles. A *benzoyl-curcumin*, pale yellow needles, m.p. 176°–178°, was also prepared, and gave by the cryoscopic method numbers harmonising with Ciamician and Silber's formula.

Molecular weight determinations, according to Jackson and Clarke (Ber. 1905, 38, 2712), indicated the correctness of the formula

and again (*ibid.* 1906, 39, 2269) these authors pointed out that unless special care is employed, Zeisel's method gives erroneous figures with curcumin. When heated with hydriodic acid at 120° a correct result is given, but above this temperature curcumin gives a colourless oil rich in iodine (75.75 p.c.) which reacts with the alcoholic silver nitrate solution.

Von Kostanecki and Lampe (*ibid.* 1910, 43, 2163) consider that Ciamician and Silber's formula $C_{22}H_{20}O_8$ correctly represents curcumin, and describe *dicarbomethoxycurcumin*

yellow prisms, m.p. 150°, and *dicarbomethoxycurcumin*, yellow leaflets, m.p. 149°–150°.

When curcumin is boiled with potassium hydroxide solution, *vanillic acid* and *ferulic acid*

are produced. As a result these authors con-

which on hydrolysis splits off acetic acid with formation of dicinnamoyl-methane—

This compound, which crystallises in yellow prismatic needles, m.p. 144°, dissolves in sulphuric acid to form an orange-red solution possessing a yellow fluorescence. Both in its chemical and physical properties it closely resembles curcumin, and dyes cotton yellow shades which, however, are weaker than those given by curcumin itself.

In 1914 (Ber. 47, 887) Heller described a stereoisomeride of curcumin which he named *iso-curcumin*, and this he obtained as a reddish-yellow crystalline solid, sintering at 140° and melting near 180°, by condensing vanillin with acetylacetone in the presence of hydrochloric acid—

Ryan and Dunlea (Proc. Roy. Irish Acad. 1915, 32, B, 657), however, criticised this statement. They find that the first product of the action of benzaldehyde on acetyl-acetone in this way is not benzylidene-acetone

but a chlorinated compound which on heating *in vacuo* gives

Iso-curcumin thus may be the trivanillin condensation product, with which indeed Heller's analytical results agree—

Heller (Ber. 1914, 47, 2998), however, states that this criticism of Ryan and Dunlea is unjustified in that *iso-curcumin* is a chlorine free colouring matter. *Iso-curcumin* shows a faint reaction with ferric chloride, and is to be regarded as a mixture of ketone with a little enol, whereas curcumin is decidedly enolic. *Ethyl-carbamato-iso-curcumin* melts at 142°. See also Ber. 1917, 50, 1244, and Ber. 1921, 54, 1118.

Ghosh (Chem. Soc. Trans. 1919, 292), by the simple conversion of curcumin into *iso-curcumin*, confirms Heller's view that the two substances are geometrical isomerides.

Curcumin has been synthesised by an application of the method employed for the synthesis of dicinnamoyl-methane (Lampe and Milobedzki, Ber. 1913, 46, 2235). In this cinnamoyl chloride was condensed with ethyl acetoacetate and the product hydrolysed, when cinnamoyl-acetone resulted. Condensation of this product with a second molecule of cinnamoyl chloride and hydrolysis of the product gave dicinnamoyl methane

By employing carbomethoxyferuloyl chloride (I)

in the place of cinnamoyl chloride, the dicarbomethoxy-derivative of curcumin was obtained. It gave curcumin on hydrolysis (Lampe, Ber. 1918, 51, 1347)

It is well known that a mixture of boric and hydrochloric acids imparts to turmeric paper a red colour which is turned blue by alkalis. This reaction was investigated by Schlumberger (Bull. Soc. Chem. [ii.] 5, 194), who found that when an alcoholic extract of turmeric is heated in a sealed tube with boric acid, a red crystalline boric acid derivative is produced, soluble in alkaline solutions with a purple-violet colour. Boiling water decomposes this compound with elimination of boric acid, and formation of *pseudo-curcumin*, a yellow powder. In the alcoholic solution of the boric acid compound is digested with strong hydrochloric acid, a black substance separates, whereas boric acid remains in the liquid.

On extracting the black powder with a mixture of alcohol and acetic acid, the filtrate deposits green iridescent crystals of rosocyanine.

Rosocyanine is readily soluble in alcohol containing a trace of mineral acid and dissolves in ammonia solution with a blue colour. It is, according to Schlumberger, an unstable substance, and if boiled for a long time with alcohol, is converted into *pseudo-curcumin*.

Jackson and Clarke (l.c.) prepared rosocyanine by heating a solution of curcumin in dilute alcohol with boric and sulphuric acids, and describe it as a purplish-red powder, closely resembling powdered rosaniline. These authors considered it to be isomeric with curcumin $\text{C}_{14}\text{H}_{14}\text{O}_4$, and described an *ammonium salt* $\text{C}_{14}\text{H}_{13}\text{O}_4\text{NH}_4$, and a *potassium salt* $\text{C}_{14}\text{H}_{13}\text{O}_4\text{K}$, both of which possess an intense blue colour.

The tinctorial properties of curcumin are of special interest, for not only is it a strong colouring matter towards mordants, but with cotton, wool, and silk it behaves also as a substantive dyestuff. In the latter case it is only necessary to add the material to a boiling decoction of the colouring matter. Though considerably employed up to within recent years by the wool and silk dyer in the formation of olives, browns, and other compound colours, turmeric is now but rarely used for dyeing purposes in England. In India, however, it appears to be still in vogue.

Cotton is usually dyed in a decoction of turmeric rendered slightly acid by the addition of a little acetic acid, or alum may be employed. The colour does not resist either the action of light or of alkalis, and readily acquires a brownish-red tint. Wool may be dyed without any addition, keeping the temperature about 80°. By previously mordanting with alum a brighter effect is produced, whereas tin mordant gives a more orange colour. Potassium dichromate and ferrous sulphate employed in a similar manner yield respectively olive and brown-coloured shades.

Silk is preferably dyed in an acid bath, and is sometimes previously mordanted.

Turmeric oil is the thick orange-coloured aromatic oil present to the extent of 3.23 p.c. in turmeric from which it can be extracted by means of carbon disulphide. Bolley examined the portion distilling over at 230°-250°, and considered it to be identical with carvol, whereas Gajewsky (l.c.) found the portion distilling over at 220°-228° contains less carbon and more hydrogen than that which passes over at a higher temperature. On oxidising the latter portion with chromic acid, an acid oil is obtained which contains valeric, caproic, and terephthalic acids. Jackson and Menke (l.c.) analysed that portion which distils over at 285°-290°, and gave it the formula $C_{15}H_{18}O$, and the name *turnerol*, and obtained *turnerol chloride* $C_{15}H_{17}Cl$, *sodium turnerol* $C_{15}H_{17}ONa$, and *turnerol iso-butyl ether* $C_{15}H_{27}O \cdot C_4H_9$. With permanganate turnerol gave *terephthalic acid*, *turmeric acid* $C_{11}H_{14}O_2$, and *apoturmeric acid* $C_{10}H_{12}O_4$ or $C_{10}H_{10}O_4$. According to Rüpe (Ber. 1907, 40, 4909), when turmeric oil is boiled with dilute sodium hydroxide solution a substance, b.p. 156°/12 mm., apparently not identical with Jackson and Menke's turnerol, is produced. Stronger alkali yields an optically active ketone $C_{15}H_{18}O$, *curcumone*, b.p. 119°-120°/8 mm., which gives a semicarbazone, m.p. 119°-120°-5°, an oxime, b.p. 159°/11 mm., and condensation products with aromatic aldehydes. With permanganate the ketone gives *p-methylacetophenone* and *terephthalic acid*, and with alkaline hypobromite the acids $C_{12}H_{16}O_8$, m.p. 150°, and $C_{12}H_{16}O_2$, m.p. 33°-34°. By the further action of permanganate the latter yields a dicarboxylic acid $C_{12}H_{14}O_4$, m.p. 228°. Rüpe, Luksch, and Steinbach (Ber. 1909, 42, 1515) were unable to isolate from turmeric oil the turnerol of Jackson and Menke, having sp.gr. 0.9388 at 20° and $[\alpha]_D^{20} = -27.46$. By digestion with alcohol and 30 p.c. potassium hydroxide solution the ketone $C_{15}H_{18}O$, *curcumone*, was obtained, which has b.p. 121°/10 mm., sp.gr. 0.9566 at 20°, $n_D^{20} 1.50526$, $[\alpha]_D 80.55$, and yields the *p-bromophenylhydrazone*, m.p. 71°. It condenses with benzaldehyde to form the compound $C_{15}H_{16}O : CH \cdot C_6H_5$, m.p. 106°, and with piperonal and anisic aldehydes similar compounds melting respectively at 86° and 77°-78° are produced.

The acid $C_{12}H_{16}O_2$ (l.c.), m.p. 33°-34°, is called *curcumatic acid*, and appears to be identical with Jackson and Menke's turmeric acid (Rüpe and Steinbach, Ber. 1910, 43, 3465). By oxidation with permanganate it gives terephthalic acid, *p*-tolyl methyl ketone, and the acid $C_{12}H_{14}O_4$, m.p. 226°-228° (l.c.), and this possibly consists of *apoturmeric acid* (Jackson and Menke). Although it was considered that curcumatic acid might be γ -*p*-tolylvaleric acid, the synthesis of this latter compound showed that the substances are similar but not identical (*ibid.* 1911, 44, 584). Again, curcumatic acid is not *p*-tolyl- α -methylbutyric acid (Rüpe and Bürgin, *ibid.* 1218). Rüpe and Steinbach (l.c.) consider that curcumone is to be regarded as a benzene derivative containing two parasubstituents, one being methyl, and the second, one or other of the groups

whereas in curcumatic acid the group COMe is replaced by COOH. See also Schimmel & Co. Ber. April, 1911).

TURNER'S YELLOW. *Patent yellow.* Lead oxychloride $3PbO \cdot PbCl_2$.

TURNIP. A biennial, cruciferous plant, producing in the first year a large root stock containing a store of carbonaceous and nitrogenous matter intended for the formation of flower-stem and seeds in the second year. This 'root' is the chief valuable product for which the crop is grown. Many varieties, differing in the shape, size, and colour of the root, are known, but they may all be classed as belonging to two species—the 'white turnip,' or simply 'turnip,' *Brassica rapa* (Linn.), or *B. rapa rapifera* (Metzger), and the 'Swedish turnip,' or 'Swede,' known often as 'ruta-baga' in America, *Brassica campestris rutabaga* (Linn.), or *B. napus esculenta* (DC.). There are many varieties of each, but as a rule 'turnips' have rougher leaves, of greener colour, and the root has white, or, in some cases, yellow flesh; whilst 'swedes' possess smoother leaves of a bluish-green colour, and the roots have yellow flesh. The leaves of the turnip spring directly from the root, whilst those of the swede arise from a distinctly marked 'neck.'

Both types grow best in cool, damp climates; in hot, dry countries the roots tend to become very woody and fibrous. Swedish turnips resist frost better, and can be grown in stiffer soils than the white varieties; they also keep better after gathering.

According to König, the following figures represent the average composition of the two types—

	Pro-	Other	
	Water	N-free	
	tein	Fat	Sugar ext. Fibre Ash
White turnips	90.67	1.12	0.24 2.55 3.55 1.11 0.76
Swedes	88.88	1.39	0.18 3.02 4.35 1.44 0.74

Great variations in composition, however, have been observed, the most important factors, in order of importance, being apparently, season, variety, size of root, district, and soil. Even with the same variety, grown under the same conditions, and with roots of approximately the same size, considerable variations in the composition of individual roots are found, especially in the amount of sugar. Thus, Collins (J. Soc. Chem. Ind. 1920, 20, 536) found in 25 individual roots of XL All swedes, the proportion of sugar varied from 4.5 to 7.8 p.c., with an average of 6.27 p.c.

The variation with season is considerable; Collins, as the average of 12 varieties of swedes grown in 1900, found a sugar content of 6.26 p.c., while the same varieties, in 1901, gave an average of only 4.05 p.c. of sugar. Analogous to the effect of season is that of local climate; even in Britain this effect is seen. In 1904 several varieties of swedes were grown simultaneously in Cambridgeshire, Norfolk (2 centres), and Ross-shire (4 centres), and the resulting

crops were examined for dry matter and sugar content.

The following figures show the sugar contents of 5 varieties, as grown at the various centres—

Variety	Cam-bridge			Norfolk			Ross-shire		
	1	2	Mean	1	2	3	4	Mean	
Fell's Bronzetop.	6.5	6.1	8.0	7.0	7.2	7.3	7.1	8.0	7.4
New Arctic	6.1	6.0	8.1	7.0	6.9	7.2	7.1	7.9	7.3
Magnum Bonum	6.3	5.7	7.6	6.6	6.8	7.2	6.6	8.1	7.2
XL All	6.0	6.0	7.4	6.7	6.8	6.8	6.7	7.5	7.0
Carter's Elephant	6.3	5.8	7.0	6.3	6.7	6.9	6.8	7.4	7.0
Average	6.2	5.9	7.6	6.7	6.9	7.1	6.9	7.8	7.2

These results clearly show that the roots grown in the moist, cool climate of Ross-shire were, on the average, richest in sugar, while those grown in the hot, dry climate of Cambridgeshire were the poorest (Guide to Expts. 1906, Dept. of Agric. Univ. of Cambridge).

So, too, Hendrick (Bull. 1, Coll. Agric. Univ. of Aberdeen, 1904) found, as the average of analyses of 21 varieties of swedes, grown in Aberdeenshire, 11.7 p.c. of dry matter, and 5.15 p.c. of sugar, while 9 varieties of turnips yielded an average of 9.48 p.c. of dry matter, and 4.55 p.c. of sugar; and Wood (Guide to Expts. Dept. of Agric. Univ. of Camb. 1906) found as the mean of the analyses of 5 varieties of swedes, grown in Cambridgeshire (1 centre, and Norfolk (2 centres), 10.8 p.c. of dry matter and 6.6 p.c. of sugar, and for 7 varieties of white turnips 7.81 p.c. of total dry matter, and 4.24 p.c. of sugar.

The effect of soil upon the composition of the roots, although perceptible, is not great. That of manuring is very great upon the yield, but is comparatively small upon the composition, except in so far as it affects the size of the roots.

The effect of size of root, in any variety, is considerable, small roots being invariably richer in solid matter, especially sugar, than large ones. This is well seen from the following analyses by Hendrick (J. Soc. Chem. Ind. 1897, 16, 213) of two samples of 'Achilles' turnips—

Average wt.	Dry		Water		Sugar		Total N		Alb. N		Ash	
of 1 root	Water	matter	Water	matter	Sugar	Total N	Alb. N	Ash	Water	matter	Sugar	Total N
5lb. 10z.	92.8	7.2	3.93	0.102	0.108	0.56						
2lb. 14oz.	91.3	8.7	4.62	0.148	0.076	0.64						

In view of these many circumstances affecting the composition of the roots, it is obviously of little value to attempt to give any representative composition of turnips.

It may, however, be of interest to quote the figures given by Kellner and by Warrington as representing the average composition of turnips and swedes.

Kellner gives—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Swedes	87.8	1.5	0.2	8.2	1.3	0.9
Turnips	91.5	0.9	0.1	6.0	0.8	0.7

Warrington's figures are—

	Water	Proteids etc.	Amides, Fat	N-free extract	Crude fibre	Ash
Swedes	89.3	0.7	0.7	0.2	7.2	1.1
Turnips	91.5	0.5	0.5	0.2	5.7	0.9

The protein, i.e. total N \times 6.25, in the above analyses, contains a considerable and variable quantity of non-proteid substance. König states that from 35 to 55 p.c. of the total nitrogen is present, partly as amides or amino acids,

partly as nitrates. Warrington estimates the non-albuminoid nitrogen in turnips at 49 p.c. of the total nitrogen, but gives as the average digestible albuminoids 0.2 p.c. in swedes, and 0.1 p.c. in turnips. Collins (l.c.) found, in 'Monarch' swedes, the real albuminoids varied from 0.47 to 0.63 p.c., while the amides, &c., ranged from 0.34 to 0.61 p.c. Hendrick (l.c.) found the proportion of non-albuminoid nitrogen to total nitrogen varied from 27 to 42 p.c. in yellow turnips, and from 23 to 59 p.c. in 'Best of All' swedes. In the days when the 'nitrogenous substances' or 'albuminoids' in food-stuffs were estimated by multiplying the total nitrogen by 6.25, turnips, in common with other roots, gave results on analysis which indicated that they possessed greater feeding value than actual experience showed them to have. If, however, distinction is made between true proteids and amino compounds, amides and nitrates, the nutritive value of turnips, as assessed by analysis, seems, in most cases, to be much less than their actual efficiency as foods (v. Ingle, Trans. High. & Agric. Soc. Scotland, 1910, 22, 178; also Hendrick, *ibid.* 150). It would seem, in fact, that either the true albuminoids in turnips are much more digestible than has hitherto been admitted, or, more probably, that the amino compounds may, under certain conditions, behave like albuminoids, in building up animal tissue.

For a study of the hydrolysis of the soluble protein of swedes, v. Williams (J. Agric. Sci. 1917, 8, 182).

The sugars present in turnips are dextrose, lævulose, and sucrose, the invert sugars largely predominating. The other N-free extractives include pectins, pentosans, and cellulose.

The ash of turnips varies greatly in composition and amount. According to figures compiled by König, the whole ash varies from 4.9 to 14.0 p.c. of the dry matter, while the potash in the ash may range from 26 to 62 p.c., the lime from 5 to 15.9 p.c., and the phosphorus pentoxide from 5.5 to 18.9 p.c. The mean of 32 analyses of the ash gave—

	K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₂	SiO ₂	Cl
	45.4	9.8	10.6	3.7	0.8	12.7	11.2	1.9	5.0

The upper half of a root is richer in solid matter than the lower, and due allowance must be made for this fact in sampling turnips for analysis.

Turnip leaves are sometimes used for feeding purposes; according to Kellner they contain, on the average—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
88.4	2.2	0.5	5.3	1.5	2.1

Turnips, like other plants of the genus *Brassica*, contain thio compounds, and when they decay or even suffer slight decomposition by boiling, they evolve unpleasant-smelling sulphur compounds, among which mercaptans are probably included.

Turnips require liberal supplies of phosphates, and phosphatic manures, generally superphosphates, are almost invariably used for this crop. For a study of the destination of phosphates and nitrogen when applied as a manure to turnips, v. Somerville and Smith (J. Soc. Chem. Ind. 1897, 16, 19), H. I.

TURPENTINE v. OILS, ESSENTIAL: also TURPENTENS.

The production of turpentine and rosin in France during the last 10 years has been as follows:—

Year.	Turpentine metric tons.	Rosin metric tons
1913 . . .	25,000	85,000
1914 . . .	19,000	64,000
1915 . . .	15,000	51,000
1916 . . .	17,000	60,000
1917 . . .	17,000	60,000
1918 . . .	20,000	60,000
1919 . . .	25,000	85,000
1920 . . .	35,000	120,000
1921 . . .	31,000	105,000
1922 . . .	32,000	118,000

For the temperature coefficient of refractive index of American turpentine, see G. Thompson (Chem. News, Jan. 12, 1923, 126, 20-21).

About 75 p.c. of the world's supply of turpentine is produced in the United States, chiefly from the southern longleaf yellow pine (*Pinus palustris*), but other species, such as the Cuban or slash pine (*P. caribæa* or *heterophylla*), the rosemary pine (a variety of the Loblolly pine, *P. taeda*), and the western yellow pine (*P. ponderosa*) are also tapped; most of the remaining 25 p.c. is obtained in the south-western coast regions of France from the maritime or cluster pine (*P. pinaster* or *maritima*). The following States contribute to the American supply: Florida, 37 p.c.; Georgia, 19 p.c.; Louisiana, 15 p.c.; Alabama, 12 p.c.; Mississippi, 9 p.c.; Texas, 7 p.c.; North and South Carolina, which formerly produced the bulk of the world's supply, now furnish less than 1 p.c.

The oleo-resin is obtained by scarifying or 'chipping' the living trees. A V-shaped cut is made about once a week immediately above the last cut, thereby forming a 'face' down which the gum exuding from the cut flows, collects in galvanised iron or baked clay cups holding 1 to 2 quarts. The tapping season lasts from early spring to late autumn, the oleo-resin being removed from the cups about once a month and taken to the stills in barrels.

The distillation plant is simple and has not been improved materially during the last 50 to 60 years. It consists of a copper still of 500 to 1000 gallons capacity, with a still-head (generally removable) connected to a large copper condensing-coil cooled in water. From 7 to 14 barrels of oleo-resin go to make a charge, depending on the size of the still and the nature of the oleo-resin.

The oleo-resin contains some water and the distillate at the beginning consists of about 45 p.c. of turpentine and 55 p.c. of water. When the water decreases to about 30 p.c., a small stream of water is admitted to the still. The yield of turpentine varies from 16 to 22 p.c. It is mostly shipped in wooden casks holding 50 to 53 U.S. gallons (231 cub. in.), treated internally with glue to prevent absorption of turpentine by the wood. Tank cars of 5000 to 10,000 gallons capacity are used in the Western States (F. P. Veitch and V. E. Grotliach, U.S. Dept. Agric., Bureau of Chem. Bulletin No. 898, 1920, in abstract, J. Soc. Chem. Ind. 1921, 165 R.).

Ordinary American turpentine is able to

attack iron in the presence of air, thus acquiring a deep red colour. This appears to be due to organic acids of high molecular weight (Levy and Defries, J. Soc. Chem. Ind. 1923, 42, 472 T.; 1924, 43, B. 103).

Wood turpentine is obtained from stumps, sawmills slab, &c., by destructive distillation or by steam distillation; the crude product is redistilled over soda-ash, and when thus refined, can scarcely be distinguished from the volatile portion of the oleo-resin exuded from the living tree (spirits of turpentine.) Refined wood-turpentine has the following characteristics: sp.gr. at 15° 0.863; n_D^{20} 1.468; initial b.p. 153°; distillation range 91 p.c. below 170°; acidity, trace. About 70 p.c. distils below 160°, and this portion has been identified as α -pinene (Lambert, J. Ind. Eng. Chem. 1922, 14, 491; Analyst, 1922, 406).

The following are suggested by the U.S. Dept. of Agric. as specifications for three standard grades of turpentine:—

Standard or No. 1 turpentine should have a sp.gr. at 20° of from 0.862 to 0.870; a refractive index at 20° of from 1.468 to 1.476; 95 p.c. should distil below 170°, and a layer of not less than 200 mm. should be required to equal in colour the Lovibond yellow glass No. 1. On polymerisation with 38-normal sulphuric acid the residue should not exceed 1 p.c., should be reddish in colour and viscous, and its refractive index at 20° should be from 1.500 to 1.520. An unadulterated turpentine which does not agree with these requirements may properly be regarded as not of standard or No. 1 quality.

Second quality or No. 2 turpentine should have a sp.gr. at 20° of from 0.862 to 0.875; a refractive index at 20° of from 1.468 to 1.480; 90 p.c. should distil below 170°, and a depth of not less than 100 mm. should be required to equal the Lovibond yellow glass No. 1. The polymerisation residue must not exceed 1 p.c., and must have a refractive index of not less than 1.50.

Third quality or No. 3 turpentine should have a sp.gr. at 20° of from 0.865 to 0.880; a refractive index at 20° of from 1.468 to 1.485; 60 p.c. should distil below 170°, and a depth of not less than 50 mm. should be required to equal the Lovibond yellow glass No. 1. The polymerisation residue must not exceed 1 p.c., and must have a refractive index of not less than 1.500.

The following are the tests for adulteration:—

'Straight' wood turpentines are readily distinguished from gum turpentines by their odour, or when they have been very carefully refined by the odour of the first fraction, or of the residue from fractional distillation. One or both of these portions have the peculiar 'sawmill smell,' and the residue has a camphoric and somewhat nauseating odour characteristic of wood turpentine, which is quite different from the mild, sweet fragrance of gum turpentine.

Destructively distilled wood turpentine and also rosin spirits are more readily distinguished from gum spirits by their odour than is wood turpentine prepared by steam distillation, and they also give distinguishing colour reactions when mixed with sulphurous acid or with hydrochloric acid. When steam-distilled wood turpentine has been carefully refined so that 95 p.c.

95 p.c. of it distils at from 155° to 170° , both of these colour tests are practically useless.

At the present time a number of highly refined grades of pine wood oil ("kienöl"), obtained as a by-product from the manufacture of sulphate wood pulp, are on the market and employed for the adulteration of true turpentine oil. An extremely simple test for this adulteration is obtained with the ferric ferricyanide reagent. Two solutions are made up (a) with 0.5 grm. of potassium ferricyanide in 250 c.c. of water and (b) 0.1 grm. of ferric chloride in 250 c.c. Four c.c. of each of the two solutions are mixed together and 3-5 drops of the sample to be tested are added. With impure turpentine oils the formation of Prussian blue is observed within a few minutes. Pure turpentine oil within 3 minutes produces only a faint green coloration, or at the most slightly blue colour at the line between the oil and aqueous layer (H. Wolff, Zeitsch. angew. Chem. 1923, 36, 233; J. Soc. Chem. Ind. 1923, 42, 730 A).

Turpentine adulterated with more than 10 to 20 p.c. of coal-tar oils, or of gasoline or kerosene which have not been deodorised, may usually be readily detected by the characteristic odour of the mixture. The odour of rosin spirits, while quite distinctive, is difficult to detect in mixtures with turpentine. The presence of petroleum oils is also indicated by bubbles or 'beads' persisting for a few moments on the surface of the turpentine shaken in a partly filled bottle.

The presence of more than 10 p.c. of kerosene or similar mineral oils is readily detected by the spot which a few drops of the sample placed on white paper leaves on drying. Gasoline and other light mineral oils do not leave this spot.

It is possible so to adulterate turpentine that neither the specific gravity, refractive index, or flash-point is materially altered. Such careful adulteration is rare, but as adulterants cannot invariably be detected by making these determinations, and further, as mineral oil is the most probable adulterant, it is more rational at once to polymerise the suspected sample, note the volume, colour and consistency of the unpolymerised residue, and determine its refractive index.

If rosin spirits is present in notable quantities, it may be detected by the amount of residue on polymerisation in conjunction with lowered initial boiling-point and the deep coloration produced by mixing portions of the original turpentine of the first fraction with sulphurous acid and with hydrochloric acid.

If the initial distilling temperature of the turpentine is less than 154° and the original sample gives a reddish colour with sulphurous acid and a greenish-red with hydrochloric acid, and the residue from polymerisation is less than 5 p.c., it is probable that the sample is adulterated with rosin spirits. An odour of rosin spirits in the sample, or in any fraction, would be confirmatory, and all tests should be repeated on the first fraction obtained with a fractionating column. At best the detection of small amounts of rosin spirits is very difficult, and the procedure outlined may often fail to detect its presence.

The presence of marked quantities of coal-tar oils, benzol, toluol, and xylol is detected by the odour, the lower initial distilling temperature,

i.e. between 80° and 155° , and by further examination of the first fractions which distil below 155° . The rise of temperature on shaking during polymerisation is also indicative of the nature of the sample. Coal-tar and petroleum oils do not raise the temperature more than 35° or 40° when mixed with sulphuric acid. When the temperature of turpentine mixed with 38-normal sulphuric acid does not rise above 50° or 60° , mineral oil, coal-tar oil, or some other oil than turpentine is present in large quantities. The older the sample of turpentine, the greater, or at least the more rapid, the rise of the temperature of the mixture.

Benzene in turpentine may also be detected by the precipitate of $\text{Ni}(\text{Cy}_3\text{NH}_2)_2\text{C}_6\text{H}_6$, which it forms with nickel ammonium cyanide (Pritzke and Jungkunz, Chem. Zeit. 1924, 48, 555; Analyst, 1924, 49, 450).

Non-volatile oils are easily detected by a distillation test (J. Soc. Chem. Ind. 1911, 30, 559).

For the constituents of Indian turpentine from *Pinus longifolia*, Roxb., see J. L. Simonsen and M. G. Rau (Chem. Soc. Trans. 1923, 123, 549-560); J. L. Simonsen (Chem. Soc. Trans. 1923, 123, 2642-2666).

Oil of turpentine from *Pinus laricio* of Spain contains over 90 p.c. of *l*-pinene (Dupont and Barraud, Bull. Soc. Chem. 1924, 35, 784; J. Soc. Chem. Ind., 1924, 43, B, 720).

Venice Turpentine.—The production of Venice turpentine (trementina) in Italy is confined to the Province of Venetia Tridentina, formerly Austrian Tyrol territory, in the northern part of Italy. In this region that species of pine known as larch is found in abundance on the slopes of the Apennines, and the distillation of turpentine from the wood of this tree forms an important industry. There seems to be no monopoly of the industry as, according to the Journal of the Royal Society of Arts, quoting a United States Consular report, the production of Venice turpentine (known to the producers as olio greggio di larice or Tyrol larch turpentine) is divided among a great number of individuals and small concerns. In some cases the municipal government owns and operates distillation plants for the production of turpentine—an unusual occurrence in Italy. Venice or Tyrol larch turpentine is sold by weight (Pharm. J. Sept. 8th, 1923).

TURPETH or TURBITH MINERAL. An old name for basic mercuric sulphate $\text{HgSO}_4 \cdot 2\text{HgO}$, sometimes called Queen's yellow, v. MERCURY.

TURPETH or TURBITH ROOT. The root of the convulvulaceous plant *Ipomoea Turpethum* (R.Br.) [*Operculina Turpethum* (Peters)], found in India and Australia. It contains a volatile oil and a drastic resin, turpethin $\text{C}_{27}\text{H}_{44}\text{O}_{10}$, isomeric with jalapin and scammonin. When treated with dilute mineral acids this substance is hydrolysed into glucose and turpetholic acid $\text{C}_{16}\text{H}_{28}\text{O}_8$ (v. Bonttron-Charlard, J. Pharm. Chim. 8, 131; Spirgatis, J. pr. Chem. [i.] 92, 97).

TURPETHIN v. GLUCOSIDES.

TURQUOISE or CALAITE (Turkic, Ger.). A gem-stone which has often been regarded as a hydrated aluminium phosphate

accidentally coloured by copper and iron phosphates. It has been shown, however, by S. L. Penfield (Amer. J. Sci. 1900, 10, 346) that the latter enter into the constitution of the mineral, and he writes the formula

representing a derivative of orthophosphoric acid with the hydrogen atoms largely replaced by the univalent radicles $Al(OH)_2$, &c. In some analyses approximately two-thirds of the hydrogen atoms are so replaced, and the formula becomes $R_2'HPO_4$. The amount of copper ranges from 2.0 to 8.5 p.c. CuO , and the iron from 0.1 to 4.0 p.c. Fe_2O_3 . The mineral is soluble in hydrochloric acid without discoloration; when heated it loses water and blackens. It is opaque (or translucent in thin chips) with a sky-blue to green colour, and on the polished surface shows a soft, waxy lustre; sp.gr. 2.6-2.8; H. 6. Turquoise occurs as cryptocrystalline masses, sometimes with nodular or stalactitic surfaces, in crevices in rocks, more especially in those of volcanic origin. The best quality of material has for centuries been mined near Nishapur in Persia, and being exported to the west through Turkey it came to be known as turquoise. Deposits in the Sinai Peninsula were worked by the ancient Egyptians. Ancient mines, worked in prehistoric times, are also known in Mexico and in the state of New Mexico. Considerable quantities (17 tons in 1909, and 8½ tons in 1910) are now obtained from Nevada, New Mexico, Arizona, California, and Colorado (D. B. Sterrett, Min. Res. U.S., Annual Reports for 1910 and earlier). Minute crystals of turquoise have been described from Campbell Co., Virginia; these are triclinic and isomorphous with chalcosiderite. Analysis of them gave the formula $CuO \cdot 3Al_2O_3 \cdot 2P_2O_5 \cdot 9H_2O$; written in the form of Penfield's formula this becomes

(W. T. Schaller, Amer. J. Sci. 1912, 33, 35).

Turquoise has been imitated by subjecting to pressure a mixture of aluminium and copper phosphates. Very clever imitations are also made of glass; these may be detected by the bright, glassy, conchoidal fracture when chipped at the edges—the fracture of turquoise being dull and finely granular.

Bone-turquoise or **odontolite** is fossil bone or ivory coloured by the iron phosphate vivianite, or perhaps sometimes artificially stained by a copper solution. It can be recognised under the microscope by its organic structure. It effervesces with acid, and gives a smell of burning when heated.

L. J. S.

TUSSOL. Antipyrine mandelate.

TUTENAG or **TUTENAGUE.** Chinese silver. *Packfong.* An alloy resembling German silver.

TUTOCALINE. A local anæsthetic of the novocaine type (cf. Vol. vi. p. 637). Its action is more powerful than that of novocaine (Schulemann, Lancet, 1924, 206, 965; Pharm. J. 1924, 113, 46; Wagner, Arch. Exp. Path. Pharm. 1925, 109, 64; Chem. Soc. Abstr. 1925, 128, i. 1503).

TYLCAISIN (*kalmopyrin*). Trade name for calcium acetyl salicylate.

TYLLITHIN (*appron*). Trade name for lithium acetyl salicylate.

TYLNATIN. Trade name for acetyl-o-

coumaric acid, used in the treatment of inoperable cancer.

TYLNATRIN. Trade name for sodium acetyl salicylate.

TYNDALLMETER. See NEPHELOMETRY.

TYPE METAL v. TIN.

TYRAMINE. Trade name for *p*-hydroxyphenylethylamine hydrochloride, v. ERGOT.

TYRIAN PURPLE v. PURPLE OF THE ANCIENTS. In Costa Rica a dyestuff apparently of the 'Tyrian purple' class is obtained from shell-fish, and is used for dyeing silk thread a fast purple colour.

TYROSINE, *p*-hydroxyphenylalanine, *p*-hydroxy-β-phenyl-α-aminopropionic acid

was so named by Leibig, who first obtained it by fusing freshly prepared cheese (*rupós*) with caustic potash (Annalen, 1846, 57, 127). It occurs widely spread both in the animal and vegetable kingdoms, forming one of the most common products of proteid hydrolysis, and occurring in the free state in the seedlings and young shoots of the vetch (*Vicia sativa*) (Gorup-Besanez, Ber. 1877, 10, 781); the gourd (*Cucurbita pepo*) (Schulze and Barbieri, *ibid.* 1878, 11, 710, 1233); the lupins (*Lupinus luteus*, *L. albus*) (Schulze, *ibid.* 1878, 12, 1924; Wassilieff, Landw. Versuchs Stat. 1901, 55, 45); in the tubers of potatoes (*Solanum tuberosum*) (Schulze, Ber. 1879, 12, 1924), the swede (*Brassica rapa*), the dahlia (*Dahlia variabilis*) (Borodin, Botan. Zeit. 1882, 590; Leitgeb, Chem. Zentr. 1888, 1397; Bertrand, Compt. rend. 1896, 122, 1215); in the tubercules of *Stachys tubifera* (Planta and Schulze, Ber. 1890, 23, 1698); in the juice of sugar beet (*Beta vulgaris*) (v. Lippmann, *ibid.* 1884, 17, 2835), in celery (*Apium graveolens*) (Bamberger and Landsiedl, Monatsh. 1904, 25, 1030); in the unripe seeds of the French bean (*Phaseolus vulgaris*) (Pfenninger, Ber. Deut. bot. Ges. 1909, 27, 227), the pea (*Pisum sativum*) (Schulze and Winterstein, Zeitsch. physiol. Chem. 1910, 65, 431); in the green pods of the broad bean (Bourquelot and Hérissé, J. Pharm. Chim. 1898 [vi.] 8, 385); in the juice of elderberries (*Sambucus nigra*) (Sack and Tollens, Ber. 1904, 37, 4115); in fungi (Winterstein, Zeitsch. physiol. Chem. 1899, 26, 438). In the animal kingdom, tyrosine is found in caterpillars, crabs, spiders, and beetles (v. Lippmann, *l.c.*) and in cochineal (Warren de la Rue, Annalen, 1848, 64, 1); in the larva of *Lucilia Caesar* (Gessard, Compt. rend. 1904, 139, 644); it occurs in Emmenthaler and in Roquefort cheeses (Benecke and Schulze, Landw. Jahrbücher, 1887, 16, 317; Winterstein and Thöny, Zeitsch. physiol. Chem. 1902, 36, 28; Dox, J. Amer. Chem. Soc. 1911, 33, 423). Under normal conditions, tyrosine is not found in the liver or blood of men and animals, but occurs under certain pathological conditions (Frerichs and Staedeler, J. 1856, 702; Hoppe-Seyler, Zeitsch. physiol. Chem. 1881, 5, 348; Neuberg and Richter, Deut. med. Wochensach. 30, 499; Huber, Archiv. Heilkunde, 18, 485; Wyss, Schweiz. Zeitsch. Heilkunde, 1864). The presence of tyrosine in muscle and in all other organs which do not normally contain products of digestion suggests putrefaction (Pietre, Compt. rend. 1914, 158, 1934); v. Juge (J. Pharm. Chim. 1913, [vii.] 8, 559) for its presence

in urine. It can be detected by the Frerichs-Städeler method in normal or pathological urines, in quantities of 0.2 gram in 400 c.c. of urine and by Lippich's method in quantities of 0.01-0.02 gram in 100 c.c. Tyrosine is sometimes present in cases of acute yellow atrophy (Schumm and Papendieck, *Zeitsch. physiol. Chem.* 1922, 121; 1).

Preparation.—Tyrosine is most conveniently prepared from silk by hydrolysing with fuming hydrochloric acid, and evaporating the product under reduced pressure to dryness; the residue is dissolved in water and a stream of ammonia passed through the solution; it is then again evaporated to dryness, and the residue treated with cold water, when the tyrosine is left undissolved; or the whole residue may be boiled with water and animal charcoal, and from the filtrate pure tyrosine crystallises out quantitatively: one kilo of silk yielding 50.65 grms. of tyrosine (Abderhalden, *Zeitsch. physiol. Chem.* 1912, 77, 75; Abderhalden and Teruuchi, *ibid.*, 1906, 48, 528). Marshall (J. Biol. Chem. 1913, 15, 85) recommends obtaining it from the pancreatic digestion of caseinogen; the liquid on cooling deposits an abundant crystalline yield of tyrosine.

For the preparation of tyrosine from peptones, see Beijerinck (*Chem. Weekblad*, 1919, 16, 1494).

Synthesis.—Staedeler (*Annalen*, 1860, 116, 57) was the first to show that tyrosine was an aromatic compound, since it yielded chloranil (tetrachloroquinone) on treatment with chlorine; but its constitution as *p*-hydroxy- β -phenyl- α -aminopropionic acid was not established until 1882 when Erlenmeyer and Lipp (*Ber.* 1882, 15, 1544; *Annalen*, 1883, 219, 161) prepared racemic tyrosine from phenylacetaldehyde by the following series of reactions: *phenylacetaldehyde* on treatment with hydrogen cyanide gave *phenyllactonitrile*; this was converted by ammonia into the *nitrile* of *phenylalanine* which, on hydrolysis, gave *phenylalanine*; *p*-nitro-*phenylalanine* on reduction gave the corresponding amino compound from which *p*-hydroxyphenylalanine (*r*-tyrosine) was produced by the action of nitrous acid.

A more convenient method of synthesis is that due to Erlenmeyer jun., and Halsey (*Annalen*, 1899, 307, 138), in which *p*-hydroxybenzaldehyde and hippuric acid condense in the presence of acetic anhydride and anhydrous sodium acetate to form the *acetyl* derivative of the *lactimide* of *p*-hydroxy- α -benzoylamino-

cinnamic acid, $\text{OAc}\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{C} \begin{smallmatrix} \text{NBz} \\ \text{CO} \end{smallmatrix}$. This, on hydrolysis with alkali, gives *p*-hydroxy- α -benzoyl-aminocinnamic acid

from which by reduction *benzoyltyrosine*

is obtained and converted by hydrolysis with

acids into *r*-tyrosine. Another method of synthesis which can also be extended to the preparation of halogenated derivatives of tyrosine is described by Wheeler and Hoffmann (*Amer. Chem. J.* 1911, 45, 368; cf. Wheeler, Hoffmann and Johnson, *Bio-Chem. J.* 1911, 10, 147; Johnson and Bengis, *J. Amer. Chem. Soc.* 1912, 34, 1061). This method consists in condensing a suitable aldehyde with hydantoin, reducing and hydrolysing the product; thus hydantoin and anisaldehyde yield *anteylidene-*

when boiled with hydrogen iodide is converted into *tyrosine* together with a small quantity of 4-*p*-hydroxybenzoylhydantoin (*tyrosinehydantoin*)

from which tyrosine can be obtained by boiling with baryta water; *dl*-tyrosine may also be synthesised by condensing ethyl phthalimino-malonate with *p*-methoxybenzyl bromide and hydrolysing the product (Stephen and Weizmann, *Chem. Soc. Trans.* 1914, 105, 1152).

Properties.—*l*-Tyrosine, the natural product, is also obtained by the resolution of *dl*-benzoyltyrosine through its brucine salt and subsequent hydrolysis of the *l*-benzoyltyrosine. It crystallises in long flexible silky needles, soluble in 2491 parts of water at 17° (Erlenmeyer and Lipp, *l.c.*), more readily soluble in hot water; dissolves in 13,500 parts of cold 90 p.c. alcohol (Staedeler, *l.c.*), insoluble in acetone, ether or absolute alcohol. It melts and decomposes at 314°–318° (corr.) when rapidly heated (Fischer, *Ber.* 1899, 32, 3638); at 295° (Cohn, *Zeitsch. physiol. Chem.* 1896, 22, 166); at 272° (Habermann and Ehrenfeld, *ibid.* 1902, 37, 18); 287° (*Trans. Guinness Lab.* 1903, i. 57). *l*-Tyrosine is levorotatory both in acid and in alkali solution; the specific rotation varies with the concentration. For a 4 p.c. solution in 21 p.c. hydrochloric acid, the natural product has $[\alpha]_D^{16} = -7.98^\circ$ (Mauthner, *Monatsh.* 1882, 3, 345), $[\alpha]_D^{20} = -8.07^\circ$ (Landolt, *Ber.* 1884, 17, 2838); $[\alpha]_D = -8.48^\circ$ (Schulze, *Zeitsch. physiol. Chem.* 1884, 9, 98); the synthetic product has $[\alpha]_D^{20} = -8.64^\circ$ (Fischer, *Ber.* 1899, 32, 3638). In a 4.6 p.c. solution in 4 p.c. hydrochloric acid, the synthetic compound has $[\alpha]_D^{20} = -13.2^\circ$ (Fischer), and the natural product $[\alpha]_D^{16} = -14.6^\circ$ to -16.1° (Schulze and Winterstein, *Zeitsch. physiol. Chem.* 1902, 35, 299); in a 5.8 p.c. solution of 11.6 p.c. potassium hydroxide, the natural product has $[\alpha]_D = -9.01^\circ$ (Mauthner, *l.c.*). The molecular heat of combustion is 1071.2 Cal., heat of formation 156.4 Cal. (Berthelot and André, *Compt. rend.* 1890, 110, 884). The affinity constants of tyrosine are: first acid dissociation constant $K_s = 4 \times 10^{-9}$, second acid dissociation constant $K_s = 4 \times 10^{-10}$, basic dissociation constant $K_b = 2.6 \times 10^{-11}$ (Kanits, *Pflügers Archiv.* 1907, 118, 589). The single band ultra violet absorption spectrum exhibited by solutions of tyrosine, is practically identical with that of proteids containing tyrosine;

gelatin, and other proteids that contain no tyrosine show continuous spectra (Blyth, Chem. Soc. Trans. 1899, 1164). Tyrosine is not affected by diazomethane (Geake and Nierenstein, Bio-Chem. J. 1915, 9, 309). For the oxidation of tyrosine, v. Denis (J. Biol. Chem. 1911-12, 10, 73).

L-N-methyltyrosine,

may be obtained from natural *L*-tyrosine by means of the monotoluene sulphonyl derivative; it has $[\alpha]_D^{21} + 19.75$, and it is identical with natural ratatine (Fischer and Lipschitz, Ber. 1915, 48, 360).

d-Tyrosine, obtained by the resolution of *dl*-benzoyltyrosine through its cinchonine salt and subsequent hydrolysis, has $[\alpha]_D^{20} + 8.64^\circ$ in 4.6 p.c. solution of 21 p.c. hydrochloric acid (Fischer); the dextrorotatory tyrosine obtained by v. Lippmann from the white shoots of sugar beet gave $[\alpha]_D = +6.85^\circ$ in 25 p.c. hydrochloric acid; a feebly dextrorotatory tyrosine was found by Winterstein and Thöny (Zeitsch. physiol. Chem. 1902, 36, 28) in a very old Emmenthaler cheese.

dl-Tyrosine prepared by hydrolysis of the synthetic benzoyl derivative crystallises in stout needles, melting and decomposing at 316° (corr.) when rapidly heated (Fischer, *l.c.*); its hydrochloride is much less soluble in concentrated hydrochloric acid than are the salts of the optically active forms, and the racemic compound can thus be separated from admixture with *d*- and *l*-tyrosine. By fermentation with large amounts of yeast in the presence of sugar and nutritive salts, tyrosine is converted to the extent of 60-80 p.c. into *p*-hydroxyphenylethanol (tyrosol) $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{CH}_2\text{OH}$, m.p. 93° , b.p. 310° (compare also Hirai, Acta Scholae Med. Univ. Imperial, Kido, 1918, 2, 425). The *dibenzoyl derivative* melts at 111° ; tyrosol is also obtained by the action of yeast on *p*-hydroxyphenylethylamine (Ehrlich, Ber. 1911, 44, 139; Ehrlich and Pishtschimuka, *ibid.* 1912, 45, 1006). According to Teudji (Acta Schol. Med. Kyoto, 1917, 1, 439, from Physiol. Abstr. 1917, 2, 320; 1918, 3, 165) *Bacillus proteus vulgaris* attacks *r*-tyrosine, and 65.7 p.c. of *d*-tyrosine can be isolated. Tyrosine is converted to *p*-hydroxyphenylethylamine to the extent of 78.7 p.c. by the action of *B. coli* in a suitable medium (Sasaki, Biochem. Zeitsch. 1914, 59, 429). Bacterial action degrades tyrosine to phenol by removal of the alanine side-chain. Sieke (Z. Hyg. 1921, 94, 314) describes experimental conditions for the culture of phenol-forming bacteria and the morphological, cultural, and serological behaviour of *Bacillus coli phenologenes* and *B. paracoli phenologenes*. Varieties of *B. coli* capable of forming phenol are widely distributed.

By putrefactive decomposition, tyrosine is successively broken down into hydro-*p*-coumaric acid $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$, *p*-hydroxyphenylacetic acid $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$, *p*-cresol and phenol (Baumann, Ber. 1880, 13, 279; Zeitsch. physiol. Chem. 1880, 4, 304). The administration of tyrosine to normal animals causes the production of phenol in the urine, but no excess of hydroxy acids (Blendermann, *ibid.* 1882, 6,

234; Bied. Zentr. 1883, 209; Cohn, Zeitsch. physiol. Chem. 1894, 14, 189), except in one case when a man took 50 grms. of tyrosine in 24 hours, and this produced alcaptonuria, homogentisic acid being found in the urine (Abderhalden, *ibid.* 1912, 77, 454). Inactive tyrosine administered to cats undergoes selective decomposition, so that the urine contains more of the dextro- than of the naturally occurring laevo- variety, and on evaporating the neutral or alkaline urine containing the tyrosine, it is converted into the corresponding uramino acid which, on subsequent treatment with acid, readily loses water, yielding tyrosine hydantoin (Dakin, J. Biol. Chem. 1910, 8, 25). In the case of alcaptonurics, the administration of tyrosine or certain derivatives of tyrosine, such as mono-palmityl-*l*-tyrosine, distearyl-*l*-tyrosine, *p*-aminotyrosine, causes an increase in the amount of homogentisic acid excreted (Abderhalden and Massini, Zeitsch. physiol. Chem. 1910, 66, 140; Wolkow and Baumann, *ibid.* 1891, 15, 228).

Detection and estimation.—Tyrosine develops a red colour when warmed with Millon's reagent, and can be estimated by means of this reaction (Weiss, Biochem. Zeitsch. 1919, 97, 170). When tyrosine is dissolved in a few drops of warm concentrated sulphuric acid, and the diluted solution neutralised with barium carbonate, the filtrate gives a beautiful violet colour with ferric chloride (Pirea, Annalen, 1852, 82, 252). If a few drops of a solution of tyrosine are added to 2 c.c. of sulphuric acid containing 3 to 5 drops of a solution of aldehyde in twice its volume of alcohol of 90° , the liquid acquires a gooseberry red colour, the intensity of which is proportionate, between certain limits, to the quantity of tyrosine present (Denigès, Compt. rend. 1900, 130, 583). When tyrosine is added to a reagent consisting of 1 part of formalin, 45 parts of water and 55 parts of concentrated sulphuric acid, a green coloration is developed on boiling the mixture (Mürner, Zeitsch. physiol. Chem. 1902, 37, 86). Cf. Totani (Bio-Chem. J. 1915, 9, 391).

Tyrosine develops a rose-red colour under the influence of *tyrosinase*, the colour changing to a dirty violet, and finally a black precipitate of melanin is deposited (*v. Tyrosinase, art. FERMENTATION*). See also Raper and Wormal (Bio-Chem. J. 1925, 19, 84); Happold and Raper (Bio-Chem. J. 1925, 19, 92); Gortner (Proc. Soc. Exp. Biol. Med. 1924, 21, 543; Chem. Soc. Abstr. 1925, 128, i. 474).

Tyrosine is readily estimated by titration with *N/5* sodium bromate in the presence of hydrochloric acid and sodium bromide, the liberated bromine being absorbed by the tyrosine with formation of dibromotyrosine (Millar, Trans. Guinness Lab. 1903, I. Part 1; Brown and Millar, Chem. Soc. Trans. 1906, 145). For the estimation of tyrosine in proteins, v. Plimmer and Eaves (Bio-Chem. J. 1913, 913, 7, 297); Johns and Jones (J. Biochem. 1918, 36, 319).

For the estimation of tyrosine in the presence of uric acid, see Herzfeld and Klinger (Biochem. Zeitsch. 1918, 88, 283; Fürth and Fleischmann (Biochem. Zeitsch. 1922, 127, 137); Folia and Looney (J. Biol. Chem. 1922, 51, 421).

For a microchemical method of estimating

tyrosine, *see* Hanke and Koessler (J. Biol. Chem. 1922, 50, 235).

Salts and derivatives.—*L*-Tyrosine forms crystalline salts with mineral acids which dissociate in water, the *hydrochloride* $C_9H_{11}O_3N \cdot HCl \cdot 2H_2O$, *hydrobromide* $C_9H_{11}O_3N \cdot HBr$, *hydriodide*

nitrate $C_9H_{11}O_3N \cdot HNO_3$, and *sulphate*

are described (Haushofer, J. 1883, 1177; Aloy and Rabaut, Bull. Soc. chim. 1908, [iv.] 3, 391; Staedeler, Annalen, 1860, 116, 64); the *platinichloride* $(C_9H_{11}O_3N \cdot HCl)_2PtCl_4$ forms yellowish-brown readily soluble crystals (Gintl, Zeitsch. Chem. 1869, 704); the *picrolonate* blackens and sinters at 260° (Levene and van Slyke, J. Biol. Chem. 1912, 12, 127). The following metallic salts have been prepared, those of the heavy metals and the alkaline earth metals are sparingly soluble; the *copper salt* $(C_9H_{10}O_3N)_2Cu$ dissolves in 1230 parts of cold or 240 parts of boiling water (Hofmeister, Annalen, 1977, 189, 24); the *silver salts* $C_9H_9O_3NAg_2 \cdot H_2O$

the *mercury salts*, $C_9H_{11}O_3N \cdot 2HgO \cdot 2H_2O$

$C_9H_{11}O_3N \cdot 2HgO \cdot H_2O$ and $C_9H_{11}O_3N \cdot 3HgO \cdot H_2O$ the *barium salt* $(C_9H_{10}O_3N)_2Ba$; *calcium salt* $C_9H_9O_3N_2Ca$, the *mercury-calcium salt*

and the *sodium salt* $C_9H_9O_3NNa_2$ (Vintschgau, J. 1869, 895; Baumann, Zeitsch. physiol. Chem. 1880, 4, 320; Causse, Compt. rend. 1900, 130, 1196). Certain mercury salts are of therapeutic application, *v.* Dr. Bayer & Co., D. R. PP. 267411, 267412, and Hoffmann-La Roche & Co., D. R. P. 279957).

L-Tyrosine methyl ester $C_9H_{11}O_3N \cdot CH_3$ forms colourless prisms, m.p. 135°–136° (corr.); $[\alpha]_D^{20} = +25.75^\circ$ in methyl alcohol solution; the *hydrochloride* $C_9H_{10}O_3N \cdot CH_3 \cdot HCl$ forms colourless needles; *L*-tyrosine ethyl ester

has m.p. 108°–109°, $[\alpha]_D^{20} = +20.4^\circ$ in 5 p.c. alcoholic solution; the *hydrochloride*

has m.p. 166° (Fischer and Schrauth, Annalen, 1907, 354, 21; Fischer, Ber. 1908, 41, 850; Lilienfeld, Archiv. Physiol. 1894, 383, 555; Röhmman, Ber. 1897, 30, 1978; Fischer, *ibid.* 1901, 34, 433). Tyrosine amyl ester, m.p. 68°–70°, yields a hydrochloride, m.p. 181°–182° (Curtius and Donselt, J. pr. Chem. 1917, [ii.] 95, 327).

L-Tyrosine anhydride $C_{18}H_{18}O_4N_2$ has m.p. 277°–280° (corr.), $[\alpha]_D^{20} = -223.8^\circ$ in N/1 sodium hydroxide (Fischer and Schrauth); *cf.* Graziani (Atti R. Accad. Lincei, 1916, [v.] 25, 1, 500); an anhydride $(C_9H_9O_3N)_2$, slender white crystals, m.p. 278°–279° (uncorr.), and an isomeric anhydride, a powder, m.p. 279°, are described. *d*-Tyrosine anhydride, m.p. 273°, has $[\alpha]_D = +37.59^\circ$ in alkaline solution, and $[\alpha]_D = +93.87^\circ$ in acid solution (Fränkel and Feldsberg, Biochem. Zeitsch. 1921, 120, 218).⁴ *L*-Tyrosineamide $C_9H_{10}ON \cdot CONH_2$ has m.p. 153°–154° and

$[\alpha]_D^{20} = +19.47^\circ$, condenses readily with ethyl chlorocarbonate to form the *monocarbethoxyl*

m.p. 155°–157°, and the *dicarbethoxyl*

m.p. 185° (corr.), derivatives; the *dinaphthalene-sulphonyl derivative* $C_{22}H_{18}O_3N_2S_2$ has m.p. 204° (corr.) (Koenigs and Mylo, Ber. 1908, 41, 4427).

The following *acyl derivatives* of *L*-tyrosine are described: *N*-acetyl-*L*-tyrosine, m.p. 165°, by methylation with methyl sulphate gives *N*-acetyl-*O*-methyl-*L*-tyrosine, m.p. 147°–148°, which on hydrolysis yields *O*-methyl-*L*-tyrosine, m.p. 243° (Karrer, Gisler and others, Helv. Chim. Acta, 1922, 5, 469); the *benzoyl derivative*

m.p. 165°–166° (corr.), $[\alpha]_D^{20} = +19.25^\circ$ in 8 p.c. alkali solution, the *brucine salt* is crystalline; the *dibenzoyl derivative*

has m.p. 211°–212° and forms a *potassium* and a *cadmium salt* (Fischer, Ber. 1899, 32, 3638, 2454); the *formyl derivative*

m.p. 171°–174° (corr.), $[\alpha]_D^{20} = +84.8^\circ$ in 6 p.c. alcoholic solution (Fischer, *ibid.* 1907, 40, 3704); the *palmityl derivative*

m.p. 133°, $[\alpha]_D^{20} = +24.35$ in 1.8 p.c. alcoholic solution; *palmityl-L*-tyrosine-*palmitylether* $C_{41}H_{71}O_5N$, m.p. 95°–96°, $[\alpha]_D^{20} = +15.28^\circ$ in 1.7 p.c. alcoholic solution; *stearyl-L*-tyrosine-*stearylether* $C_{45}H_{79}O_5N$, m.p. 98°–108° (Abderhalden and Funk, Zeitsch. physiol. Chem. 1910, 65, 61); *glycyl-L*-tyrosine methyl ester, m.p. 123°–124° (Geake and Nierenstein, Bio-Chem. J. 1915, 9, 309); the β -*naphthalene-sulphonyl derivative* forms a *hydrochloride* $C_{21}H_{19}O_3NSCl$, m.p. 170°, a *sodium salt* $C_{21}H_{18}O_3NSNa$, that decomposes at 175°, an *ethyl ester* $C_{21}H_{21}O_3NS$, m.p. 140°–143° (Abderhalden and Funk, *ibid.* 1910, 64, 436); the *di-β-naphthalenesulphonyl derivative* $C_{30}H_{26}SO_4 \cdot O \cdot C_6H_4 \cdot CH_2 \cdot CH(CO_2H) \cdot NH \cdot SO_2 \cdot C_{10}H_7$, m.p. about 120°, forms a *sodium salt*

m.p. 252°–254°, an *ammonium* and a *barium salt* (Fischer and Bergel, Ber. 1903, 36, 2592); the *phenylisocyanate derivative*

has m.p. 104°, and forms a *barium*

and a *silver salt* $C_{18}H_{18}O_4N_2Ag \cdot H_2O$ (Paal and Zitelmann, *ibid.* 1903, 36, 3337); the α -*naphthylisocyanate derivative* melts at 205°–206° (Neuberg and Manasse, *ibid.* 1905, 38, 2359).

For the *hydrazides* of the esters of tyrosine and benzoyltyrosine, *see* Curtius and Donselt (J. pr. Chem. 1917, [ii.] 95, 327).

dl-Tyrosinylcarbamide

decomposes at 240° (Hugouvenq and Morel,

Compt. rend. 1906, 142, 48); *l*-tyrosinehydantonic acid $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{CH}(\text{CO}_2\text{H})\text{NH}\cdot\text{CONH}_2$, m.p. 218°, forms a crystalline silver salt (Jaffé, Zeitsch. physiol. Chem. 1882, 7, 306).

l-Tyrosinehydantoin $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{CH}$ $\begin{matrix} \text{NH}\cdot\text{CO} \\ | \\ \text{CO}\cdot\text{NH} \end{matrix}$ melts and decomposes at 242°–245° (Blendermann, l.c.).

Tyrosyl-glycinehydantoin

has m.p. 217°–218° (Johnson and Hahn, J. Amer. Chem. Soc. 1917, 39, 1255).

The alkaloid *surinamine* or *geoffroyine* from *geoffroya* bark is a *methyltyrosine*, in which the methyl has replaced one of the hydrogens of the amino group (Hiller-Bombien, Arch. Pharm. 230, 513; Blau, Zeitsch. physiol. Chem. 1908, 58, 153; Walpole, Chem. Soc. Trans. 1910, 97, 94).

O-Methyltyrosine choline forms a crystalline iodide, m.p. 137°–139°, the aurichloride has m.p. 112°–115°; the platinichloride, m.p. 204°.

Tyrosine-choline yields a crystalline iodide, m.p. 176°, and chloride (Karrer, Gisler and others, l.c.).

Derivatives of *l*-tyrosine containing substituents in the aromatic nucleus are: 3-nitro-*l*-tyrosine $\text{C}_8\text{H}_9\text{O}_5\text{N}_2$, obtained by nitration of *l*-tyrosine, forms yellow needles, m.p. 222°–224° (decomp.); $[\alpha]_D^{25} + 3.21^\circ$, hydrochloride, m.p. 237° (decomp.); cf. Johnson and Kohmann (J. Amer. Chem. Soc. 1915, 37, 1863 and 2598); Waser and Lewandowski (Helv. Chim. Acta, 1921, 4, 657). The barium and silver salts have been prepared, also the nitrate and sulphate (Strecker, Annalen, 1850, 73, 70; Casimir Funk, Chem. Soc. Trans. 1912, 1004). 3-Amino-*l*-tyrosine $\text{C}_8\text{H}_{11}\text{O}_3\text{N}_2$, needles, m.p. 287.5° (decomp.), $[\alpha]_D^{15} - 3.61^\circ$; hydrochloride, prisms, m.p. 175° (decomp.) (Waser and Lewandowski, l.c.), prepared by reducing nitrotyrosine. 3:5-Dinitrotyrosine $\text{C}_8\text{H}_5\text{O}_5\text{N}_2(\text{NO}_2)_2\cdot\text{H}_2\text{O}$, golden yellow crystalline plates, the ammonium and mercury salts, also the hydrochloride and the hydantoin and thiohydantoin derivatives have been prepared (Johnson and Kohmann, l.c. 2164).

Tyrosine sulphonic acid

is strongly acidic and gives a beautiful violet colour with ferric chloride. The ammonium, calcium and barium salts are described (Staedeler, l.c.).

3-Bromotyrosine

has a sweet taste, decomposes at 247°–248°; the hydrobromide decomposes at 190°–191°, the picrate and platinichloride are very soluble in water (Johnson and Bengis, J. Amer. Chem. Soc. 1912, 34, 1061).

3:5-Dibromo-*l*-tyrosine, m.p. about 245°

(decomp.), prepared by the action of bromine vapour on the finely divided tyrosine (Mörner, Zeitsch. physiol. Chem. 1913, 88, 124), is obtained in anhydrous, long, slender needles grouped into bundles or in thin plates hydrated with two molecules of water; it has $[\alpha]_D^{20} + 1.3^\circ$, dissolves in 218 parts of water at 16° or 26 parts of boiling water; the silver salt, the hydrochloride, hydrobromide and sulphate are crystalline, and it forms an unstable perbromide (Gorup-Besanez, Annalen, 1863, 125, 281; Millar, Trans. Guinness Lab. 1903, I. Part 1). 3:5-Di-bromo-*dl*-tyrosine crystallises with one molecule of water in transparent four-edged prisms or thick plates, m.p. about 245° (decomp.); it is nearly twice as soluble in water as the *l*-isomeride, it is not decomposed by concentrated sulphuric acid even on heating (Mörner, l.c.).

Chlorotyrosine, formed by the action of sulphuryl chloride on tyrosine suspended in acetic acid, melts at 257° and forms a benzoyl derivative, m.p. 195°, and a formyl derivative, m.p. 198° (Zeynek, Zeitsch. physiol. Chem. 1925, 144, 246).

3:5-Dichlorotyrosine, m.p. 252° (decomp.), prepared by chlorinating tyrosinehydantoin and decomposing with barium hydroxide the resulting 3:5-dichlorotyrosinehydantoin; the hydrochloride has m.p. 260°–265° (Wheeler, Hoffmann and Johnson, J. Biol. Chem. 1911, 10, 147). 3:5-dichloro-*l*-tyrosine, prepared by the action of chlorine on tyrosine in the presence of glacial acetic acid, has m.p. 256°–260° (decomp.), and the anhydrous hydrochloride gives in 5 p.c. aqueous solution $[\alpha]_D^{20} - 7.8^\circ$ (Zeynek, Zeitsch. physiol. Chem. 1921, 114, 275).

3:5-Di-iodotyrosine, iodogorgonic acid

is not found free in nature but is one of the constituent amino acids of certain proteids; it was first obtained by Dreschel (Zeitsch. Biol. 1896, 33, 85) from *gorgonin*, derived from the horny skeleton of *Gorgonia cavolinii*. This, on hydrolysis with barium hydroxide, yielded an iodo amino acid, hence name *iodogorgonic acid*. It was shown by Wheeler and Jamieson (Amer. Chem. J. 1905, 33, 365) that iodogorgonic acid is a di-iodotyrosine and can be prepared by the direct action of iodine on tyrosine. That it is the 3:5-di-iodotyrosine was shown later by Wheeler and Johns (*ibid.* 1910, 43, 11), for on treatment with methyl iodide and potassium hydroxide it yields the methylether of a di-iodotyrosinetrimethylammonium iodide

which on boiling with sodium hydroxide yields 3:5-diiodo-*p*-methoxyloinnamate. Iodogorgonic acid occurs in a large number of proteids, and has been isolated from *iodo-albacid*, *iodoglidin*, *iodocasein*, *gorgonin* and *spongine* (Oswald, Zeitsch. physiol. Chem. 1911, 70, 310; 71, 200; 74, 290; 75, 353).

3:5-Di-iodo-*dl*-tyrosine, prepared by hydrolysis of the above-mentioned proteids, crystallises from hot water in glassy right-angled plates, from alcohol in hexagonal plates, dissolves in 2164 parts of water at 15°, melts and decomposes at 200°.

3:5-Di-iodo-*l*-tyrosine, prepared by the

action of iodine on *L*-tyrosine, melts at 204° (Oswald), 196°–205° with decomposition (Wheeler and Jamieson); it has $[\alpha]_D^{20} = +2.27^\circ$ in 4.5 p.c. solution of 25 p.c. ammonia (Abderhalden and Guggenheim, *Zeitsch. physiol. Chem.* 1907, 54, 331). The hydrochloride

forms colourless needles, decomposed by water; the sulphate $\text{C}_9\text{H}_9\text{O}_3\text{NI}_2\cdot\text{H}_2\text{SO}_4$ is readily soluble; the silver salt $\text{C}_9\text{H}_9\text{O}_3\text{NI}_2\cdot\text{Ag}_2$ and copper salt $(\text{C}_9\text{H}_9\text{O}_3\text{NI}_2)_2\cdot\text{Cu}\cdot\text{H}_2\text{O}$ form amorphous precipitates. The acetyl derivative

decomposes at 225° (Wheeler and Jamieson, *Amer. Chem. J.* 1905, 33, 365). The methyl ester $\text{C}_9\text{H}_9\text{OI}_2\cdot\text{CH}_3\cdot\text{CH}(\text{NH}_2)\text{CO}_2\text{Me}$ decomposes at 192°; its hydrochloride forms colourless needles that decompose at 211° (corr.), and yields the nitrate on treatment with dilute nitric acid (Abderhalden and Guggenheim, *Ber.* 1908, 41, 1237). *Palmityl-3.5-di-iodo-tyrosinepalmityl ether* $\text{C}_{44}\text{H}_{84}\text{O}_8\text{NI}_2$ melts at 55°–60° (Abderhalden and Slavu, *Zeitsch. physiol. Chem.* 1909, 61, 405).

Tyrosinebisazobenzenearsenic acid

is a yellow microcrystalline powder which is insoluble in the usual organic solvents (Pauly, *Zeitsch. physiol. Chem.* 1915, 94, 234).

For the synthesis of *o*-tyrosine, v. Johnson and

Scott (*J. Amer. Chem. Soc.* 1915, 37, 1846). Starting with 2-thiohydantoin *o*-tyrosine-hydantoin is prepared, and this on hydrolysis with barium hydroxide yields *o*-tyrosine

m.p. indefinite; the hydrochloride crystallises from dilute hydrochloric acid in prismatic crystals which decompose at 180°.

A full account of the chemistry and physiological properties of tyrosine will be found in *Biochemisches Handlexikon*, von Abderhalden, vol. iv. part 2, 681–702. M. A. W.

TYSONITE. Fluoride of cerium metals (Ce, La, Di) F_3 , crystallised in the hexagonal system. It is pale wax-yellow with resinous lustre, and a perfect pearly cleavage parallel to the basal plane. Sp.gr. 6.13. The mineral alters very readily to the fluo-carbonate bastnäsité, and the chestnut-brown crystals as usually found are really pseudomorphs of bastnäsité after tysonite with sometimes still a nucleus of the original mineral. Crystals and irregular masses up to several pounds in weight are found at several places in the coarse-grained granite of the Pike's Peak district in El Paso Co., Colorado. P. Geijer (*Geol. För. Förh. Stockholm*, 1921, 43, 19) suggests that tysonite is identical with the Swedish fluorite. L. J. S.

TYUYAMUNITE v. TURANITE.

U

UARANA v. GUARANA.

ULCO. An alloy of lead with small amounts of barium and calcium, used as a substitute for antimonial lead in the manufacture of shrapnel. It is suggested that it may be employed as a bearing metal on account of its high melting-point, excellent structure, and low coefficient of friction.

ULEXINE v. CYTISINE.

ULEXITE (*Boronatrocalcite* of G. L. Ulex, 1849; *Natroborocalcite*). A hydrated borate of sodium and calcium $\text{NaCaB}_5\text{O}_9\cdot 8\text{H}_2\text{O}$, containing 43.0 p.c. B_2O_3 ; sp.gr. 1.65; H. 1; slightly soluble in hot water, and readily soluble in acids. It forms rounded, white masses, 2–3 ins. in diameter, consisting of a loose aggregate of fine, silky fibres; hence the popular name 'cotton-ball.' It occurs abundantly in the borate deposits of Nevada and California, and forms the main mass of those near Iquique in Chile, and Jujuy province in Argentina. L. J. S.

ULLMANNITE. Nickel sulph-antimonide NiSbS , crystallised in the cubic system with tetrahedral symmetry. The antimony is sometimes partly replaced by arsenic; and in the *willymanite* variety, from Broken Hill in New South Wales, half the nickel is replaced by cobalt. The mineral is easily mistaken for galena, since it has a good cubical cleavage. The cleavage is, however, less perfect than in galena, and the colour is steel-grey rather than bluish-grey; further, ullmannite (H. 5½) readily scratches galena. Sp.gr. 6.6–6.7. The mineral is decomposed by nitric acid with separation of antimony oxide and sulphur. It occurs in mineral

veins at several places in the Rhineland, at Lölling and Waldenstein in Carinthia, Mount Ar in the Pyrenees, and as good crystals at Monte Narba in the Sarrabus district of Sardinia. It has been found in small amount in a barytes vein in the New Brancepeth Colliery near Durham. L. J. S.

ULMARENE (*mesoten*). Trade name for salicylic methoxymethyl ester.

ULMITE. A term applied to a form of humus-covering grains of a black friable sandstone found along the coast of New South Wales (Steel, *Proc. Linnæan Soc. N.S.W.* 1921, 46, 213).

ULTRAMARINE. Ultramarine was first artificially made on a commercial scale in 1828, by Guimet, who earned the prize of 6000 francs offered by the 'Société d'Encouragement' of France for its production at a cost not exceeding 90s. per lb. About the same time, Gmelin (*Ann. Chim.* 1828, [ii.] 37, 409) independently discovered how to prepare ultramarine on a laboratory scale. According to Heintze (*J. pr. Chem.* 1891, [ii.] 43, 98), ultramarine was being made by Kottig, director of the laboratory of the Königl. Porzellan-manufaktur in Meissen, at the time when Guimet and Gmelin were claiming the priority of the discovery.

Until 1828 ultramarine was obtained by powdering and washing *lapis-lazuli* (q.v.); its composition was first determined by Clément and Désormes (*Ann. Chim.* 1806, [i.] 57, 317).

Properties.—Artificial ultramarine blue occurs in commerce as a bright, azure blue, impalpable powder, insoluble in water. Its constituent elements are sodium, aluminium, silicon,

sulphur, and oxygen. Heated to 200°–300° with water in a sealed tube, it leaves a colourless residue free from sulphur, while sodium sulphide passes into solution. It also loses its sulphur when heated with mercuric oxide (Chabrie and Levallois, *Compt. rend.* 1906, 143, 222). Ultramarine is quite stable towards alkalis, but is readily decomposed by dilute acids, some sulphur being precipitated and hydrogen sulphide evolved. It is also decomposed by alum solution, owing to the formation of an aluminium derivative. Yellow phosphorus reduces it to a leuco compound, which again becomes blue when heated in air. The preceding reactions seem to indicate the presence of some kind of polysulphide in ultramarine; but it is unaltered by concentrated and fuming sulphuric acid, and also by a mixture of glacial acetic acid and acetic anhydride (Hoffmann and Metzner, *Ber.* 1905, 38, 2482), reagents which instantly decompose polysulphides and thiosulphates. Ultramarine withstands a red heat fairly well, although it loses its brilliancy, and becomes greenish; hence it is difficult to imagine that the blue colour is due to free sulphur, as has been suggested (Paterno and Mazzucchelli, *Atti R. Accad. Lincei*, 1907, [v.] 16, i. 465). Ultramarine blue when strongly heated in hydrogen loses some of its sulphur, but still retains its blue colour. It becomes violet when heated to dull redness in chlorine. It possesses hydraulic properties and increases the binding power of cement (Rohland, *Zeitsch. angew. Chem.* 1904, 17, 609).

When heated with aqueous silver nitrate at 120°–140° in a sealed tube for 15 hours, no silver sulphide is produced, but a dark yellow *silver ultramarine* is obtained, together with silver nitrite and other products (Unger, *Dingl. poly. J.* 1874, 212, 232; Heumann, *Ber.* 1877, 10, 991, 1345, 1888; 1897, 12, 60, 784; *Bull. Soc. chim.* 1877, [ii.] 28, 570; 1878, 30, 326, 327; 1880, 33, 60, 302; *Annalen*, 1879, 189, 253; 1880, 201, 262; Philipp, *Ber.* 1877, 10, 1227; Forcrand and Ballin, *Bull. Soc. chim.* 1878, [ii.] 30, 112; Chabrie and Levallois, *l.c.*). Silver ultramarine is produced by replacement of the sodium in ordinary ultramarine by silver; when fused with various metallic chlorides or iodides the silver is replaced by other metals, and in this way have been obtained *potassium* (blue), *lithium* (blue), *barium* (yellowish-brown), *zinc* (violet), *manganese* (grey), *ultramarines*, &c. Heated with the requisite organic iodide, silver ultramarine is decomposed, yielding *ethyl*, *amyl*, *benzyl*, and *phenyl ultramarines*, and silver iodide (Forcrand, *Compt. rend.* 1879, 88, 30; *Bull. Soc. chim.* 1879, [ii.] 31, 161). Mercurous nitrate solution heated with ultramarine yields a greyish-blue mercurio-ultramarine, which loses mercury on heating and leaves a pure blue residue, which becomes yellow on heating and again blue on cooling, this change being capable of indefinite repetition. Cadmium yields an olive-green product. Lead replaces the sodium completely. Ammonium and calcium ultramarines have also been prepared. Ferrous ultramarine is dark greyish-blue and is readily decomposed by acids. These substances regenerate ultramarine when heated with sodium chloride. They do not evolve hydrogen sulphide when treated with cold hydrochloric acid

(Chabrie and Levallois, *l.c.*). *Selenium* and *tellurium* ultramarines have also been produced, in which sulphur is substituted by either selenium or tellurium (Guimet, *Ann. Chim.* 878, [v.] 13, 102; Plicque, *Bull. Soc. chim.* 877, [ii.] 28, 518; 1878, 29, 522; 1878, 30, 51; Morel, *ibid.* 28, 522). Light blue *boron ultramarine* has been prepared by fusing together anhydrous borax, boric oxide, and either sodium or potassium sulphide, sulphite, or thiosulphate (Hoffmann, *Zeitsch. angew. Chem.* 1906, 19, 1089; 1907, 20, 568; *Chem. Ind.* 1911, 34, 699).

Ultramarine blue crystallises in the regular system, isomorphous with the minerals *hauyn*, *sodalite*, and *nosean*.

Green ultramarine is formed as an intermediate product in the manufacture of ultramarine blue, and is converted into the latter by roasting with sulphur. According to Philipp (*Ber.* 1876, 9, 1109), sulphur is not taken up in the change from green to blue, which can be effected by heating with water in a sealed tube at 100°; a small amount of sodium compound is removed by the water. Heated in chlorine, green ultramarine turns bluish-violet; sodium sulphide solution turns it grey.

White ultramarine is obtained by completely excluding air during the roasting of the materials in the manufacture of ultramarine, and is converted into blue ultramarine when heated in either chlorine, oxygen, or sulphur dioxide (Philipp, *Ber.* 1876, 9, 1109; 1877, 10, 1227; Böttger, *Annalen*, 1876, 182, 311; Hoffmann, *ibid.* 1878, 194, 1).

Red ultramarine was first obtained by Scheffer in the course of preparing the ordinary substance, by heating the materials very strongly in a muffle freely exposed to air; it contains less sodium and more aluminium than the blue variety (Scheffer, *Ber.* 1873, 6, 1450; Büchner, *Dingl. poly. J.* 1879, 231, 446; Zettner, *Ber.* 1875, 8, 259, 353).

Red ultramarine has been prepared by passing chlorine and steam over heated ultramarine blue. It is also obtained by the action of nitric oxide on the blue compound, sulphur being removed in the process. It is decomposed by acids without evolution of hydrogen sulphide, but evolves sulphur dioxide, and is not changed by alum solution. Heated out of contact with air it is changed into a blue product. It now yields hydrogen sulphide with acids.

Yellow ultramarine is obtained by heating the red variety in air for a short time at 360°, or at a little higher temperature (Hoffmann, *Annalen*, 1878, 194, 1). According to Büchner (*Ber.* 1874, 7, 990), both the yellow and red forms are produced by heating blue ultramarine to 300°–400° in oxygen or sulphur dioxide; the colour changes to red and then to yellow. If chlorine is passed over ultramarine before the formation of the blue variety is completed, at 410°, the colour goes green and then reddish-yellow (Zettner, *Ber.* 1875, 8, 259, 353).

Violet ultramarine is obtained when the reddish-yellow product previously mentioned is heated with sodium hydroxide (Zettner, *l.c.*). It becomes blue when heated to dull redness or when further heated with an alkali hydroxide, and nitric acid vapours turn it red.

The violet variety was first prepared by

Leykauf in 1859 by allowing moist calcium chloride to react with warm ultramarine blue. In 1872 Wunder prepared it by heating the blue form in chlorine at 300° and treating the product with water. It has been manufactured from ultramarine blue by heating the latter, in thin layers, on earthenware trays at 280°, and passing steam over it to remove sulphur. The temperature was then lowered to 160°, and a mixture of chlorine and steam led over it for 3 hours. For further details, and other methods, v. Wunder, *Chem. Zeit.* 1890, 14, 1119; *ibid.* *Zeitsch. anorg. Chem.* 1912, 77, 209.

Composition.—The various varieties of ultramarine have not yet been satisfactorily shown to possess uniform compositions. In fact, commercial blue ultramarines are manufactured in three different grades, containing different proportions of silica and sulphur. Moreover, it is not possible to obtain products of identical composition even when, in repeated operations, the relative amounts of the different raw materials are maintained constant and the working conditions duplicated as exactly as possible. The following analyses of different samples of ultramarine blue rich in silica indicate its variable composition:—

	Rawlins			Parry and Coste		
	1	2	3	4	5	6
H ₂ O	0.7
SiO ₂	38.9	39.6	42.7	42.3	41.7	42.4
Al ₂ O ₃	29.5	24.0	24.5	26.8	25.2	24.0
Na ₂ O	21.0	19.2	20.0	19.5	18.8	18.7
S	10.8	13.1	13.0	12.0	14.2	15.4

The differences in composition between ultramarines of different colours are shown by the following numbers, taken from Jordan (*Zeitsch. angew. Chem.* 1893, 684):—

	White (Hofma)	Green (Philipp)	Blue (Philipp)	Blue (Philipp)	Violet (Wunder)	Red (Wunder)	Light bl (Wunder)
Na	21.5	17.02	15.66	14.66	11.7	8.1	11.9
Al	16.6	15.81	15.39	12.55	13.1	13.3	13.1
Si	17.0	17.51	16.87	17.29	19.4	19.3	19.7
S	6.4	7.91	5.69	11.38	13.3	15.2	12.7
O	38.4	—	—	—	42.1	43.4	42.0
H	—	—	—	—	0.4	0.7	0.6

The two analyses of ultramarine blue (Philipp) in the table refer to the varieties poor and rich in silica respectively.

The constitution of ultramarine is naturally a matter of great uncertainty, in view of what has been said concerning its composition. It is commonly regarded as a combined silicate and polysulphide of sodium and aluminium, but objections to this view have already been mentioned. For the numerous formulae that have been proposed for ultramarines, v. Rawlins, *J. Soc. Chem. Ind.* 1887, 6, 791; Szilasi, *Annalen*, 1889, 251, 97; Guckelberger, *ibid.* 1882, 213, 182; Dingl. poly. J. 1883, 247, 343; Clarke, *Amer. Chem. J.* 1888, 10, 126; Brögger and Bäckström, *Jahresber. Tech.* 1891, 454; Rohland, *Zeitsch. angew. Chem.* 1909, 17, 609; Abegg's *Handbuch der Anorganischen Chemie*, vol. iii. pt. i.

The blue colour is considered to depend on (1) the presence of an alkali metal; (2) the

direct union of a part of the sulphur with metal; (3) the presence of a part of the sulphur in a lower state of oxidation. Neither aluminium nor silicic acid is essential (Wunder, *Zeitsch. angew. Chem.* 1915, 28, 147; 1917, 30, i. 161; 1920, 33, 23).

The similarity in composition exhibited by ultramarines of quite different colours suggests that the actual colouring material may represent only a small fraction of the total mass; it has been supposed that such a small amount of a coloured substance is present, disseminated throughout a colourless body in a state of solid solution (Rohland, *l.c.*). J. Hoffmann (*Chem. Zeit.* 1910, 34, 823) has suggested that this coloured substance is sulphur; the comparative stability of ultramarine at a red heat does not lend support to this assumption. It is noteworthy, however, that were it not for the presence of sulphur, ultramarine would be expected to be colourless.

Alkali fusion of ultramarine converts the blue colour into a dark red. Since, according to Ostwald, alkali appears to enhance the dispersion of disperse sulphur systems, and since, as in the case of colloidal gold, greater dispersion is accompanied by a change in colour from blue to red, it is considered that the above experimental result is in support of the theory that the colour principle of ultramarine is colloidal sulphur (I. T. Keine, *Chem. Zeit.* 1923, 47, 513).

The silicon dioxide in ultramarine may be displaced by boron trioxide without the disappearance of the blue colour, and the amount of this substance may greatly vary without much alteration in colour. Other solvents for colloidal sulphur manifest a blue colour; thus potassium thiocyanate if dehydrated and heated to redness becomes blue, but it becomes colourless on cooling; phosphoric oxide also acquires a deep blue colour on fusing with sodium sulphide at 900°, but the colour disappears on cooling. The blue colour of the solution obtained by dissolving disulphur trioxide in concentrated sulphuric acid is probably due to the presence of colloidal sulphur.

Uses.—Ultramarine is extensively used in a variety of manufactures. Its large consumption is due to two characteristics: brilliancy as a body colour, and high colouring power. As a body colour it is used in calico-printing, and wall-paper printing, for colouring writing paper and printing-ink, preparing blue pigments, and blueing mottled soap. As a 'whitening' agent it is very valuable, its great strength and purity of tone correcting the yellow tinge in writing and printing papers, cotton and linen goods, paper pulp, whitewash, soap, starch, and ven sugar. It is extensively used in the manufacture of square and ball blue for laundry use.

Tests and analysis.—(i) Dilute 0.1 grm. of a standard sample of ultramarine with 0.6 grm. of pure powdered chalk, and determine the amount of chalk that must be added to 0.1 grm. of the sample under examination in order to match the colour of the diluted standard; this gives an indication of the value of the sample. (ii.) Heat a sample in hydrogen to 400°. A good ultramarine becomes grey and then green, the change taking about half an hour; a bad specimen changes in a few minutes. (iii.) Stir

a little of the powder under examination in a cold saturated solution of alum, and note the length of time required for decolorisation; compare with a standard sample ground equally fine (iv.) Shake up with water and alcohol to detect adulteration with coal-tar dyes.

For the quantitative analysis, the substance may be treated as a silicate readily attacked by dilute hydrochloric acid (*v. ANALYSIS*); in the filtrate from the aluminium the sodium may be determined as the sulphate. The determination of sulphur should be effected on a separate portion, by oxidation to sulphuric acid with *aqua regia* or fuming nitric acid, and subsequent estimation as barium sulphate. See also Andrews, Analyst, 1910, 35, 157.

MANUFACTURE OF ULTRAMARINE.

The only ultramarines prepared on a large scale are the blue and green sodium-sulphur-ultramarines. Three chief varieties of ultramarine blue are found in commerce:—

Glauber salt or sulphate ultramarine, the palest variety. It has a slight greenish tinge, small covering power, and is the form most readily attacked by alum.

Soda ultramarine low in sulphur, a pure blue variety, darker than the preceding, and having more covering power.

Soda ultramarine rich in sulphur and silica, the darkest variety, with a reddish tinge. It has high covering power, and is the form most resistant towards alum; consequently it finds extensive use in paper blueing.

Ultramarine is produced when aluminium silicate is calcined with sodium sulphide; the silicate is employed in the form of china clay, or a similar material, with the addition of silica if necessary; sodium sulphide is produced during the manufacture, either from sodium carbonate, carbon, and sulphur, or from sodium sulphate, carbon, and sulphur. The relative proportions of the ingredients is an important factor in the manufacture of ultramarine, but different authorities recommend different mixtures. With materials of the best quality, the following mixtures are said to be the best for producing the three varieties mentioned above:—

Ultramarine blue	Pale	Medium	Dark
China clay . . .	100	100	100
Soda	9	100	103
Glauber salt . . .	120	0	0
Carbon	25	12	4
Silica (Kieselguhr) .	0	16	16
Sulphur	16	60	117

If the clay employed differs in composition from china clay, the relative proportions of clay and silica must, of course, be suitably adjusted.

The manufacture of ultramarine blue is carried out either by (i.) the *direct* or (ii.) the *indirect* process. All ultramarines rich in silica and a certain amount of the other varieties poorer in silica are made by the former method; but the majority of the ultramarines poor in silica are prepared by the latter method, in which ultramarine green is found as an intermediate product. Both these are dry processes; wet methods have been described and patented, but

do not seem to have been adopted on a large scale (Knapp, J. pr. Chem. 1885, [ii.] 32, 375; 1888, 38, 48; Molvor, Eng. Pat. 9200, 1890; Molvor and Cruickshank, Eng. Pat. 19411, 1892).

For general accounts of the manufacture of ultramarine, *v. Rawlins*, J. Soc. Chem. Ind. 1884, 6, 791; Pichot and Grangier, *ibid.*, 1888, 7, 573; Röhrig, Chem. Zeit., 1883, 567; Wunder, *ibid.*, 1890, 14, 1119; Jordan, Zeitsch. angew. Chem. 1893, 684.

Raw materials.—*China clay*, and French, German, and Bohemian *pottery clays* are used, and always require levigation. The clay must be very finely divided, and free from excessive amounts of iron and manganese oxides. For *soda*, the best soda ash, known as carbonated ash, is employed; it must be stored in a dry place. The *Glauber salt* must be free from acid and iron, and well calcined; it should be ground in stone edge-runner mills before use. *Rod or stick sulphur*, containing very little non-volatile matter, is usually employed, since poorer forms of sulphur produce dirty shades of colour; like the Glauber salt, it is reduced to a fine powder before use. *Carbon* should not contain more than 4 p.c. of moisture; that made from pine trunks is preferred, and is ground in ball mills

FIG. 1.

and stored in a dry place. Charcoal is sometimes replaced by pitch, tar, colophony, &c. If coal is used, it must be of good quality, and free from sand, stones, and pyrites. *Silica* is usually employed in the form of kieselguhr, but sometimes quartz is used; the latter is ignited and then quenched in water to cause it to break up, being finally dried and ground to powder. Silicious carbon, such as charred rice husks, may partly or wholly replace the carbon and silica (Cross, Eng. Pat. 3174, 1903).

Direct process.—The formation of ultramarine blue by this process is effected by roasting the well-mixed raw materials, allowing access of air during the operation. The successive operations involved are mixing, roasting, lixiviating, wet-grinding, levigating, pressing, drying, and sifting.

The most intimate and cheapest mixture is obtained when the various raw materials have been ground first in edge-runner mills, and then in balance mills. With mixtures containing much sulphur, the other ingredients should first be well mixed, the sulphur then added, and further mixing effected. The mixtures should, in any case, be calcined as soon as they are prepared.

The 'mass' oven, so called from the mixture being treated in a mass, produces directly very good ultramarine if carefully managed. Fig. 1 gives an idea of the arrangement. The raw materials, well mixed and ground, are shovelled

on to the floor of the oven, pushed up to the end with a broad rake, and, after being piled up to nearly the level of the bridge, are nearly flattened, and covered with thin tiles, the joints being filled in with a very thin mortar made with china clay and sand. The oven having been thus filled with about 1 ton of raw material, the front is built up, leaving a hole just above the level of the tiles for observation, fitted with a loose brick. A small hole below this and about opposite the centre of the mass, fitted with a clay stopper, affords a means of taking samples as the burning proceeds. The heat is slowly raised to a bright red, and as it rises small jets of sulphur dioxide are seen to come from the cracks between the covering tiles and burn with feathery flames, increasing in length as the heat becomes greater, and gradually dying away as the reaction is completed. The heat is maintained at its highest point for from 12 to 18 hours, or until the process appears to be finished, when a sample is taken through the small hole by means of a long auger inserted right into the middle of the mass. The sample presents, if sufficiently burnt, a greenish-blue appearance, gives off sulphur dioxide freely without actually burning, and on being spread upon a clean tile quickly loses its heat, and appears a blue colour with a tinge of green. The changes experienced by the mixture are interesting and remarkable. As introduced it is a yellowish-grey, and becomes successively brown, green, and blue. The brown, a dark rich colour, is very unstable, and burns on exposure to air to a greenish half-formed ultramarine, and, even if not exposed, slow combustion goes on until oxidation has taken place. The green is almost equally unstable.

When the drawn sample is found to be sufficiently burnt, the operation is concluded by closing the oven, plastering up cracks, and excluding the air as far as possible. It is then left to cool down, which takes a week or 10 days. On opening, the mass should appear dark blue, the bottom portion not being quite equal in brilliancy to the top owing to the greater degree of heat to which it has been subjected. A loss of about one-third of the original weight occurs, and the mass shrinks considerably.

Charges amounting to 5 tons are treated in stone troughs, 17-20 ft. long and 10-13 ft. wide, placed in a furnace in such a way that they can be reached on all sides by the flame. The troughs are filled to a depth of 12-16 ins. covered with firebricks, and calcined for about 3 weeks.

Ultramarine blue is also prepared directly in shaft furnaces (Fig. 2), described later on (p. 259). Various special furnaces have been patented (Fr. Pata. 410055, 1909; 407098, 403247, 399211, 400103, 1908; 403077, 1909; 425585, 1910).

A rapid process for the direct preparation of the blue has been patented (Fr. Pata. 391770, 391790, 1908). A mixture of china clay (35 parts), carbon (10 parts), sodium alum (40 parts), rosin (8 parts), and sulphur (7 parts) is heated rapidly to 600°-700°, and maintained at that temperature for about 3 hours; the temperature is then raised to 900°, and the mass stirred well for an hour to oxidise it. Powdered sodium

chlorate is then added and the mass stirred for 15 mins.; a further 30 mins. heating then follows. Ultramarine of very superior quality is said to be thus obtained.

Curtius has patented a continuous process. Cast-iron retorts, similar to gas retorts, are employed, lined inside with fire-proof cement. They are set in brickwork, and connected with flues for removing the gases and receivers for condensing sulphur vapour. The charged retorts are closed back and front, but arrangement is made for the admission of air from behind, in order to quickly convert the green ultramarine initially formed into blue. In a modified form of the process, green ultramarine is first produced, discharged into brickwork receptacles beneath the retorts, and directly oxidised to blue (Eng. Pat. 18527, 1890).

The lixiviating, &c. is described later (p. 259).

Indirect process.—The successive stages in

FIG. 2.

this process are mixing, calcining for ultramarine green, crushing, roasting to ultramarine blue, and lixiviating, &c., as in the direct process.

The preparation of the ultramarine green is carried out in either a *crucible* furnace or a *shaft* furnace. The former is a kind of muffle furnace, similar to those used in porcelain works, of square (seldom round) section and lined with firebrick. The ground mixture is filled into tapered crucibles of 12-16 ins. high, the lids are fixed on with a mortar of clay, and the crucibles piled in regular rows in the furnace. A furnace will hold several hundred crucibles, the aggregate charge being 6-8 cwt. of mixture. The temperature is slowly raised until the crucibles are at a bright-red heat, and this temperature is then maintained until the formation of ultramarine green is completed; from 7 to 10 hours are required. It is essential to maintain a uniform temperature throughout the furnace.

When the reaction is finished all openings into the furnace are shut tightly and the furnace allowed to cool down, a process that takes several days.

Shaft furnaces are used for calcining larger quantities, up to 2 tons, of material. These are large, cylindrical, vertical furnaces, lined with firebrick. The furnace is situated at the bottom of the shaft; it is covered in by a firebrick vault, the flat top of which forms the floor upon which the bottom layer of crucibles rests. Numerous openings in the vault allow the heating gases from the furnace to pass up into the shaft. The shaft is filled with crucibles charged with the ground mixture, and arranged layer upon layer. Another vault forms the roof of the shaft proper, and through openings in this the gases pass into a dome and thence into the chimney. Fig 2 shows such a furnace. These furnaces possess many advantages; they require no special fuel, accommodate large charges and permit the heat to be equally distributed in a very satisfactory manner. Soda mixtures low in sulphur must be heated slowly at first in these furnaces, a bright-red heat being only attained in 4 hours.

The green ultramarine thus produced exhibits a blue tinge on the surface, and if required to be sold as such, the blue outer portions must be

FIG 3.

removed. This is unnecessary if the product is to be directly converted into blue; it must, however, be crushed and ground to powder.

The material is crushed in roller mills to pieces about the size of peas. Glauber salt greens are then ground in dry mills to a degree of fineness that must be determined by preliminary trials, since if ground beyond a certain degree, the brightness of the final ultramarine blue suffers. Soda greens are much softer than Glauber salt greens, and the application of further pressure during the final grinding must be avoided as much as possible. They are usually ground in ball mills, which may be so constructed as to render the preliminary crushing of the raw green superfluous.

The crushed ultramarine green is converted into blue by roasting it with sulphur; the change is completed in a shorter time by this process than if ammonium chloride, hydrochloric acid, chlorine, &c., are used in the place of sulphur. During the process part of the sodium contained in the green becomes converted into sodium sulphate. Two types of furnace are in extensive use (i.) cylindrical or retort furnaces, and (ii.) muffle furnaces.

The former type consists of an arrangement of strong cast-iron tubes, not exceeding 80 in. long by 16 in. diameter, generally arranged in

sets of three, so that the flame entirely surrounds them. They project about 2 in. from the furnace, both at the back and front, and the ends are closed by tight-fitting sheet-iron caps. The arrangement adopted in large works is indicated in Fig. 3; the furnaces are mounted in pairs, back to back. All the gaseous products pass into the narrow corridor A, closed at both ends by doors; through openings in the roof they pass into the flue B, and thence to the chimney.

In the other type of furnace, the muffle is built into the furnace. The hearth is made of strong fireclay plates with lap joints, luted together, the whole surface being then smoothed. The hearth of the muffle forms the cover of the heating chamber; the products of combustion pass from the grate upwards through flues arranged on the sides of the muffle-walls, thence over the arched roof to the chimney. If the muffle is constructed entirely of fireclay, it is built in completely at the back, and a semi-circular hole left in the front, the base of which is on a level with the hearth. This opening, through which the muffle is charged and discharged, can be closed when necessary by a counterpoised iron slide; and since sulphurous gases escape from this opening, it is arched over with a hood for leading these gases to the chimney, an arrangement that is far less convenient and safe than that employed in the cylindrical furnaces. Sometimes the muffle is built with an iron top, and the front of the muffle closed with an iron cap.

The actual roasting process is carried out either (i.) by adding sulphur to the ultramarine green before heating, or (ii.) by heating the green and gradually adding the sulphur during the process. The requisite amount of sulphur is 7 p.c. with soda green, and 9-10 p.c. with Glauber salt green, of the weight of the crude green taken. In carrying out process (i.), the empty retorts or muffles are heated to a medium red heat for soda green, or to bright redness for Glauber salt green. The mixture of green and sulphur is then quickly introduced, and the containing vessels closed. After half an hour, the product is thoroughly mixed and levelled down, a process that is repeated at half-hourly intervals, until all the sulphur has been burnt off. This is indicated by the manner in which the green colour changes to blue. A further 45 mins. heating is given, and then the fire slowly reduced. The retorts and muffles are then tightly closed and allowed to cool. When method (ii.) is employed, the retorts or muffles are charged with ultramarine green, which is raked over and levelled. The successive portions of sulphur added amount to about 1½ lbs. each with retorts (½ cwt. charge), and 4½ lbs. each with muffles (1½ cwt. charge). The first addition of sulphur may be made when a lump of that substance ignites as soon as it is thrown on the ultramarine; the charge is then raked over, and the sulphur allowed to burn away. This operation is repeated until a bright blue product is obtained; samples are withdrawn at intervals and spread out with a steel spatula to examine the colour. The product is then cooled as described under (i.).

The filtering boxes employed in the *lithiation* process are made of pins, 5-7 ft. long.

40–60 in. wide. About 6 or 8 in. above the solid bottom a false bottom is mounted, perforated with many $\frac{1}{4}$ -in. holes, and covered with strong cotton filtering cloth. The cold, calcined ultramarine blue is mixed with a small quantity of hot water (75°–80°) in a vat, thoroughly mixed, and transferred to a filtering box. In this manner all the numerous filtering boxes are charged. The clear filtrates are united, and if sufficiently concentrated (15°B. or more) the liquid is run into crystallising tanks for the recovery of sodium sulphate. Weaker solutions, and the first two or three washings, are concentrated by utilising waste heat from the furnaces. The ultramarine is washed with hot water until quite free from soluble sulphate, of which the crude blue contains about 15 p.c. It is then ground wet in upright mills between hard stones until the requisite fineness is obtained. During this operation sodium silicate passes into solution, and it is therefore necessary to use soft water for the grinding. The whole is then run into a large wooden vat and allowed to settle for 36–48 hours.

The *levigating process* follows next. The top blue liquor is baled out into another vat and left until the extremely finely divided particles of colour have settled; the product is afterwards added to other preparations. The paste remaining in the large vat is distributed in quantities of about 2 cwt. into levigating tanks, three-fourths filled with soft water, and the colour equally distributed throughout the water. The larger particles settle rapidly, and after 2 hours standing the liquids are run into other tanks. The next deposition of ultramarine takes 5 or 6 hours; the liquid is then baled into other tanks, and a further settling of colour for 12 hours is allowed. The liquid now baled off contains extremely finely divided particles; they are precipitated in a fourth series of tanks by the addition of alum, dilute mineral acid, milk of lime or other saline solutions, and the resulting blue paste is pressed. Passing from the first to the fourth series of tanks, the ultramarine becomes successively lighter, finer, bluer, and stronger. The different grades of product are then dried in sheds exposed to air, or on drying hearths heated by waste furnace heat, or in special drying rooms, &c.

The product dries in hard lumps, which must be powdered and sifted; for this purpose ball mills fitted with a continuous sifting device are employed. Very fine brands of ultramarine are sifted in centrifugal sifters or else in a Jasse sifter. It then remains to mix together the various shades and sorts in order to produce the standards of sale; this part of the work is of great importance, as the tinctorial power, fineness of division, depth and purity of colour in each standard, have to be exactly reproduced in bulk.

In making the cheaper brands of ultramarine blue, the pure material is mixed with from 10 to 50 p.c. of gypsum. The latter has an extremely bad effect upon the brightness of certain kinds of ultramarine, which is minimised by incorporating a little glycerol or vaseline into the

competition soon brought this down, and created a demand. Guimet commenced the manufacture in 1828. Between 1830 and 1840 manufactories were established at Cologne and Nuremberg; between 1840 and 1850 nine more were started; 1850–1860 saw nine more; 1860–1870 at least a dozen, and from 1870–1888 four or five, while an equal number of the others had closed down. At the present day there are about a hundred factories, mainly in Germany and France, although a few are in England, Austria, and the United States, and the annual production of ultramarine is between ten and fifteen thousand tons.

For further information on ultramarine, *v.* Zerr and Rübenkamp's *Treatise on Colour Manufacture*, translated by Mayer (Griffin & Co.); Bersch's *Mineral and Lake Pigments*, translated by Wright (Scott, Greenwood & Son); and Hoffmann's *Ultramarine* (Vieweg u. Sohn, Braunschweig).

ULTRAMARINE, GREEN, *v.* **ULTRAMARINE**; also **CHROMIUM**.

ULTRAMARINE, YELLOW, *v.* **ULTRAMARINE**. The term is also applied to *Barium Chromate*, *v.* **BARIUM**; also **CHROMIUM**.

UMBELLIFERONE *v.* **GUM RESINS**.

UMBELLULARIA CALIFORNICA (Nutt). An evergreen tree indigenous to California, known locally as 'California Laurel,' 'Mountain Laurel,' 'California Bay-tree,' 'Spice-tree,' 'Pepper-wood,' &c. The essential oil is an aromatic liquid possessing a peculiar pungency due to the presence of a ketone *umbellulone* ($C_{10}H_{14}O$)

which forms 60 p.c. of the essential oil; the other constituents are eugenol, 1.7; eugenol methyl ether, 10; *l*-pinene, 6.0; cineol 20.0 p.c.; saffrole and fatty acids, traces (Power and Lees, *Chem. Soc. Trans.* 1904, 85, 629; Tutin, *ibid.* 1906, 89, 1104; 1908, 93, 252).

UMBELLULIC ACID *v.* **HEXDECANOIC ACIDS**.

UMBELLULONE *v.* **LAURUS NOBILIS**.

UMBER. A brown mineral pigment, consisting of a mixture of the hydrated oxides of iron and manganese, mechanically associated with a large proportion of earthy matter of variable character. The material is prepared for the market by grinding and levigation. Raw umber is exported from Cyprus, Turkey, and Umbria in Italy (hence the name). It is also worked to a limited extent in Derbyshire and Pennsylvania.

Sir A. H. Church (*The Chemistry of Paints and Painting*, London, 1901) gives the following analysis of a choice sample of raw umber from Cyprus; water, given off at 100°C., 4.8 p.c.; water expelled at a red heat, including organic matter, 8.8; Fe_2O_3 , 48.5; MnO_2 , 19; CaO , 1.4; MgO , 0.5; Al_2O_3 , 2.1; P_2O_5 , 0.9; SiO_2 , 13.7; CO_2 , &c., 0.3. Part of the manganese probably exists as Mn_2O_3 . For other analyses of umber, *siennas*, and *ochres*, *v.* G. H. Hurst in *Chem. News*, 1889, 59, 172. He found crude Darby-

development of the manufacture of ultramarine has been remarkable. The price in the year of its discovery was about 16s. per lb., but

shire amber to yield the following results: hygroscopic water, 13.47 p.c.; combined water, 5.17; BaSO_4 , 30.10; SiO_2 , 4.43; CaSO_4 , 2.15; CaCO_3 , 2.61; Al_2O_3 , 8.08; Fe_2O_3 , 22.50; MnO_2 , 11.53. A sample of amber, from Caldbeck Fells, Cumberland, as prepared for market by grinding and washing gave: Fe_2O_3 , 47.14; MnO_2 , 11.17; CuO , 3.23; Al_2O_3 , 7.66; SiO_2 , 24.70; combined water, 6.18; CaO , MgO , traces=100.08 (J. Soc. Chem. Ind. 1890, 953, where are given details of the method of preparation).

Hurst regards most ochres as alteration products, formed mainly by the oxidation and hydration of pyrites *in situ*, and mechanically mixed with silica, clay, and other earthy matter. Umbers may have been washed as a fine sediment from deposits of iron and manganese ores. The pigment termed *burnt umber* is merely umber which has been exposed to heat, whereby its colour becomes somewhat reddened. *Cologne umber* is an earthy lignite.

URACIL v. **ERGOT** and **PYRIMIDINES**.

URALITE. A name proposed by G. Rose in 1831 for pseudomorphs of hornblende after augite from the Ural Mountains. (For a *résumé* of the literature, v. A. Wilmore, *Geol. Mag.* 1910, [v.] 7, 357.) Also used as a trade-name for a preparation of serpentine-asbestos, made into the form of boards for fire-proof partitions (v. **ASBESTOS**).

URAMIL v. **PYRIMIDINES**.

URANINITE v. **PITCHBLEND**.

Alfred Schoep (*Bull. Soc. chim. Belg.* 1923, 32, 274–281) has analysed specimens of Katanga pitchblende, estimating total uranium as U_3O_8 and UO_2 in presence of UO_2 by Hillebrand's method of heating the mineral in a sealed tube with dilute sulphuric acid in an atmosphere of carbon dioxide, and volumetric estimation of the dioxide with potassium permanganate. The results lead to the conclusion that the purified mineral (i.e. uraninite) has the formula $(\text{UO}_2)_2(\text{UO}_3)_2$ (cf. Blomstrand, *Chem. Soc. Abstr.* 1884, 1102). This is discussed in comparison with results obtained by other workers for pitchblende from Katanga and other sources, and also for thorianite, and reasons are given for regarding the UO_2 as an oxidation product of the UO_3 , of which the original mineral consisted. Thus the author maintains that the formula of uraninite is UO_3 , as that of thorianite is ThO_2 , the two minerals being isomorphous and analogous in chemical composition. The percentage of the dioxide is greater in fresh specimens of the mineral; some consist of $\text{ThO}_2 \cdot \text{UO}_2$, in which all the uranium compound has undergone oxidation. Thorianite contains

various proportions of UO_2 , and isomorphous mixtures of the two dioxides may be prepared artificially (*Chem. Soc. Abstr.* 1923, 124, ii. 647).

URANITE. An early name for the 'uranium micas' in use before these had been separated into the following species, the most important of which are autunite (calco-uranite) and torbernite (cupro-uranite) (*qq.v.*).

Torbernite $\text{Cu}(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, tetragonal.

Zeunerite $\text{Cu}(\text{UO}_2)_2(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$, tetragonal.

Autunite $\text{Ca}(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, orthorhombic.

Uranospinite $\text{Ca}(\text{UO}_2)_2(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$, orthorhombic.

Uranocircite $\text{Ba}(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, orthorhombic.

L. J. S.

URAMINO ANTIPYRIN. Trade name for antipyrilurea.

URANIUM. Sym. U. At.wt. 238.2 (238.17 Hönigschmid; 238.5 Richards and Merigold; Lebeau). In 1789 Klaproth prepared from *pitchblende* some compounds of a new element, which he called *uranium* (Crell's *Ann.* 1789, [ii.] 400). The compounds of uranium were studied by Richter, Arfvedson, Berzelius, and others. In 1840 Péligot showed that what had previously been thought to be uranium was really one of its oxides; he prepared the metal by reducing uranous chloride with potassium (*Ann. Chim.* 1842, [iii.] 5, 5). The work of Péligot was confirmed and extended by Ebelmen (*ibid.* 1842, [iii.] 5, 189), Wertheim (*ibid.* 1844, [iii.] 11, 49), Rammelsberg (*Pogg. Ann.* 1842, 55, 318; 56, 125), and Hermann (Ueber einige Uranverbind. Göttingen, 1861).

Occurrence.—Uranium is not very abundant; its chief ore is *pitchblende* or *uraninite*, which consists of impure U_3O_8 , and is found in Cornwall, at Joachimsthal (Bohemia), and other localities. It contains from 40 to 90 p.c. of U_3O_8 (Hermann, *J. pr. Chem.* 1859, [i.] 76, 326; Ebelmen, *Ann. Chim.* 1843, [iii.] 8, 498; Whitney, *Amer. J. Sci.* 1849, [ii.] 7, 434; Gentz, *ibid.* 1857, 23, 421; Zimmermann, *Annalen*, 1886, 232, 300). *Clevite* and *bröggerite* are varieties of pitchblende rich in rare earths. *Carnotite* is a vanadate of potassium and uranium, found in Utah and Colorado (Friedal and Cumenge, *Bull. Soc. chim.* 1899, [ii.] 21, 328). *Samarskite* is a uranotantalite of iron and yttrium, found in Siberia (Miask) and North Carolina (Rammelsberg, *Pogg. Ann.* 1877, 160, 658); *fergusonite* is a complex columbate of yttrium, cerium, uranium, calcium, and iron (Rammelsberg, *ibid.* 1873, 150, 200).

Schoep, of the University of Ghent, has identified several new uranium minerals, to which he has assigned the following formulae: *curite*, $\text{PbO} \cdot 5\text{UO}_2 \cdot 4\text{H}_2\text{O}$; *kasolite*

dewindtite, $\text{PbO} \cdot 2\text{UO}_2 \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$; *soddite*

becquerelite, $\text{UO}_2 \cdot x\text{H}_2\text{O}$. A uranotitanocolumbate of calcium containing small amounts of rare earth has been designated as *mendeleeffite*; the chemical formula has not been established definitely, but the mineral contains approximately U_3O_8 23.6 p.c., and CaO 15 p.c. It is considered as a variety of *betafite*, but contains

no water of crystallisation (J. Soc. Chem. Ind. 1923, 42, 1061).

Nearly all the phosphates, silicates, and zirconates of the rare earths contain small quantities of uranium, notably *zenotime*, *ascshenite*, *columbite*, *cerite*, and *monazite*. *Thorianite* (v. THORIUM) contains from 10 to 20 p.c. of uranosouranic oxide. See also Szilárd, Le Radium, 1909, 6, 233.

Naturally occurring uranium minerals are radioactive; it was from the pitchblende of Joachimsthal that radium was first prepared, whilst helium was originally obtained from cleveite.

Treatment of uranium minerals; preparation of uranium.—The chief source of uranium compounds is pitchblende, which, after a preliminary roasting, is heated in a reverberatory furnace with sodium carbonate. The product is extracted with warm dilute sulphuric acid and filtered, the residue being used in the preparation of radium salts. The filtrate is worked up commercially for uranium compounds as described under sodium diuranate (p. 265). The following method is due to Wöhler; the liquid is treated with hydrogen sulphide to remove arsenic, antimony, copper, lead, and bismuth, and after oxidising the filtrate with nitric acid, excess of ammonia is added. The washed precipitated iron hydroxide and ammonium uranate are digested at 100° with concentrated ammonium carbonate, containing ammonia in excess, to dissolve the ammonium uranate. The double salt, ammonium uranyl carbonate, crystallises out on cooling the filtered liquid. From the mother liquor a quantity of ammonium uranate can be obtained by precipitating any zinc, nickel, and cobalt with ammonium sulphide, and evaporating the filtrate. Both ammonium uranate and ammonium uranyl carbonate leave the green oxide U_3O_8 when ignited in the air.

Carnotite is fused with potassium hydrogen sulphate and the mass extracted with water; from the solution the double sulphates of uranium and vanadium with potassium sulphate are crystallised out. The crystalline product is reduced with zinc and sulphuric acid, and the vanadium then precipitated with ammonia and ammonium carbonate. From the filtrate the uranium is thrown down as ammonium uranate by boiling (Gin, Chem. Zentr. 1906, ii, 1172; cf. Haynes, Mines and Minerals, 1909, 30, No. 3, 139).

Separation of uranium from thorium and rare earths in pitchblende.—The mineral is dissolved in nitric acid and the silica removed in the usual manner. The filtrate is repeatedly evaporated to dryness for the elimination of free acid. The residue is dissolved in water; the solution in a beaker is neutralised exactly with a few drops of very dilute ammonia, strongly diluted, and boiled for 10 minutes with excess of thiosulphate. After standing 24 hours the precipitate is filtered off, well washed with water containing a little thiosulphate, dissolved in hydrochloric acid, and re-precipitated, after elimination of free acid, as before. If properly performed, the second precipitation removes the last of the cerium. The precipitate, which contains part of the uranium, is dissolved in hydrochloric acid, and the thorium precipitated as oxalate. The

filtrate is evaporated to dryness in a porcelain dish, and the residue cautiously heated with strong sulphuric acid for the decomposition of the oxalic acid; the acid is finally heated until strong fumes appear, and the uranium precipitated with ammonia after cooling and diluting the solution. The filtrate from the thiosulphate precipitate, containing the balance of the uranium is freed from rare earths by means of oxalic acid. The excess of precipitant is destroyed as before, and the iron separated from uranium by precipitation with ammonium carbonate, uranium being again precipitated with ammonia. The united uranium precipitates are ignited and weighed (W. Riss, Chem. Zeit. 1923, 47, 765–766; Analyst, 1923, 48, 626).

Metallic uranium was first prepared by Péligot (l.c.) by reducing the tetrachloride with potassium. Zimmermann (Annalen, 1883, 216, 1) replaced the potassium by sodium (cf. Lely and Hamburger, Zeitsch. anorg. Chem. 1914, 87, 209). It is better to employ the double chloride of uranium and sodium, and magnesium may be used in place of potassium (Moissan, Compt. rend. 1896, 122, 1088). These methods are unsatisfactory, since uranium tetrachloride is extremely hygroscopic. Uranium is best prepared by heating 500 parts of the oxide U_3O_8 with 40 parts of sugar carbon in the electric furnace in a carbon tube. The product, which contains a little carbon, is purified by heating it in a crucible brasqued with uranium oxide, and embedded in another crucible brasqued with titanium, to prevent access of nitrogen to the uranium (Moissan, Compt. rend. 1893, 116, 349). Reduction of uranium dioxide by carbon begins at 1500° (Greenwood, Chem. Soc. Trans. 1908, 93, 1492). The oxides of uranium may also be reduced by heating with aluminium powder (Aloy, Bull. Soc. chim. 1901, [iii.] 25, 153; Stavenhagen, Ber. 1899, 32, 3065; Stavenhagen and Schuchard, *ibid.* 1902, 35, 909; Giolitti and Tavanti, Gazz. chim. ital. 1908, 38, ii, 239; cf. E. Rideal, J. Soc. Chem. Ind. 1914, 33, 673). Uranium may also be prepared by the electrolysis of the fused double chloride of uranium and sodium, in an inert atmosphere, using carbon electrodes (Moissan, Compt. rend. 1896, 122, 1088); and is obtained in the pyrophoric state by heating its amalgam in a vacuum (Féree, Bull. Soc. chim. 1901, [iii.] 25, 622).

According to R. W. Moore (Trans. Amer. Electrochem. Soc. 1923, 96), metallic uranium is conveniently prepared by reducing with metallic sodium the green crystalline tetrachloride, obtained by heating the oxide U_3O_8 to 500°C. for several hours in a current of sulphur chloride, vapour, and subliming the product in a current of chlorine. The resulting mass is broken up in an atmosphere of nitrogen and mixed with metallic sodium that has been distilled *in vacuo* and cut into small pieces under anhydrous benzene. The mixture is heated in a steel bomb in a vacuum, and the reaction product is extracted first with absolute alcohol to remove excess of sodium, then with water to remove sodium chloride, and finally with 2 p.c. acetic acid. The heavy brownish residue of metallic uranium is washed with acetone and dried *in vacuo*. A yield of 90 p.c. of the theo-

retical quantity of metal containing 99.8 p.c. U is readily obtained. The powder is very pyrophoric, but may be pressed into discs in a hydraulic press in an atmosphere of nitrogen, and is then no longer pyrophoric. These discs may be melted by the arc in an atmosphere of rarefied argon to bright, steel-grey, ductile, metallic buttons, which readily tarnish on exposure to the air (J. Soc. Chem. Ind. May 11th, 1923, 406).

Properties.—Pure uranium is a white metal, which takes a high polish; its density is 18.7, and its specific heat 0.02765 (Zimmermann, *Annalen*, 1886, 232, 310; Ber. 1882, 15, 851). It melts at a white heat, and can be distilled in the electric furnace (Moissan, *Compt. rend.* 1906, 142, 425; cf. *ibid.* 1893, 116, 1429; 1896, 122, 1088). The most prominent lines in the emission spectrum are in the yellow (Thalén, *Ann. Chim.* 1869, [iv.] 18, 239; Hasselberg, K. Svenska. Vet.-Akad. Handl. 1910, 45, 3; Pollok, *Sci. Proc. Roy. Dubl. Soc.* 1909, 11, 331). Most uranium compounds possess marked absorption spectra (Morton and Bolton, *Chem. News*, 1873, 28, 47, 113, 164; Jones and Strong, *Phil. Mag.* 1910, [vi.] 19, 566; Strong, *Zeitsch. physikal. Chem.* 1910, 11, 668) and are fluorescent, the fluorescence spectra having been studied by E. Becquerel (*Ann. Chim.* 1872, [iv.] 27, 539) and H. Becquerel (*Compt. rend.* 1885, 101, 1252; 1907, 144, 459); v. also Becquerel and Kamerlingh-Onnes (*ibid.* 1910, 150, 647) for phosphorescence at low temperatures.

Uranium in the form of powder is unaltered in dry air at ordinary temperatures; it burns in oxygen at 170°. It unites directly with fluorine in the cold, and with chlorine, bromine, and iodine when gently heated. At 500° it combines with sulphur and selenium, and at 1000° unites readily with nitrogen. It forms a crystalline carbide decomposed by water (Moissan, *Compt. rend.* 1896, 122, 1088). It forms alloys with certain metals; that with iron is pyrophoric, this property varying directly with the content of uranium.

Uranium powder decomposes water slowly at ordinary temperatures, more rapidly at 100°. It dissolves readily in hydrochloric, sulphuric, and nitric acids.

Uranium is closely allied to the elements chromium, molybdenum, and tungsten; they all exhibit a maximum valency of six, yield acidic trioxides, and form numerous halogen derivatives in which their valencies vary from two to six. These halogen derivatives in general bear little resemblance to well-defined salts, as is indicated by their volatility, solubility in numerous organic media, and the ease with which they are hydrolysed by water. There are two principal series of uranium salts: (i.) the *uranous* compounds, corresponding to the basic oxide UO_2 ; and (ii.) the *uranyl* compounds, in which the group UO_2 functions as a bivalent metallic radiola. Besides these, there exist *uranates*, *diuranates*, and *peruranates*, analogous to the corresponding chromium derivatives (v. O. de Coninck, *Bull. Acad. roy. Belg.* 1909, 175). The *uranous* salts are usually green or blue, and in solution are readily oxidised to uranyl compounds, even by air, the rate of oxidation being

proportional to the concentration of the solution and inversely proportional to the square of the concentration of the hydrogen ions present (McCoy and Bunzel, *J. Amer. Chem. Soc.* 1909, 31, 367.) They are obtained by the reduction of uranyl compounds (v. Alloy and Auber, *Bull. Soc. chim.* 1907, [iv.] 1, 569; Colani, *Ann. Chim.* 1907, 12, 59). The *uranyl* salts are generally yellow, with a greenish fluorescence. They are highly sensitive to light, and are employed in photography (Niepce de Saint Victor, *Compt. rend.* 1858, 46, 448, 489; Titlestad, *Zeitsch. physikal. Chem.* 1910, 72, 257; Bacon, *Philippine J. Sci.* 1910, 5, 281). Under the influence of light, uranyl salts are converted into uranous salts in the presence of the acid entering into the constitution of the salt and a readily oxidisable substance such as alcohol. The reaction which occurs is as follows:—

Two molecules of acid are necessary for each molecule of uranyl salt. In this way, the fluoride, chloride, bromide, iodide, and sulphate have been prepared, and an aqueous solution of the nitrate. If an insufficient amount of acid is present, basic salts are obtained. If the reaction is allowed to proceed further, a black precipitate of uranous hydroxide is obtained (Bauer, *Schweiz. Chem. Zeit.* 1918, 2, 40; Hatt, *Zeitsch. physikal. Chem.* 1918, 92, 513). Oxidations and reductions brought about by uranium compounds under the influence of light are closely related to the changes which the uranium salt itself undergoes. Thus when alcohol or dextrose is added to a 1 p.c. solution of uranium acetate the former is oxidised and the latter is reduced to the violet oxide $\text{U}_3\text{O}_8\cdot 2\text{H}_2\text{O}$. If in addition methylene blue is added to the above solution the dextrose is oxidised and the methylene blue is reduced, the uranium salt playing the rôle of an oxido-reducing catalyst. Aldehydes and lower fatty alcohols can all be similarly oxidised, and the progress of the reaction can be followed by the reduction of the uranium salt or of methylene blue; the phenols, although readily oxidisable under ordinary circumstances, behave anomalously, owing to the antioxygen character of these substances, and they are not oxidised themselves, nor do they allow the oxidation of other substances to proceed. A red coloration is produced on adding the uranium compound to the phenol solution, but no other apparent change occurs. The solution does, however, contain a certain amount of uranous salt, and the violet oxide can be precipitated from it by heating to 100°C. (Alloy and Valdignié, *Compt. rend.* 1923, 176, 1229; *J. Soc. Chem. Ind.* 1923, 42, 574 A). Uranyl salts are somewhat analogous to basic salts, but they are stable in solution, being only hydrolysed to a slight extent. On electrolysis the uranyl ion UO_2^{2+} migrates to the cathode. Uranyl salts form numerous complex derivatives, especially with salts of organic acids (Dittrich, *Zeitsch. physikal. Chem.* 1899, 29, 449; Ley, *ibid.* 1900, 30, 193; Ber. 1900, 33, 2658; Kohlschütter, *Annalen*, 1900, 311, 1).

Uranium salts are radioactive, emitting α rays, and producing a radioactive element.

called *Uranium-X* (*v. infra*, URANIUM-X and RADIOLOGY).

For the relation of uranium-X to uranium-Z, see Hahn (Zeitsch. physikal. Chem. 1923, 103, 461).

Atomic weight.—This was taken as *circa* 120 until Mendeléeff pointed out the similarity of uranium to chromium, molybdenum, and tungsten, and proposed the value 240 (Annalen, Suppl. 1872, 8, 178; Chem. News, 1880, 41, 39), which assigned to uranium a position in the Periodic Classification in the same Group as the elements just mentioned. The determination of the specific heat of the metal and the vapour densities of uranous chloride and bromide (Zimmermann, Annalen, 1882, 216, 1) confirmed the views of Mendeléeff. The actual value at present adopted (238.5) rests mainly on the work of Zimmermann (Annalen, 1886, 232, 299), Aloy (Ann. Chim. 1901, [vii.] 24, 418); of Richards and Merigold (Proc. Amer. Acad. 1902, 37, 365; Zeitsch. anorg. Chem. 1902, 31, 235); of Lebeau (Compt. rend. 1912, 155, 163); and of Hönigschmid (Compt. rend. 1914, 158, 2004).

OXIDES AND OXYACIDS.

Uranium dioxide or *Uranous oxide* UO_2 is obtained by heating the green oxide or uranyl oxalate in a stream of hydrogen (Berzelius, Péligot, Ebelmen); or by electrolysing uranyl nitrate solution (O. de Coninck and Camo, Bull. Acad. Roy. Belg. 1901, 321); these methods yield a brown pyrophoric powder of sp.gr. 8.2. The reduction of uranyl chloride solution with magnesium or aluminium yields uranous oxide as a black powder (de Coninck, *ibid.* 1909, 744). It is obtained as black, microscopic crystals by reducing crystalline uranic hydroxide in hydrogen (Aloy, Bull. Soc. chim. 1900, [iii.] 23, 368); and as jet black octahedra by fusing the amorphous form with borax, and washing the product with dilute hydrochloric acid (Hillebrand, Zeitsch. anorg. Chem. 1893, 3, 249). It is a basic oxide, and dissolves in concentrated acids to form green uranous salts. It combines directly with chlorine and bromine, forming uranyl chloride and bromine, and burns when heated in air, the oxide U_2O_3 being produced.

On a technical scale it is prepared for the production of ferro-uranium by fusing 35 parts of sodium chloride, 20 parts of sodium uranate, and 1 part of powdered charcoal in a cast-steel pot. The cooled mass is lixiviated with water and the uranium oxide washed by decantation, and is freed if necessary from iron and aluminium by treatment with 5 p.c. hydrochloric acid.

Uranous hydroxide $\text{UO}_2 \cdot 2\text{H}_2\text{O}$ is precipitated by adding an alkali to a solution of a uranous salt and boiling; it forms black flakes, and readily dissolves in dilute acids (Aloy, Bull. Soc. chim. 1899, [iii.] 21, 613).

Uranium trioxide, uranic oxide, uranic anhydride, or uranyl oxide UO_3 is a chamois yellow powder, obtained by heating uranyl nitrate to 250° ; also by heating the hydroxide or double uranyl ammonium carbonate to 250° (Ebelmen, Ann. Chim. 1842, [iii.] 5, 199; de Coninck, Compt. rend. 1901, 132, 204; Bull. Acad. Roy. Belg. 1904, 363, 448; Lebeau, Compt. rend. 1912, 154, 1808). It oxidises to

the green oxide when heated in air, and is reduced by hydrogen to uranous oxide. In contact with water it is transformed into uranic acid $\text{UO}_2(\text{OH})_2$. When heated *in vacuo* at 502° it forms the oxide U_2O_5 .

This oxide is slightly basic, but only one-third of its oxygen can be replaced by acidic radicles; the salts thus produced are of the type UO_2R_2 , and are called *uranyl* compounds. Towards strong bases, uranic oxide behaves as an acid anhydride, similar to chromic anhydride.

For heat of formation see, Mixter, Amer. J. Sci. 1912, [iv.] 34, 141.

Uranic hydroxide or uranic acid $\text{UO}_2 \cdot \text{H}_2\text{O}$ or $\text{UO}_2(\text{OH})_2$ is best prepared by heating a solution of uranyl nitrate in alcohol until no more brown fumes are evolved, and washing the yellow precipitate with boiling water (Malaguti, Ann. Chim. 1843, [iii.] 9, 463). It may also be obtained, mixed with the dihydrate, by evaporating a solution of uranyl nitrate to complete dryness (de Coninck, Compt. rend. 1909, 148, 1462). The *dihydrate* $\text{UO}_2 \cdot 2\text{H}_2\text{O}$, which is obtained as a yellow precipitate by boiling the double uranyl ammonium carbonate with water, loses water at 100° , and yields the hydroxide $\text{UO}_2 \cdot \text{H}_2\text{O}$ (Ebelmen, *l.c.*; for other methods, *v.* Jacquelin, Ann. Chim. 1842, [iii.] 5, 199; Riban, Compt. rend. 1881, 93, 1140; Aloy, Bull. Soc. chim. 1900, [iii.] 23, 368). Uranic hydroxide has a sp.gr. of 5.9; it does not alter in air, and when heated to 300° it is dehydrated. For the preparation of the colloidal hydroxide, *v.* Szilárd, J. Phys. Chem. 1907, 5, 488, 636.

Uranosouranic oxide or Green oxide of uranium $\text{U}_2\text{O}_5 (= \text{UO}_2 \cdot 2\text{UO}_3)$ occurs more or less pure as *pitchblende*. It can be obtained by heating any of the other oxides to a red heat in air, also by igniting ammonium uranate or any uranium salt of a volatile acid. It forms a dark-green, lustrous powder of sp.gr. 7.2, insoluble in water; in concentrated acids it dissolves, forming a mixture of uranous and uranyl salts. This oxide is employed for producing a black glaze on porcelain. It is radioactive, and has been suggested as a suitable standard of α -ray radioactivity (McCoy and Ashman, Amer. J. Sci. 1908, 26, 521).

A violet hydroxide can be obtained by the action of light on aqueous uranyl oxalate or alcoholic uranyl acetate (*v.* Aloy, Bull. Soc. chim. 1900, [iii.] 23, 368; *cf.* Aloy and Rodier, *ibid.* 1920, [iv.] 27, 101). A large number of violet compounds of uranium exist, all of which, by loss of their acid radicles, tend to become transformed into the green hydrated oxide $\text{U}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$. When heated in a current of hydrogen the oxide U_2O_5 shows signs of reduction at 625° , the reduction being complete at 650° , the product being UO_2 . In a vacuum U_2O_5 may be heated to 2000° before it dissociates to UO_2 .

Uranium pentoxide is a black powder, used for producing a black glaze on porcelain. According to Zimmermann (Annalen, 1886, 232, 273) it is a mixture of U_2O_5 and UO_3 .

Uranium peroxide UO_4 is only known in the hydrated form as *peruranic acid* $\text{UO}_4 \cdot 2\text{H}_2\text{O}$. It is obtained by adding hydrogen peroxide to a mixture of uranyl and uranous sulphate in aqueous solution, and drying the precipitate

over concentrated sulphuric acid (de Coninck, Bull. Acad. Roy. Belg. 1909, 692; cf. Fairley, Chem. Soc. Trans. 1877, 31, 133; Zimmermann, Annalen, 1886, 232, 273; Alibegoff, *ibid.* 1886, 233, 123). It forms a yellow powder, which loses oxygen when heated; when treated with alkali hydroxides it yields a mixture of alkali uranate and peruranate.

Other hydrates are also known (Hüttig and von Schroeder, Zeitsch. anorg. Chem. 1922, 121, 243). These substances are probably compounds of uranium trioxide and hydrogen peroxide. It is doubtful if uranium tetroxide exists.

URANATES.

The alkali uranates are formed by precipitating uranyl salts with alkali hydroxides; those of the other metals by adding ammonia to a mixture of a uranyl and a metallic salt. They are yellow, insoluble in water, but soluble in acids. The majority are of the type $M_2O \cdot 2UO_3$, analogous to the dichromates (v. Drenkmann, J. 1861, 255; Patera, J. pr. Chem. 1850, 51, 125; Debray, Ann. Chim. 1861, [iii.] 61, 514; Grandeau, *ibid.* 1886, [vi.] 8, 224; Zimmermann, Annalen, 1882, 213, 290; Ditte, Compt. rend. 1882, 95, 988; de Coninck, Bull. Acad. roy. Belg. 1909, 173, 835).

Ammonium uranate. This is obtained as a yellow, voluminous precipitate by adding ammonia to a solution of a uranyl salt. It is prepared by boiling a solution of uranyl sodium carbonate with ammonium sulphate; or by boiling sodium diuranate (*q.v.*) with concentrated ammonium chloride solution, and forms a fine, deep yellow-coloured powder, that is sometimes used commercially, under the name *uranium yellow*, in the preparation of uranium glass (v. Stolba, Zeitsch. anal. Chem. 1864, 3, 74) and sodium diuranate.

Potassium uranate K_2UO_4 , obtained by fusing uranyl chloride with a mixture of potassium and ammonium chlorides (Zimmermann, *l.c.*), forms yellow, rhombic crystals.

Potassium diuranate $K_2U_2O_7$ is obtained in the form of a trihydrate by precipitating a uranyl salt with potassium hydroxide and drying the product at 100° (Patera, *l.c.*).

Sodium uranate Na_2UO_4 may be obtained by fusing the green oxide with sodium chloride and sodium carbonate (Ditte, *l.c.*; Zimmermann, *l.c.*).

Sodium diuranate $Na_2U_2O_7$ is prepared commercially from pitchblende, which is powdered and roasted to remove the greater part of the sulphur, arsenic, and molybdenum. The ore is then heated in a reverberatory furnace with sodium carbonate and a little sodium nitrate. The product is washed with water, when soluble arsenate, molybdate, tungstate, and vanadate of sodium are removed; sodium uranate is insoluble in water. The insoluble residue is dissolved in dilute sulphuric acid, the solution evaporated to remove excess of acid, diluted and filtered from silica, lead sulphate, and basic sulphate and arsenate of bismuth, and an excess of sodium carbonate solution added. A solution of uranyl sodium carbonate is thus obtained, while the basic

carbonates of iron, aluminium, nickel, and cobalt are precipitated and removed. The uranium is then precipitated as sodium diuranate by adding sodium hydroxide, or by neutralising with sulphuric acid and boiling. The yellow precipitate is thoroughly washed, dried, and pulverised (Patera, J. pr. Chem. 1849, [i.] 46, 182; 1850, 51, 122; Gieseke, J. 1852, 779; Anthon, J. 1860, 698; Kessler, J. 1857, 199; Hofmann and Strauss, Ber. 1900, 33, 2316; cf. Metzger and Heidelberger, J. Amer. Chem. Soc. 1909, 31, 1040).

Sodium diuranate is found in commerce as the hexahydrate $Na_2U_2O_7 \cdot 6H_2O$. It is a fine yellow powder, known as *uranium yellow*, and is used in painting and staining glass and porcelain, and for making the fluorescent 'uranium glass.'

PERURANATES.

These salts are formed by the action of hydrogen peroxide and alkali hydroxides on uranyl salts, and are usually precipitated by means of alcohol as orange-yellow crystals. The sodium salt has the formula $Na_2UO_6 \cdot 8H_2O$. These compounds have been studied by Fairley (Chem. Soc. Trans. 1877, 31, 134) and Melikoff and Pissarjewsky (Ber. 1897, 30, 2092; Zeitsch. anorg. Chem. 1898, 18, 59; J. Russ. Phys. Chem. Soc. 1902, 24, 472).

A red potassium peruranate $K_2UO_6 \cdot 3H_2O$ is obtained when peruranic acid is added to hydrogen peroxide containing alcohol, and the solution treated with potassium hydroxide (Aloy, Bull. Soc. chim. 1903, [iii.] 29, 292). The formation of this substance may be employed as a delicate colorimetric test for the presence of uranium (Aloy, *ibid.* 1902, [iii.] 27, 734).

URANIUM COMPOUNDS.

Uranium tetrafluoride or *Uranous fluoride* UF_4 is the main product of the action of fluorine on uranium. It is prepared by adding hydrogen fluoride to a solution of uranous chloride, and forms a green powder, insoluble in water and dilute acids (Smithells, Chem. Soc. Trans. 1883, 43, 125; Bolton, J. 1886, 209). It leaves a residue of oxide when heated in air; and forms double fluorides with the alkali fluorides.

Uranium hexafluoride UF_6 is best obtained by the action of fluorine on the cooled pentachloride—

It forms colourless, monoclinic prisms, which sublime at ordinary temperatures under diminished pressure. It melts at 69.2° under a pressure of two atmospheres, and boils at 56.3° . The solid has a density of 4.68; the vapour gives a value 11.7 (air=1). It is very hygroscopic, and highly reactive (Ruff and Heinzelmann, Zeitsch. anorg. Chem. 1911, 72, 63; cf. Ber. 1909, 42, 492).

Uranium trichloride UCl_3 is obtained by heating the tetrachloride in hydrogen (Péligot, Ann. Chim. 1842, 5, 20), and is a reddish-brown substance, which easily dissolves in water, forming a red solution that slowly evolves hydrogen and becomes green.

Uranium tetrachloride or *Uranous chloride*

UCl_4 is produced when uranium is heated in chlorine, and is prepared by passing chlorine over heated uranium carbide or a mixture of any oxide of uranium with carbon (Péligot, *Annalen*, 1842, 43, 258; Zimmermann, *ibid.* 1882, 213, 320; 1883, 216, 8; Roscoe, *Chem. Soc. Trans.* 1874, [ii.] 12, 933; Aloy, *Bull. Soc. chim.* 1899, [iii.] 21, 264; Roderburg, *Zeitsch. anorg. Chem.* 1913, 81, 122). It forms dark-green octahedra, is volatile at a red heat, and the vapour has a density (air=1) of 13.33 (Zimmermann). In molten bismuth chloride as solvent the molecular weight is 373 (theory=380.3) (Rüchcimer and Gonder, *Annalen*, 1908, 364, 45). It is extremely deliquescent, fumes in the air, and readily dissolves in water with evolution of heat; the solution is a powerful reducing agent. The solution reacts acid, and on evaporation, leaves an oxychloride. Boiling water completely hydrolyses the chloride.

It forms double chlorides with the chlorides of the alkali and alkaline earth metals (Moissan, *Compt. rend.* 1896, 122, 1088; Aloy, *Bull. Soc. chim.* 1899, [ii.] 21, 264).

Uranium pentachloride UCl_5 is obtained by the direct union of the tetrachloride and chlorine. It exists in two forms: (i.) long, dark needles which are green by reflection, and ruby-red by transmission, light, and (ii.) a light-brown, mobile powder. It is very hygroscopic, and is decomposed by water. It cannot be volatilised without decomposition; in an atmosphere of carbon dioxide, dissociation into the tetrachloride and chlorine is complete at 235° (Roscoe, *Chem. Soc. Trans.* 1874, 12, 933).

Uranium tetrabromide or Uranous bromide UBr_4 is obtained by heating the green oxide of uranium with excess of sugar charcoal, and passing bromine vapour over the heated mixture of uranous oxide and carbon thus produced (Zimmermann, *Annalen*, 1883, 216, 2; Alibegoff, *ibid.* 1886, 232, 132; Richards and Merigold, *Zeitsch. anorg. Chem.* 1902, 31, 250). It forms lustrous, dark-brown tablets of sp.gr. 4.838 at $21^\circ/4^\circ$. At a red heat it is volatile; the vapour density (air=1) is 19.46 (Zimmermann). It closely resembles the tetrachloride in properties.

Uranium tetraiodide or Uranous iodide UI_4 is prepared by passing the vapour of iodine over powdered uranium heated to 500° in the absence of air (Guichard, *Compt. rend.* 1907, 145, 921). It forms black, crystalline needles, which melt at about 500° , and have a sp.gr. of 5.6. The aqueous solution is dark green and closely resembles the chloride in properties.

Uranous oxyfluoride UOF_2 is obtained by the action of hydrofluoric acid on uranoauranic oxide—

It is a fine green powder, insoluble in water (Giollitti and Agamennone, *Atti R. Acad. Lincei*, 1905, 14, i. 114).

Uranyl fluoride UO_2F_2 is formed in the preceding reaction, and is a yellow soluble mass. It also exists, according to Smithells (*Chem. Soc. Trans.* 1883, 43, 125) in a white crystalline form, which can be sublimed; this modification is prepared by carefully heating the tetrafluoride in air. It is hygroscopic and forms a yellow solution in water. Both forms unite with

potassium fluoride forming a lemon-yellow crystalline double salt $\text{UO}_2\text{F}_2 \cdot 3\text{KF}$, which can also be obtained from uranyl acetate and an excess of potassium fluoride. This salt is trimorphous (Baker, *ibid.* 1879, 35, 763). The corresponding double salts of other metals are also known, and are converted into deep yellow-coloured peroxyfluorides by hydrogen peroxide (Lordkipanidzé, *J. Russ. Phys. Chem. Soc.* 1900, 32, 283).

Uranyl chloride UO_2Cl_2 is obtained by heating uranous oxide to redness in a stream of chlorine. It is a yellow crystalline mass, stable in dry air; it is reduced by hydrogen at a red heat to the dioxide. Uranous chloride is soluble in water, alcohol, and ether, and its aqueous solution yields the monohydrate $\text{UO}_2\text{Cl}_2 \cdot \text{H}_2\text{O}$ on evaporation. A solution of uranyl chloride may be prepared by oxidising uranous chloride with nitric acid or by dissolving uranium trioxide in concentrated hydrochloric acid (Mylus and Dietz, *Ber.* 1901, 34, 2774; de Coninck, *Compt. rend.* 1909, 148, 1769; *Bull. Acad. roy. Belg.* 1909, 836). For a table of specific gravities of its aqueous solutions, v. de Coninck, *Ann. Chim.* 1904, [viii.] 3, 500.

Uranyl bromide UO_2Br_2 may be obtained in an impure state by heating uranous oxide in bromine vapour. It is obtained in aqueous solution by acting on uranous oxide with bromine water, or by dissolving uranic oxide in hydrobromic acid. Yellow needles of the hydrated compound separate on concentrating the solution; they decompose when heated (de Coninck, *Bull. Acad. roy. Belg.* 1902, 12, 1025).

Uranyl iodide UO_2I_2 is obtained by adding barium iodide in slight excess to an ethereal solution of uranyl nitrate. It separates from ether in red deliquescent crystals, and is not very stable (Aloy, *Ann. Chim.* 1901, [vii.] 24, 412).

Uranium monosulphide US is a black, amorphous powder formed by heating the sesquisulphide in hydrogen (Alibegoff, *Annalen*, 1886, 233, 131, 135).

Uranium sesquisulphide U_2S_3 is a greyish-black substance formed by heating the tribromide of uranium in hydrogen sulphide (Alibegoff, *l.c.*).

Uranium disulphide US_2 is formed by the direct union of its elements at 500° (Moissan); at a higher temperature uranium burns vividly in sulphur vapour. The sulphide is best prepared by heating the double chloride of uranium and sodium in a current of hydrogen laden with the vapour of sulphur; or the double chloride may be fused with sulphide of sodium, aluminium, magnesium, antimony or tin (Colani, *Compt. rend.* 1903, 137, 382; *Ann. Chim.* 1907, [viii.] 12, 59). It forms large, slender, pearly crystals; the amorphous powder, obtained by heating uranous chloride in hydrogen sulphide, is greyish-black in colour. It oxidises in the air to uranyl sulphide, and with nitric acid is rapidly converted into uranyl sulphate.

A black, hydrated disulphide is obtained by precipitating a uranous salt with ammonium sulphide; it rapidly oxidises in the air to uranyl sulphide.

Uranyl sulphide UO_2S is obtained by adding ammonium sulphide to an alcoholic solution of uranyl nitrate, washing the precipitate with alcohol and drying *in vacuo*. By precipitating in aqueous solution a brown hydrated form is obtained (Remelé, *Compt. rend.* 1864, 58, 716). It rapidly decomposes by heating to 180° ; warm water converts it into hydrated uranous oxide and sulphur. It dissolves in dilute acids and in ammonium carbonate. When digested for 48 hours with cold ammonium sulphide exposed to air, a deep-red solid is obtained, soluble in acids with the evolution of hydrogen sulphide and deposition of sulphur. This substance is called *uranium-red* (Patera, *J. pr. Chem.* 1850, [i.] 51, 122; Remelé, *Pogg. Ann.* 1865, 124, 158; Hermann, *J.* 1861, 14; Zimmermann, *Annalen*, 1880, 204, 204). A complicated substance of the formula $5\text{UO}_2 \cdot 2\text{K}_2\text{O} \cdot \text{KHS}_2 \cdot x\text{H}_2\text{O}$ is obtained by precipitating uranyl nitrate with potassium sulphide and treating the precipitate with potassium carbonate (Kohlschütter, *Annalen*, 1900, 314, 311). This is also called *uranium-red*; acids decompose it, liberating sulphur and hydrogen sulphide.

Uranyl sulphide is formed in black, tetragonal needles by heating uranosouranic oxide with sulphur and potassium thiocyanate (Milbauer, *Zeitsch. anorg. Chem.* 1904, 42, 448).

The *oxysulphide* $2\text{US}_2 \cdot \text{UO}_2$ has been described by Hermann (*J.* 1861, 260).

Uranium selenides USe_2 and U_2Se_3 are obtained in the crystalline state by heating the double chloride of uranium and sodium in a current of hydrogen containing the vapour of selenium (Colani, *Compt. rend.* 1903, 137, 382; *Ann. Chim.* 1907, [viii.] 12, 59).

Uranyl selenide is produced by heating uranosouranic oxide with selenium and potassium cyanide (Milbauer, *Zeitsch. anorg. Chem.* 1904, 42, 450).

Uranium telluride U_2Te_3 is prepared by fusing the double chloride of sodium and uranium with sodium telluride in an atmosphere of hydrogen (Colani, *l.c.*).

Uranium nitride U_2N_3 is a stable, greyish-black powder, prepared by heating uranous chloride in ammonia, and igniting the product mixed with ammonium chloride, once more in a stream of ammonia (Kohlschütter, *Annalen*, 1901, 317, 158). Uranium unites directly with nitrogen at 1000° , a yellow nitride being produced, the composition of which is not known (Moissan, *Compt. rend.* 1896, 122, 274).

Uranium phosphide U_2P_3 is obtained by fusing sodium uranous chloride with aluminium phosphide in a stream of hydrogen (Colani, *l.c.*). The *arsenide* U_2As_3 and *antimonide* U_2Sb_3 are similarly prepared. All three compounds are obtained as black crystalline powders; they are easily oxidised by nitric acid.

Uranium boride UB_2 is obtained by submitting a mixture of the finely powdered constituents to hydraulic pressure and using the mass as an electrode in the vacuum electrical furnace.

Uranium carbide U_2C_3 is prepared by strongly heating a mixture of 500 parts of uranosouranic oxide and 60 parts of carbon in the electric furnace. It is a lustrous, crystalline solid of

ρ 11.28 at 18° , and is harder than quartz, though not so hard as corundum. It is decomposed by fluorine when gently warmed; chlorine readily attacks it at 350° , whilst it reacts with oxygen at 370° . Uranium carbide is decomposed by water, a very complex change occurring. About one-third of the carbon is evolved in combination with hydrogen, mainly as methane, propane, butane, but mixed with a little ethylene and traces of acetylene; the gaseous mixture contains about 15 p.c. of free hydrogen. The remainder of the carbon is converted into a mixture of solid and liquid hydrocarbons (Moissan, *Compt. rend.* 1896, 122, 274; Lebeau and Damiens, *Compt. rend.* 1913, 156, 1987). A shower of brilliant sparks is produced when two pieces of the carbide are rubbed together.

Uranium silicide USi_2 is obtained from a mixture of silica and uranosouranic oxide by the aluminothermic process (*v.* THERMIT PROCESS). It crystallises in the cubic system, and has a density of 8.0. At 500° it reacts with chlorine giving a mixture of uranous and silicon chlorides (Defacqz, *ibid.* 1908, 147, 1050).

SALTS OF URANIUM.

Saturated aqueous solutions of uranyl formate, acetate, benzoate, and citrate are unstable even in the dark. The propionate, butyrate, oxalate, tartrate, and salicylate are stable in the dark. The benzoate and salicylate are not reduced even in sunlight (Courtois, *Bull. Soc. chim.* 1923, 33 [iv.] 1773; *Chem. Soc. Abstr.* 1924, 126, i. 285).

Uranyl formate $\text{UO}_2(\text{HCO}_2)_2 \cdot \text{H}_2\text{O}$, greenish-yellow crystals, readily soluble in methyl alcohol or water. Formed by adding hydrogen peroxide to a slightly acid solution of uranyl nitrate and treating the washed precipitate with excess of formic acid and evaporating the solution *in vacuo*.

Uranyl acetate $\text{UO}_2(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 2\text{H}_2\text{O}$ is prepared by dissolving in warm acetic acid the yellowish-red mass produced by heating uranyl nitrate until evolution of oxygen commences. It crystallises in yellow, monoclinic needles, and is used in photography and also for the volumetric estimation of phosphates.

For other uranium salts of the monocarboxylic acids of the fatty series, see Courtois, *Compt. rend.* 1914, 158, 1511, 1688.

Uranous arsenate $\text{UH}_2(\text{AsO}_4)_2 \cdot 2\text{H}_2\text{O}$ (Aloy, *Bull. Soc. chim.* 1899, [iii.] 21, 613; Rammelsberg, *Pogg. Ann.* 1842, 55, 318, 66, 125).

Uranyl arsenate $\text{UO}_2(\text{H}_2\text{AsO}_4)_2 \cdot 3\text{H}_2\text{O}$, a yellow powder, insoluble in water and acetic acid, is obtained by double decomposition (Werther, *Annalen*, 1848, 68, 313). Several arsenates occur as minerals, *e.g.* *trögerite* $(\text{UO}_2)_2(\text{AsO}_4)_2 \cdot 12\text{H}_2\text{O}$; *walpurkite*, a basic bismuth uranyl arsenate; and *uranospinite*, a calcium uranium arsenate.

Uranyl benzoate $\text{UO}_2(\text{C}_6\text{H}_5\text{O}_2)_2$ (Courtois, *Bull. Soc. chim.* 1923, 33 [iv.] 1761; *Chem. Soc. Abstr.* 1924, i. 285).

Uranyl bromate $\text{UO}_2(\text{BrO}_3)_2 \cdot x\text{H}_2\text{O}$, *v.* Rammelsberg, *Pogg. Ann.* 1842, 55, 77.

Uranous carbonate and uranyl carbonate are not known (Parkman, *Amer. J. Sci.* 1862, [ii.] 34).

326). Numerous double carbonates exist. *Potassium uranyl carbonate* $\text{UO}_2(\text{CO}_3)_2 \cdot 2\text{K}_2\text{CO}_3$ is obtained by dissolving potassium uranate in potassium bicarbonate and evaporating the solution at a moderate temperature; the corresponding ammonium and sodium salts are prepared in a similar manner (Ebelmen, Ann. Chim. 1842, [iii] 5, 189; Anthon, J. 1860, 698; de Coninck, Bull. Acad. roy. Belg. 1904, 363, 448). They form yellow, rhombic prisms, which are not very soluble in water, but much more soluble in alkali carbonate solutions. The ammonium salt loses ammonia on keeping. Another ammonium compound $2\text{UO}_2 \cdot \text{CO}_3 \cdot 3(\text{NH}_4)_2\text{CO}_3 \cdot 4\text{H}_2\text{O}$ has been obtained by mixing uranyl nitrate and ammonium carbonate (Giollitti and Vecchiarelli, Gazz. chim. ital. 1905, 35, ii. 170). *Uranyl calcium carbonate* $\text{UO}_2\text{CO}_3 \cdot \text{CaCO}_3 \cdot 10\text{H}_2\text{O}$ occurs as the mineral *liebigite* in apple-green warty masses.

Uranyl chlorate $\text{UO}_2(\text{ClO}_3)_2 \cdot 2\text{H}_2\text{O}$ is a very soluble substance, which readily decomposes when heated (Rammelsberg, l.c.).

Uranyl chromate $\text{UO}_2 \cdot \text{CrO}_4$ is obtained by adding uranic oxide to boiling chromic acid solution; it crystallises, on cooling the solution in yellow needles, containing $5\frac{1}{2}\text{H}_2\text{O}$ (Formánek Annalen, 1890, 257, 108), or $3\text{H}_2\text{O}$ (Orloff, Chem. Zeit. 1907, 31, 375). The double salt

is obtained as yellow monoclinic crystals by treating potassium uranate with chromic acid. The ammonium salt is isomorphous with the preceding salt; the sodium salt contains $10\text{H}_2\text{O}$ (Formánek, l.c.).

Uranyl cyanate $\text{UO}_2(\text{CNO})_2$, a golden-yellow precipitate obtained by mixing dilute solutions of potassium uranyl cyanate and uranyl nitrate (Pascal, Bull. Soc. chim. 1914, [iv.] 15, 11).

Uranyl iodate $\text{UO}_2(\text{IO}_3)_2$ is precipitated on mixing boiling solutions of uranyl nitrate and sodium iodate in dilute nitric acid; it forms yellow prisms, slightly soluble in water. A hydrate $\text{UO}_2(\text{IO}_3)_2 \cdot 5\text{H}_2\text{O}$ is also known (Ditte, Thèse de doctorat ès Sc. Paris, 1870).

Uranous nitrate has not yet been prepared in the solid form (Isambert, Compt. rend. 1875, 80, 1087).

Uranyl nitrate $\text{UO}_2(\text{NO}_3)_2$ is a yellow amorphous compound obtained by heating the tri- and tetra-hydrates in a current of nitric anhydride at a temperature of 170° – 180° . It reacts violently with ether and dissolves readily in water with development of heat. It combines with nitrogen dioxide to form

The trihydrate $\text{UO}_2(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ crystallises in yellow, monoclinic forms, and melts at 121.5° ; the dihydrate is rhombic and melts at 179.3° (Vasilieff, J. Russ. Phys. Chem. Soc. 1910, 42, 570). The commercial salt is the hexahydrate $\text{UO}_2(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$. It is formed when any of the oxides of uranium are dissolved in nitric acid, and is prepared commercially by heating ammonium uranate and dissolving the residue in nitric acid (Janda, Oester. Zeit. Berg-Hütt, 1901, 49, 325). For methods of preparation from pitchblende, v. Péligot, Ann. Chim. 1844, [iii.] 12, 557; Ebelmen, *ibid.* 1842, [iii.] 5, 186.

The hexahydrate forms lemon-yellow, fluorescent, rhombic prisms, which melt at 60.2° and deliquesce in the air (Vasilieff, l.c.; de Coninck, Compt. rend. 1900, 131, 1219, 1303; 1901, 133, 90, 204; Bull. Acad. roy. Belg. 1901, 222; 1909, 743). Water at 18° dissolves twice its weight of the salt. It is very soluble in alcohol and ether, and is best purified by crystallisation from the latter solvent. The aqueous solution is slightly hydrolysed, and has an acid reaction. An *icositetrahydrate* $\text{UO}_2(\text{NO}_3)_2 \cdot 24\text{H}_2\text{O}$ forms spontaneously at -35° and exists only below -20° (Germann, J. Amer. Chem. Soc. 1922, 44, 1466; Ley, Zeitsch. physikal. Chem. 1899, 30, 193; Ber. 1900, 33, 2658; Dittich, Zeitsch. physikal. Chem. 1899, 29, 449).

Uranium nitrate is triboluminescent, the crystals occasionally exploding with a bright flash in contact with water (Iwanow; Andrews, Chem. Zeit. 1912, 1463; Eichhorn, *ibid.* 1914, 38, 139). According to Müller (Chem. Zeit. 1916, 40, 38) this is not a property of the salt itself, but is due to the formation of an unstable compound of a lower oxide of nitrogen with a uranium-ether addition compound (Lebeau). The phenomenon only appears when the original aqueous solution contained free nitric acid.

Double nitrates of the type $\text{RUO}_2(\text{NO}_3)_2$, where R may be potassium, ammonium, thallium, rubidium, or caesium, but not sodium or lithium, are obtained by crystallising solutions of the mixed salts in nitric acid. Water decomposes them into their components (Meyer and Wendel, Ber. 1903, 36, 4055; Rimbach, *ibid.* 1904, 37, 461). For other double nitrates, see Lancein, Chem. Zentr. 1912, i. 208.

Uranyl nitrate is used in photography, and also for the volumetric estimation of phosphates and arsenates.

Uranous phosphate $\text{UH}_2(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$ (Aloy, Bull. Soc. chim. 1899, [iii.] 21, 613).

Uranyl phosphate $\text{UO}_2 \cdot \text{HPO}_4$. This is precipitated in an amorphous form by adding a soluble phosphate to uranyl nitrate solution. When this precipitate is continuously boiled with dilute hydrochloric acid for a long time, it is converted into $\text{UO}_2 \cdot \text{HPO}_4 \cdot 4\text{H}_2\text{O}$, which crystallises in tetragonal plates (Bourgeois, *ibid.* 1897, [iii.] 19, 733). The *dihydrogen phosphate* $\text{UO}_2(\text{H}_2\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$ is obtained by heating uranic oxide with dilute phosphoric acid, and concentrating the solution. It separates in small yellow crystals (Werther, J. pr. Chem. 1848, [i.] 43, 321). *Uranyl ammonium phosphate* $\text{UO}_2(\text{NH}_4)\text{PO}_4 \cdot x\text{H}_2\text{O}$ is a greenish-yellow precipitate formed by the addition of a soluble phosphate to a mixture of a uranyl and an ammonium salt. It is obtained in the volumetric estimation of phosphates. The precipitate is insoluble in acetic acid. Upon ignition it leaves a yellow residue of *uranyl pyrophosphate* $\text{UO}_2)_2\text{P}_2\text{O}_7$.

Various phosphates occur in nature, e.g. *halcolite* or *torberite* $(\text{Ca}(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 10\text{H}_2\text{O})$ and *autunite* or *uranite* $(\text{Ca}(\text{UO}_2)_2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O})$.

Complex uranyl hypophosphites have been described by Rosenheim and Trewendt (Ber. 1922, 55, [B] 1937). *Uranyl hypophosphite*

is a microcrystalline yellow powder, prepared by agitating solutions of one molecular proportion of uranyl nitrate with four molecular proportions of sodium hypophosphite; almost insoluble in water, but readily soluble in an excess of sodium hypophosphite or uranyl nitrate solution.

Uranyl salicylate $\text{UO}_2(\text{C}_6\text{H}_5\text{O}_2)_2$ forms orange-yellow crystals (Courtois, Bull. Soc. chim. 1923, 33, [iv.] 1761).

Uranous sulphate $\text{U}(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ is prepared by dissolving the green oxide in dilute sulphuric acid, adding alcohol and allowing the solution to crystallise. The mother liquor contains uranyl sulphate; on exposure to light it is reduced to uranous sulphate, and another crop of crystals is obtained. A large number of other hydrates are known, e.g. di-, tri-, tetra-, penta-, hexa-, hepta-, and nonohydrates (Orloff, J. Russ. Phys. Chem. Soc. 1902, 34, 381; de Coninck, Bull. Acad. roy. Belg. 1901, 483; Kohlschütter, Ber. 1901, 34, 3628; Giolitti and Bucci, Gazz. chim. ital. 1905, 35, ii. 151, 162; Giolitti and Liberi, *ibid.* 1906, 36, ii. 443). The tetrahydrate is a stable substance, and the nonohydrate $\text{U}(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$ crystallises from aqueous solution in green monoclinic prisms that frequently exhibit twinning and are isomorphous with thorium sulphate

(Rammelsberg, Zeitsch. Krystall. 1889, 15, 640). Uranous sulphate forms double salts with sulphates of the alkali metals, e.g.

(Kohlschütter, Ber. 1901, 34, 3619). Aqueous solutions of uranous sulphate are readily hydrolysed, basic sulphates being precipitated.

A sulphate of the composition $\text{UH}(\text{SO}_4)_2$, which is supposed to contain trivalent uranium, has been described (Rosenheim and Loebel, Zeitsch. anorg. Chem. 1908, 57, 234).

Uranyl sulphate $\text{UO}_2 \cdot \text{SO}_4$ is obtained by dissolving the hydroxide of uranium trioxide in concentrated sulphuric acid and crystallising the solution (Schultz-Sellack, Ber. 1871, 4, 13); or by drying either of its hydrates at 300° . It forms yellow fluorescent crystals. The hydrate $\text{UO}_2 \cdot \text{SO}_4 \cdot 3\frac{1}{2}\text{H}_2\text{O}$ is obtained by concentrating a solution of uranic hydroxide in dilute sulphuric acid; the solution does not crystallise readily. Another method is to dissolve uranosouranic oxide in concentrated sulphuric acid, dilute, and boil with nitric acid to oxidise the uranous sulphate present. The hydrate forms citron yellow prisms, which effloresce in air, losing water and leaving the trihydrate $\text{UO}_2 \cdot \text{SO}_4 \cdot 3\text{H}_2\text{O}$. This dissolves in twenty times its weight of water at ordinary temperatures (de Coninck, Bull. Acad. roy. Belg. 1901, 222, 349; 1902, 94, 161). Dried *in vacuo* or at 100° it retains 1 molecule of water. When dissolved in moderately concentrated sulphuric acid, a beautiful yellow, fluorescent, crystalline acid sulphate

crystallises out. The pyrosulphate $(\text{UO}_2)_2\text{S}_2\text{O}_7$ crystallises from a solution of the anhydrous sulphate in pyrosulphuric acid (Schultz-Sellack, Ber. 1871, 4, 13).

Uranyl sulphate forms a double sulphate with

hydroxylamine sulphate (Rimbach, Ber. 1904, 37, 461); a salt $\text{Ti}_2\text{SO}_4 \cdot \text{UO}_2 \cdot \text{SO}_4 \cdot 3\text{H}_2\text{O}$ with thalious sulphate (Kohn, Zeitsch. anorg. Chem. 1908, 59, 111); and combines with equimolecular quantities of the sulphates of ammonium, potassium, lithium, caesium, and magnesium, forming double salts which crystallise with from 2 to 5 molecules of water (de Coninck, Bull. Acad. roy. Belg. 1904, 1171; 1905, 50, 74, 151, 182; de Coninck and Chauvenet, *ibid.* 1908, 50).

A number of *basic sulphates* occur naturally, e.g. *zippéite* $(\text{UO}_2 \cdot \text{SO}_4 \cdot \text{UO}_3)$ and *uraconite* $(\text{UO}_2 \cdot \text{SO}_4 \cdot 2\text{UO}_3 \cdot 14\text{H}_2\text{O})$, which are alteration-products of pitchblende.

Uranyl sulphite. The crystalline precipitate obtained by evaporating a solution of uranic oxide in aqueous sulphurous acid, or by passing sulphur dioxide into an aqueous solution of uranyl acetate, has the empirical composition $\text{UO}_2 \cdot \text{SO}_2 \cdot 4\text{H}_2\text{O}$ (Girard, Compt. rend. 1852, 34, 22). According to Kohlschütter (Annalen, 1901, 314, 311) it is really uranyl sulphurous acid $\text{SO}_3\text{H} \cdot \text{UO}_2 \cdot \text{OH} \cdot 3\text{H}_2\text{O}$ (cf. Ley, Ber. 1900, 33, 2659).

Uranyl thiocyanate $\text{UO}_2(\text{CNS})_2 \cdot 8\text{H}_2\text{O}$, orange-yellow needles obtained by the action of barium thiocyanate on uranyl sulphate. Highly deliquescent and very soluble in water, alcohol, acetone, ether or amyl alcohol. Forms double salts with the alkali and alkaline earth metals (Pascal, Compt. rend. 1914, 158, 1672).

Tungstates, v. Rammelsberg, Pogg. Ann. 1843, 59, 31; Lefort, Compt. rend. 1878, 87, 748.

Detection and estimation.—In qualitative analysis uranium is obtained together with iron. All the uranyl salts of weak acids, e.g. carbonate, sulphide, phosphate, &c., are soluble in ammonium carbonate and the other alkali carbonates. The ferrocyanide, a brown precipitate, insoluble in dilute acids, is characteristic; alkalis turn it yellow. Uranium is usually weighed as uranosouranic oxide, or else as uranyl pyrophosphate; uranous salts may be titrated with permanganate. V. ANALYSIS; and Finn, J. Amer. Chem. Soc. 1906, 28, 1443; McCoy and Bunzel, *ibid.* 1909, 31, 367; Giolitti, Gazz. chim. ital. 1904, 34, ii. 166; Mazzucchelli, Atti R. Accad. Lincei, 1906, [v.] 15, ii. 429, 494; Campbell and Griffin, J. Electrochem. Soc. 1923, 43, 329; Jander and Reeh, Zeitsch. anorg. Chem. 1923, 129, 293; Moser, Monatsch. 1923, 44, 90.

URANIUM DISINTEGRATION PRODUCTS.

The disintegration of uranium proceeds in all probability in the following manner: Uranium I, of atomic weight 238, expels an α -particle and changes into uranium X_1 , an isotope of thorium. The half-period of this first change is 5000 million years. Uranium X_1 is short-lived, and changes with a half-period of 24.6 days into uranium X_2 , or brevium, in the Vth family, expelling a very soft β -radiation. Uranium X_2 has a half-period of only 1.15 minutes, and expels a penetrating β -radiation. It produces uranium II, which after two further α -ray changes gives, first, ionium, and then radium. Uranium II is an isotope of uranium I.

with atomic weight four units less. Its half-period is estimated to be about two million years. All uranium must thus consist of a mixture of two isotopes differing by four units in atomic weight, the proportion between the heavier and the lighter being 2500 to 1. No separation, or even partial separation, has as yet been effected. Independent evidence of the existence of uranium II is afforded by the fact that uranium gives two α -particles of different ranges per atom disintegrating.

See also A. S. Russell (Phil. Mag. 1923, 46, 642); Soddy and Hitchins (Phil. Mag. 1924, 47, 1148).

Uranium X. Estimated at.wt. 234. A radioactive element produced by the disintegration of uranium. It emits two kinds of β -rays, and also γ -rays, and its presence in ordinary uranium salts is responsible for the penetrative rays they emit. Uranium salts, when freed from uranium X, only emit α -rays. In course of a few months the β -radiation is regenerated, whilst that of uranium X decays.

Uranium X may be separated in a number of ways. When a concentrated solution of uranyl nitrate (sp.gr. of solution 2.05) is allowed to cool, the mother liquor left after removing the crystals formed contains about 85 p.c. of the uranium X present (Soddy and Russell, Phil. Mag. 1909, [vi.] 18, 620). If crystals of hydrated uranyl nitrate are shaken with ether, two layers are formed; the aqueous (lower) layer retains the uranium X. In the purification of a uranyl solution from iron, aluminium, &c., by pouring into excess of ammonium carbonate, the precipitated impurities contain all the uranium X. If this precipitate is dissolved in concentrated hydrochloric acid, and the solution extracted with ether, saturated with hydrogen chloride, the ferric chloride is removed, but not the uranium X, which remains in the aqueous layer (Lloyd, J. Phys. Chem. 1910, 14, 509; Soddy, Phil. Mag. 1909, [vi.] 18, 861). It has been recommended to add a thorium salt to a uranyl salt, and then precipitate the thorium in acid solution as fluoride; the precipitate contains the uranium X (Keetman, Jahr. Radioaktivität, 1909, 6, 269; Ritzel, Zeitsch. physikal. Chem. 1909, 67, 725). Thorium fluoride is, however, quite soluble in uranium solutions when these are concentrated. By using a lanthanum salt containing a very little thorium, converting the precipitated fluorides into sulphates and then precipitating by boiling with sodium thiosulphate, a precipitate is obtained, consisting mainly of sulphur, which on ignition leaves a very slight residue containing all the uranium X originally present (cf. Antonoff, Phil. Mag. 1911, [v.] 22, 431).

The most practical way of obtaining a continuous supply of uranium X as required is to keep a strong ethereal solution of uranyl nitrate and to shake this with a few drops of water, pour the aqueous extract into excess of N/2 ammonium carbonate and filter off the insoluble precipitate which contains the uranium X.

Chemically, uranium X is an isotope of thorium; for its radioactive properties, v. RADIOLOGY.

On the influence of substances on the adsorp-

tion of uranium X, v. Ritzel (Zeitsch. physikal. Chem. 1909, 67, 724); Freundlich and Neumann (Zeitsch. physikal. Chem. 1914, 15, 537); Brown (Chem. Soc. Trans. 1922, 1736).

On the γ -radiation from uranium X, v. Richardson (Phil. Mag. 1914, [vi.] 27, 252).

On the electro-chemical separation of uranium X and uranium, v. Rossi (Nuovo Cim. 1913, [vi.] 5, i. 5).

On the magnetic spectrum of the β -rays of uranium X, v. von Baeyer, Hahn and Meitner (Zeitsch. physikal. Chem. 1914, 15, 649).

Uranium X₁. v. Fajans and Göhring (Zeitsch. physikal. Chem. 1913, 14, 877); Fleck (Phil. Mag. 1913, [vi.] 26, 528); Hahn and Meitner (Zeitsch. physikal. Chem. 1913, 14, 758).

On the γ -rays of Uranium X₁ and their relations to Uranium X₁ and Uranium X₂, see Otto Hahn and Lise Meitner (Zeitsch. Physik. 1923, 7, 157-167; J. Chem. Soc. Abstr. 1923, 124, ii. 676).

Uranium X₁ is completely adsorbed by charcoal from a solution of uranium salt, but if a small quantity of a thorium salt is added the uranium X₁ is not adsorbed at all. If the thorium nitrate used is previously shaken with charcoal, it loses to a great extent its power of preventing the adsorption of uranium X₁. This is shown to be due to the fact that thorium nitrate contains colloidal particles, and these are responsible for the displacement of the equilibrium in the adsorption of uranium X₁ (H. Freundlich and M. Wreschner, Zeitsch. physikal. Chem. 1923, 106, 366-377; J. Soc. Chem. Ind. 1923, 42, 1220 A).

Uranium Y, v. Soddy (Phil. Mag. 1914, 215).

Uranium V, v. O. Hahn (Zeitsch. physikal. Chem. 1923, 103, 461); cf. also A. Piccard and E. Stahel (Physikal. Z. 1922, 23, 1; 24, 80).

Uranium Z (symbol U-Z), the existence of which has been announced by Hahn (Ber. 1921, 54 (B), 1131), has been further investigated by Guy and Russel (Chem. Soc. Trans. 1923, 123, 2618) (*q.v.*).

URANIUM MICA v. AUTUNITE; TORBERNITE; URANITE.

URANIUM YELLOW v. URANIUM.

URAO. A native form of sodium sesquicarbonate $\text{Na}_4\text{H}_2(\text{CO}_3)_3 \cdot 2\text{H}_2\text{O}$, found in South America, Africa, and other places. According to Chatard (Bulletin No. 60, U.S. Geol. Surv. 1887-1880), the formula of urao is

URAPURGOL (*helmitol*). Trade name for hexamethylenetetramineanhydromethylene citrate.

URARI v. CURARA.

p-URAZINE v. HYDRAZINES.

UREABROMIN. A molecular combination of carbamide and calcium bromide

prepared by mixing the two components in solution. It is readily soluble in alcohol or water, insoluble in ether, light petroleum or benzene, and melts at 186°. It gives all the ordinary reactions of its components when

dissolved in water. Used in medicine as a substitute for alkali bromides (Biltz, Pharm. Zentr. 1912, 53, 245).

UREA, carbamide, aminoformamide, $\text{CO} < \text{NH}_2$

occurs in human urine to the extent of 1.5 p.c. to 2 p.c.; in the urine of other mammalia, especially the carnivora; in small quantities in the blood, bile, milk, perspiration, the aqueous humour of the eye, and other animal fluids (Wurtz, Compt. rend. 1859, 49, 52; Popp, Annalen, 1869, 151, 88; Argutinsky, Pflüger's Archiv. 1891, 46, 594; North, Proc. Roy. Soc. 1886, 39, 443; Pautz, Zeitsch. biol. 1894, 31, 212); in the liver, muscle and blood of the dog-fish, the blood containing 2.78 p.c. (v. Shroeder, Zeitsch. physiol. Chem. 1890, 14, 576; Baglioni, Beitr. chem. Physiol. Path. 1906, 9, 50); in the bile and blood of other fish (Hammarsten, Zeitsch. physiol. Chem. 1898, 24, 322; Baglioni, l.c.). According to Marshall and Davis (J. Biol. Chem. 1914, 18, 53) urea is present in all tissues and organs of normal animals; v. also Karr and Lewis (J. Amer. Chem. Soc. 1916, 38, 1615), and v. Cullen and Ellis (J. Biol. Chem. 1915, 20, 571). In the vegetable kingdom urea has been found in *Lycoperdon bovista*, *Psolliota campestris* and other higher fungi to the extent of 4.3 p.c. of the dry weight, and is present in minute quantities in the juice from the washed leaves of a number of plants and also in seedlings of wheat, barley, maize, peas, clover, and beans (Bamberger and Landseidl, Monatsh. 1903, 24, 218; Gaze, Arch. Pharm. 1905, 243, 78; Goris and Mascré, Compt. rend. 1908, 147, 1488; Fosse, *ibid.* 1912, 155, 851; 1913, 156, 567, and 1938; Ann. Chim. 1916, 6, 13; Compt. rend. 1919, 168, 1164).

As much as 13 p.c. of urea has been found in dried mushrooms that have been cultivated in manure (Ivanov, Biochem. Zeitsch. 1923, 143, 62; Chem. Soc. Abstr. 1924, 126, 353).

A. niger and *P. glaucum* both produce urea in the presence of ammonia and carbohydrates (Fosse, Compt. rend. 1912, 156, 263). For the formation of urea by higher plants, see Fosse (Ann. Chim. Phys. [ix.] 1916, 6, 567). A number of plants hydrolyse urea in presence of chloroform (Fosse, Ann. Inst. Pasteur, 1916, 30, 642).

Urea was first obtained synthetically by Wöhler in 1828 from ammonium cyanate, which undergoes a spontaneous transformation into its isomeride urea when an aqueous solution is

evaporated at the temperature of boiling water. The mechanism of the reaction has been studied by Walker and others (Chem. Soc. Trans. 1895, 67, 746; 1896, 79, 193; 1897, 71, 489; 1900, 77, 30), who have shown: (1) that the reaction is a reversible one, equilibrium being reached in a decinormal solution when there is about 95 p.c. of urea and 5 p.c. of ammonium cyanate present (cf. Lewis and Burrows, J. Amer. Chem. Soc. 1912, 34, 1515); (2) that the reaction is a bimolecular one; (3) that the velocity of the reaction is thirty times as great in 90 p.c. ethyl alcoholic as in aqueous solutions; and (4) that pure dry ammonium cyanate passes rapidly into urea when heated at about 80°. These authors suggest that the active molecules in the reaction are ammonium ions and cyanic acid ions, $\text{NH}_4^+ + \text{CNO}^- = \text{CO}(\text{NH}_2)_2$; and that the increased velocity of the reaction in alcoholic solution is due to the effect of the alcohol in increasing the rate at which the dissociated ions interact, and this more than counterbalances the diminution in the velocity due to the diminished degree of electrolytic dissociation of the cyanate (cf. Burrows and Fawsitt, Chem. Soc. Trans. 1914, 105, 609). Another explanation of the reaction offered by Chattaway (Chem. Soc. Trans. 1912, 101, 170) is that ammonium cyanate dissociates into ammonia and cyanic acid, that these interact to form isourea, which rapidly undergoes molecular rearrangement

Wheeler and others (J. Amer. Chem. Soc. 1912, 34, 1269) offer a somewhat simpler explanation of the interaction between the cyanic acid and ammonia by introducing the idea of partial valency

Werner has shown that cyanic acid is capable of existing in equilibrium in the two forms, *normal* and *iso*-, or, as he prefers to call them, *enol* and *keto*, the relative proportions being a function of the temperature. Being a weak acid in the enolic form, cyanic acid would naturally yield a very unstable ammonium salt, easily dissociated by heat, both in the dry state and in solution, and transformable into urea according to the following scheme:

(Chem. Soc. Trans. 1913, 103), see also Werner and Fearon (*ibid.* 1920, 1356).

Urea can be obtained from lead cyanate by direct hydrolysis with boiling water (Cumming,

Chem. Soc. Trans. 1903, 83, 1391); by heating ammonium sesquicarbonate or ammonium carbamate at 130°–135° under pressure (Bourgeois, Bull. Soc. chim. 1897, [iii.] 17, 474; Fichter and

Becker, Ber. 1911, 44, 3473; J. Soc. Chem. Ind. 1915, 34, 924; Eng. Pats. 23939, 24117, 24042, 1914; Matignon and Fréjaques, Compt. rend. 1920, 171, 1003; Badische Anilin and Soda-Fabrik, D. R. PP. 332679, 301279; Eng. Pat. 145060; Krass and Gaddy, J. Ind. Eng. Chem. 1922, 14, 611; by the electrolysis of a solution of ammonium carbonate (Fichter, Steiger and Stanisch, Verh. Schweiz. Nat. ges. 1916, 28, ii, 66; Fichter, Zeitsch. Elektrochem. 1918, 24, 41); by passing a mixture of ammonia and carbon dioxide through a red hot tube (Mixer, Amer. Chem. J. 1882, 4, 34). For the explanation of the mechanism of these reactions, see Werner (Chem. Soc. Trans. 1920, 1046). Bailey (Compt. rend. 1922, 175, 279). Urea is also formed by the action of carbonyl chloride on ammonia (Natanson, Annalen, 1856, 98, 287; Bouchardat, Compt. rend. 1869, 69, 961; Fenton, Chem. Soc. Trans. 1879, 35, 793; Hantzsch and Stuer, Ber. 1905, 38, 1041; Werner, Chem. Soc. Trans. 1918, 694); by passing a stream of air charged with ammonia and benzene vapour or acetylene over a heated platinum spiral (Herroun, Chem. Soc. Trans. 1881, 39, 471); by heating a solution of carbon monoxide in ammonium cuprous chloride at 105° under pressure (Jouve, Compt. rend. 1899, 128, 114); by the decomposition of copper or ammonium fulminate with sulphuretted hydrogen (Gladstone, Quart. J. Chem. Soc. 1849, 1, 228); by the decomposition of an aqueous solution of prussic acid (Campani, Gazz. chim. ital. 1871, 1, 472), or by the oxidation of potassium cyanide with potassium permanganate or sodium hypochlorite (Volhard, Annalen, 1890, 259, 377; Reychler, Bull. Soc. chim. 1893, [iii.] 9, 327). (For industrial conversion of ammonia into urea, see Matignon and Fréjaques, Chem. Ind. 1922, 7, 1057. In abstract, J. Soc. Chem. Ind. Aug. 31, 1922, p. 646 A. See also under Patents, p. 647 A., Bad. Anil. u. Soda Fabrik, Eng. Pat. 182331). Urea is also obtained by the hydrolysis of guanidine (Flemming, Chem. Zeit. 1900, 24, 56), arginine (Schulze and Likiernik, Ber. 1891, 24, 2701) or lysatine (Drechsel, *ibid.* 1890, 23, 3096) with barium hydroxide solution; and is a constant product of oxidation with acid potassium permanganate of a large number of organic compounds containing nitrogen: for example, acid amides and amino acids (Hofmeister, Chem. Zentr. 1896, ii, 389; Jolles, Ber. 1900, 33, 2834; J. pr. Chem. 1901, [ii.] 63, 516), and proteins (Ritter, Compt. rend. 1872, 73, 1219; Hofmeister, *l.c.*; Hugouneq, Compt. rend. 1901, 132, 1240; Jolles, Ber. 1901, 34, 1447; Fosse, Compt. rend. 1912, 154, 1187, 1819; 1919, 168, 1164; 1921, 172, 684, 1240; 173, 318). Urea is found abundantly when *d*-glucose, levulose, sucrose, dextrin or cellulose is oxidised in presence of ammonia; and much higher yields of urea are obtained by oxidising under the same experimental conditions formaldehyde or urotropine (Fosse, Ann. Inst. Pasteur, 1916, 30, 642; Compt. rend. 1919, 168, 1164; 1921, 172, 684, 1240; 173, 318).

Cyanamide is slowly converted into urea by the action of water (Schmidt, Arch. Pharm. 1917, 255, 351), by the action of dilute mineral acids in the presence of ferrosulphuric oxide (Farbwerke vorm. Meister, Lucius and Brüning,

D.R.P. 301278, from Chem. Zentr. 1922, ii, 1135).

Urea is usually obtained from urine by treating the concentrated filtered liquid with a hot saturated solution of oxalic acid and decomposing the sparingly soluble urea oxalate thus obtained with powdered chalk; the filtrate is decolorised with animal charcoal and evaporated until the urea crystallises out on cooling. Another method consists in extracting the urea with alcohol from the syrup obtained by evaporating the urine, precipitating the urea as the sparingly soluble nitrate by the addition of concentrated nitric acid, and decomposing the salt by boiling with barium carbonate and alcohol; the urea is obtained by crystallisation from the filtrate. It can be purified and decolorised by boiling it in aqueous solution with hydrogen peroxide (Kunz-Krause, Kolloid Zeitsch. 1919, 25, 240).

Urea can be prepared on a large scale by passing dry ammonia into fused phenyl carbonate until the odour of ammonia is persistent. The product is poured into hot water, when it separates into two layers consisting respectively of phenol and a solution of urea; 5 kilos. of phenyl carbonate yield 1 kilo. of urea and the whole of the phenol is recovered. The phenyl carbonate is obtained in an almost theoretical yield by passing dry carbonyl chloride into a solution of phenol in its equivalent quantity of dilute caustic soda (Hentschel, Ber. 1884, 17, 1286). By a similar reaction, guaiacol carbonate is rapidly converted into urea and guaiacol when an alcoholic solution is saturated with ammonia (Cazeneuve, Compt. rend. 1896, 122, 999).

Urea crystallises in needles, or in four-sided rhombic anhydrous prisms; it is readily soluble in water, 1 grm. of water dissolving 0.779 grm. of urea at 5.5°, 1.00 grm. at 17.1°, and 1.094 grm. at 20.92° (Krummacker, Zeitsch. biol. 1905, 46, 302). It dissolves in five parts of cold alcohol, is soluble in methyl and in amyl alcohol, and is insoluble in ether, ethyl acetate or chloroform. The heat of combustion is 2.532 cal., and the heat of solution 3.57 cal. (Krummacker, *l.c.*). For the entropy changes at low temperature, see Gibson, Latimer and Parks (J. Amer. Chem. Soc. 1920, 42, 1533).

Urea melts at 130°–132°, and sublimes readily when heated under reduced pressure at 120°–130° (Bourgeois, Bull. Soc. chim. 1892, [iii.] 7, 45). When pure dry urea is heated slightly above its melting-point it undergoes rapid dissociation into ammonia and cyanic acid

Cyanuric acid is produced as a result of the polymerisation of a portion of the cyanic acid originally present in the keto-form, whilst biuret is simultaneously formed by the action of cyanic acid on unchanged urea. Biuret $\text{NH}_2 \cdot \text{CO} \cdot \text{NH} \cdot \text{CO} \cdot \text{NH}_2$, when heated at 195° decomposes into ammonia and cyanic acid, cyanuric acid $\text{C}_3\text{N}_3(\text{OH})_3$, and ammelide

(Werner, Chem. Soc. Trans. 1913, 103, 2275; Chem. Soc. Proc. 1914, 262). When urea is sublimed in a vacuum at 160°–190°, the sublimate consists of ammonium cyanate (Escalles, Chem. Zeit. 1911, 35, 595). When an aqueous solution of urea is boiled, it is partially converted into ammonium cyanate. The reaction is a reversible one, equilibrium being reached in a N/10 solution, when there is about 5 p.c. ammonium cyanate present (Walker and Hambly, Chem. Soc. Trans. 1895, 67, 746; Fawsitt, Zeitsch. physikal. Chem. 1902, 41, 602). When heated with water in a sealed tube at 180°, urea undergoes complete hydrolysis, forming ammonium carbonate. For the decomposition of urea by acids and alkalis, see Werner (Chem. Soc. Trans. 1918, 84; 1920, 1078). Urea is decomposed by the action of nitrous acid, yielding nitrogen and carbon dioxide (Claus, Ber. 1871, 4, 140); compare, however, Werner (Chem. Soc. Trans. 1914, 863). Urea is decomposed when heated with dilute hydrochloric, sulphuric, or nitric acid, yielding carbon dioxide and the ammonium salt of the acid (Fawsitt, Zeitsch. physikal. Chem. 1902, 41, 601; Werner, Chem. Soc. Trans. 1918, 113, 84; Price, *ibid.* 1919, 115, 1354; Burrows, J. Roy. Soc., New South Wales, 1919, 53, 125). It is oxidised by a hot acid solution of potassium permanganate, yielding two vols. CO₂ and 1 vol. N (Wanklyn and Gamgee, Chem. Soc. Trans. 1868, 21, 25). By the action of sodium hypochlorite or hypobromite, urea is converted into carbon dioxide, nitrogen, and water; together with a small quantity of carbon monoxide (Hurtley, Bio-Chem. J. 1921, 15, 11). For an explanation of the course of this reaction, compare Sohestakow (J. Russ. Phys. Chem. Soc. 1905, 37, 1); Dehn (J. Amer. Chem. Soc. 1910, 31, 1220); Werner (Chem. Soc. Trans. 1922, 2318). Urea is decomposed by bromine, yielding cyanuric acid, ammonium bromide, and nitrogen; chlorine has a similar reaction on fused urea (Smolka, Monatsh. 1887, 8, 64). Urea is converted into cyanamide NC-NH₂ by the action of sodium (Fenton, Chem. Soc. Trans. 1882, 41, 262) or of sulphuryl chloride (Moureu, Bull. Soc. chim. 1894, [iii.] 11, 1068). Compare Werner (Chem. Soc. Trans. 1915, 107, 715) for the relationship of cyanamide to urea, and (*ibid.* 1913, 106, 923) for the constitution of carbamides and isocarbamides.

Urea readily undergoes bacterial fermentation with production of ammonium carbonate (Miguel, Compt. rend. 1890, 111, 397; Frankland, Chem. Soc. Trans. 1885, 47, 175; Hatton, *ibid.* 1881, 39, 256; Jacoby, Biochem. Zeitsch. 1916, 74, 109); a ferment present in urine is particularly active in causing this decomposition, and if this ferment is collected on paper by filtration, washed and dried at 35°–40°, its activity revives when brought into contact with water; and such papers, when previously coloured with turmeric, form a convenient test for urea, becoming deep brown when dipped into a solution containing even $\frac{1}{1000}$ part of urea (Musculus, Compt. rend. 1874, 78, 132). For the decomposition of urea by moulds, v. Kossovitz (Amer. Chem. Abs. 1913, 807).

Detection.—Urea can be detected by the formation of its sparingly soluble nitrate or oxalate. In the case of the latter salt, the

precipitation is facilitated by using an amyl alcoholic solution of the urea and of the oxalic acid (Brücke, Monatsh. 1881, 3, 195). The *biuret* test is the commonest test for urea. It consists in heating gently the urea until it ceases to evolve ammonia freely, dissolving the residue in a little water and adding a few drops of very dilute copper sulphate solution, on the subsequent addition of a drop of concentrated potassium hydroxide, a beautiful violet colour is developed. If the urea is in solution, it may be detected by evaporating to dryness with hydrochloric acid, heating the residue until it ceases to evolve thick white fumes and then dissolving in ammonia; on adding barium chloride solution and stirring, crystals of barium cyanurate separate on the lines of friction made by the rod; or copper sulphate may be added to the ammoniacal solution of the residue, when violet crystals of cuprammonium cyanurate separate out (Bloxam, Chem. News, 1883, 47, 285; v. Werner, Chem. Soc. Proc. 1914, 30, 262, for proof that biuret is formed by the interaction of urea and its dissociation product cyanic acid). Other colour reactions that can be used for the detection of urea are (1) the formation of a fine purple violet colour, when a solution of urea is treated with a concentrated solution of furfural and a few drops of concentrated hydrochloric acid (Schiff, Ber. 1877, 10, 773; Ganassini, Arch. Farm. sperim. sci. app. 1918, 26, 238; from Chem. Zentr. 1919, ii, 473); (2) the development of an intense blue colour when minute quantities of urea (or other compounds containing the $\text{NH}\cdot\text{CO}\cdot\text{NH}_2$ group) and methylfural ($\text{C}_4\text{H}_3\text{O}\cdot\text{CO}\cdot\text{CO}\cdot\text{C}_4\text{H}_3\text{O}\cdot\text{CH}_3$) are mixed on a filter paper and treated with a drop of fuming hydrochloric acid (Fenton, Chem. Soc. Trans. 1903, 83, 187; Proc. Camb. Phil. Soc. 1911, 16, 64); (3) the development of the characteristic red colour of the sodium violurate when the urea (or its mono- or sym. di-substituted derivatives) is condensed with malonic acid by cautiously heating the mixture moistened with phosphoryl chloride, the resulting barbituric acid dissolved in water, neutralised with solid sodium carbonate, and then treated with a crystal of sodium nitrite and a drop of acetic acid (Whiteley, *private communication*); (4) urea condenses with *o*-nitrobenzaldehyde when heated in alcoholic solution, the *o*-nitrobenzodiuireide $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}(\text{NH}\cdot\text{CO}\cdot\text{NH}_2)_2$, thus obtained melts at 200°, and if present in very small amount may be readily detected by decomposing it with dilute hydrochloric acid and testing for *o*-nitrobenzaldehyde by the red colour it gives with phenylhydrazine (Lüdy, Monatsh. 1889, 10, 295); see also Arreguine and Garcia (Anal. Asoc. Quim. Argentina, 1921, 9, 183). According to Fosse (Compt. rend. 1913, 157, 948) it is possible to precipitate urea by means of its xanthhydrol derivative at a dilution of 1 in 1,000,000, to identify it by analysis at a dilution of 5 parts in 100,000, and to identify it microscopically at a dilution of 1 in 100,000; see also Werner and Fearon (Chem. Soc. Trans. 1920, 1360); and Bonnet and Haushalten (Compt. rend. Soc. Biol. 1922, 86, 395); Stübel (Anat. Anz. 1921, 54, 236).

Estimation.—The determination of the amount of urea present in urine, blood serum or other animal liquids, is a problem of great

physiological importance. Of the large number of methods that have been described for the estimation of urea, only those are now in use that involve the conversion of urea into ammonia, under such conditions that other nitrogenous substances that may be present in the specimen are not simultaneously hydrolysed. The most important methods are those of Folin and of Benedict, Möerner and Sjöquist, and of Pfüger and Bleibtreu. For estimation by the hypobromite method, see Philibert (J. Pharm. Chim. 1919 [vii.] 19, 335, 386, 434); Golse (*ibid.* 1919, [vii.] 19, 20). For estimation by the xanthhydrol method, v. Fosse (Compt. rend. 1914, 158, 1076, 1588; 1914, 159, 253, 367); Maestro (Chem. Zentr. 1915, 11, 984, from Arch. Farmacol. Sperim. 19, 572); Frenkel (Ann. Chim. anal. 1920, [ii.] 2, 234); Carra (Biochem. therapia. sper. 1921, 8, 225), who has examined the various methods for the estimation of urea, states that this method is very accurate. For a microchemical method based on this reaction, see Nicloux and Welter (Compt. rend. 1921, 173, 1490).

I. Folin's method is based on the fact that urea is quantitatively converted into ammonia and carbon dioxide when heated with fused magnesium chloride $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$. In using this method for the estimation of urea in urine, 3 c.c. of the sample are boiled for half an hour with 20 grms. of hydrated magnesium chloride (phosphoric acid or potassium acetate, v. Folin, J. Biol. Chem. 1912, 11, 507) and 2 c.c. concentrated hydrochloric acid in a small reflux apparatus supplied with a special 3-bulb safety tube. After careful dilution, 7 c.c. of 20 p.c. sodium hydroxide are added to liberate magnesium hydroxide and the ammonia distilled over into a known volume of N/10 acid, the distillation being prolonged until the contents of the flask are almost dry. Allowance must be made for the ammonia present in the magnesium chloride (Folin, Zeitsch. physiol. Chem. 1901, 32, 504; 1902, 36, 333; Folin and Farmer, J. Biol. Chem. 1912, 11, 493, 507, 523; cf. Bock, *ibid.* 1913, 14, 295). In this method creatinine yields traces of ammonia and allantoin yields all its nitrogen as ammonia. Benedict (J. Biol. Chem. 1910, 8, 405) modifies the method by adding to the urine potassium hydrogen sulphate, zinc sulphate, a little powdered pumice, and a piece of paraffin to prevent frothing; the mixture is boiled to dryness, the residue heated at 162° – 165° for an hour, then mixed with sodium hydroxide and the liberated ammonia distilled into standard acid. For the conversion of urea to ammonia by means of urease, which does not decompose allantoin, v. Marshall, J. Biol. Chem. 1913, 14, 283; Van Slyke and Cullen, *ibid.* 1914, 19, 211; 1916, 24, 117; Plimauer and Skelton, Bio-Chem. J. 1914, 8, 70; 1916, 24, 117; Fiske, J. Biol. Chem. 1915, 23, 455; Halen, Chem. Zentr. 1916, 1, 997, from Deut. med. Woch. 1916, 42, 414; Yamazaki, J. Tokyo Chem. Soc. 1918, 39, 125. This method, according to Carra (*l.c.*), gives excellent results. Folin and Denis (*ibid.* 1916, 26, 501) give directions for the estimation of the nitrogen by direct Nesslerisation after hydrolysing the urea by urease and removing the latter with phosphoric acid.

When crude soya-bean meal is used for the estimation of urea, the addition of sodium

carbonate in sufficient amount to liberate the ammonia formed in the free state is without deleterious effect upon the activity of the urease. This observation is made use of in the following method: Three large test tubes are constricted by drawing them out in a blowpipe flame in such a manner that the capacity below the constriction is about three times that of the liquid to be contained. These tubes are fitted with corks and connecting tubes as wash-bottles, the upper end of the first inlet tube being provided with a three-way piece and stopcock. Into the first tube 20 c.c. of water, 5 c.c. of urine, and 3 to 5 grms. of soya-bean meal are placed, and the central narrow tube is inserted and surrounded by a few glass beads above the constriction. The remaining tubes contain known volumes of 0.1 N sulphuric acid for absorption of the ammonia liberated. The tube containing the mixture is immersed in a water-bath at 40°C ., and a current of ammonia-free air is drawn through the apparatus at a rate exceeding $5\frac{1}{2}$ litres per minute. Two c.c. of saturated sodium carbonate solution are introduced by means of the stopcock into the tube containing the mixture, and aeration is continued for 40 minutes, after which the urea is calculated from the titration of the standard acid. Results obtained with known amounts of urea show a maximum error of 0.88 p.c. (G. M. Wishart, Bio-Chem. J. 1923, 17, 403–405; Analyst, 1923, 48, 501).

Urea in urine or in milk may be estimated by means of urease obtained from the seeds of *Canavalia ensiformis* by extracting the powder with glycerol and water, then, after about 3 hours, acidifying with hydrochloric acid and filtering. In the case of urine, the estimation is carried out by diluting about 5 c.c. with 50 c.c. of water and adding 3 c.c. of the solution of urease and 1 c.c. of 3 p.c. solution of calcium caseinate to serve as indicator; after about 3 hours, 40 c.c. of 0.1 N hydrochloric acid are added, and the excess of acid titrated back with sodium hydroxide solution, the precipitation of the casein indicating the end-point. In the case of milk, 10 c.c. are diluted with 40 c.c. of water, 3 c.c. of urease solution are added, and the estimation continued as above. Cow's milk usually contains 0.25 to 0.30 gm. of urea per litre, and, for the first few weeks after calving, 0.75 gm. per litre. Goat's milk is richer in urea than that of the cow, the average being 0.80 gm. per litre (G. Morimoto, Bio-Chem. J. Japan, 1922, 69; Ann. Chim. anal. 1923, 5, 153; Analyst, 1923, 48, 394).

II. In the Möerner-Sjöquist method of estimating urea in urine, uric acid, purine bases, tyrosine, allantoin, &c., are removed by precipitation with barium chloride and hydroxide in a mixture of alcohol and ether. The filtrate and washings are evaporated at 55° to about 25 c.c., a little water and magnesia added and the distillation continued until the steam has no longer an alkaline reaction. The volume is then concentrated to 10–15 c.c. and the nitrogen present estimated by the Kjeldahl method (Chem. Soc. Abstr. 1901, 758; compare Braunstein, Zeitsch. physiol. Chem. 1900, 31, 381).

III. In the Pfüger-Bleibtreu method for the estimation of urea in urine, the nitrogenous compounds other than urea are precipitated by

means of a mixture of hydrochloric and phosphotungstic acids; the urea decomposed in the neutralised filtrate by heating it with phosphoric acid, and the ammonia estimated. For working details of this and the other methods, see Abderhalden's *Handbuch der Biochemischen Arbeitsmethoden*, vol. iii. part 2, 776-782.

Derivatives. Salts.—Urea forms salts with metals; *silver urea* $\text{CO}(\text{NHAg})_2$ (Mulder, Ber. 1873, 6, 1019); *monopotassium urea* $\text{CON}_2\text{H}_2\text{K}$, colourless needles; *dipotassium urea* $\text{CON}_2\text{H}_2\text{K}_2$, gelatinous mass (Franklin and Stafford, Amer. Chem. J. 1902, 28, 83). It also forms salts with acids, some of which combine with metallic salts to form stable crystalline double salts. The *nitrate* $\text{CO}(\text{NH}_2)_2 \cdot \text{HNO}_3$ forms sparingly soluble monoclinic crystals that decompose at 140° (Gaubert, Compt. rend. 1907, 145, 378; v. Barker, Min. Mag. 16, 207, for crystallographic constants); it is precipitated quantitatively when concentrated solutions of cyanamide and nitric acid are mixed at below 20° (D. R. P. 285259, from J. Soc. Chem. Ind. 1915, 34, 1166); the *hydrochloride* $\text{CO}(\text{NH}_2)_2 \cdot \text{HCl}$ dissociates in aqueous solution (Datta, Chem. Soc. Trans. 1912, 101, 166); see also du Toit (Proc. K. Akad. Wetensch. Amsterdam, 1913, 16, 555); the *phosphate* $\text{CO}(\text{NH}_2)_2 \cdot \text{H}_3\text{PO}_4$, large rhombic crystals, readily soluble in alcohol or water; the *phosphotungstate* crystallises in rhombic prisms (Drummond, Bio-Chem. J. 1918, 12, 5); *acetate* $\text{CO}(\text{NH}_2)_2 \cdot \text{C}_2\text{H}_3\text{O}_2 \cdot 2\text{H}_2\text{O}$, large deliquescent crystals (Matignon, Compt. rend. 1891, 112, 1367); *glycine urea*

large crystals (Matignon, Bull. Soc. chim. 1894, [iii.] 11, 576); the *salicylate (ursal)*

has m.p. 122° ; the *acid salt* $\text{CO}(\text{NH}_2)_2 \cdot 2\text{C}_7\text{H}_5\text{O}_3$ has m.p. 115° ; the *guinate (urol, urocol)*

m.p. 107° ; the *picrate* $\text{CO}(\text{NH}_2)_2 \cdot \text{C}_6\text{H}_3\text{O}_7\text{N}_3$ decomposes at 142° (Smolka, Monatsh. 1885, 6, 915); the *oxalate* $[\text{CO}(\text{NH}_2)]_2 \cdot \text{C}_2\text{H}_2\text{O}_4$ forms rhombic plates or prisms, sparingly soluble in water (1:23), less so in alcohol (1:62), amyl alcohol, and insoluble in ether. With hydrogen peroxide urea forms the compound

in large transparent crystals (Tanatar, J. Russ. Phys. Chem. Soc. 1908, 40, 376). Urea forms crystalline compounds with *sodium chloride* $\text{CO}(\text{NH}_2)_2 \cdot \text{NaCl} \cdot \text{H}_2\text{O}$ rhombic plates or prisms, m.p. 60° - 70° ; with *ammonium chloride* $\text{CO}(\text{NH}_2)_2 \cdot \text{NH}_4\text{Cl}$ quadric plates or needles that readily dissociate; with *calcium nitrate* $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{CO}(\text{NH}_2)_2$, the compound is crystalline, readily soluble in water and not deliquescent (Boech, U.S. Pat. 1369383); with *calcium chloride* $\text{CaCl}_2 \cdot 4\text{CO}(\text{NH}_2)_2$, m.p. 158° - 160° , stable in air, said to be useful for subcutaneous injection in hay fever and asthma (Knoll & Co., D.R.P. 306804, from Chem. Zentr. 1918, ii. 420; Okuda and Fujiwaka, J. Tokyo Chem. Soc. 1919, 40, 404); with *calcium bromide (ureabromin)* $4\text{CO}(\text{NH}_2)_2 \cdot \text{CaBr}_2$, m.p. 186° , which has therapeutic properties resembling those of the alkali bromides (Biltz, Pharm.

Zentr. 1912, 53, 245); $\text{CaBr}_2 \cdot 6\text{CO}(\text{NH}_2)_2$, hexagonal plates, m.p. 146° (Okuda and Fujiwaka, l.c.); with *calcium iodide* $\text{CaI}_2 \cdot 6\text{CO}(\text{NH}_2)_2$, hexagonal plates, m.p. 168° - 169° (Okuda and Fujiwaka, l.c.); $\text{CaI}_2 \cdot \text{CO}(\text{NH}_2)_2 \cdot 2\text{H}_2\text{O}$, large transparent plates, m.p. 167° (Spitz, D. R. P. 318343, from Chem. Zentr. 1920, ii. 601); with *mercuric chloride* $\text{CO}(\text{NH}_2)_2 \cdot \text{HgCl}_2$; with *zinc chloride* $\text{CO}(\text{NH}_2)_2 \cdot \text{ZnCl}_2$; with *cadmium chloride* $\text{CO}(\text{NH}_2)_2 \cdot \text{CdCl}_2$; with *silver nitrate* $\text{CO}(\text{NH}_2)_2 \cdot \text{AgNO}_3$; with *palladium chloride* $\text{PdCl}_2 \cdot 2\text{CO}(\text{NH}_2)_2$; and with *magnesium bromide* $\text{MgBr}_2 \cdot 6\text{CO}(\text{NH}_2)_2$, m.p. 167° - 170° , with decomposition, and $\text{MgBr}_2 \cdot 4\text{CO}(\text{NH}_2)_2$ decomposes at 165° - 170° (Menschutkin, Petersburger polytechn. Inst. 1906, 6, 101). Among the double salts formed by urea are the *platinichlorides* $[\text{CO}(\text{NH}_2)_2 \cdot \text{HCl}]_2 \cdot \text{PtCl}_4 \cdot 2\text{H}_2\text{O}$, hygroscopic yellow prisms (Heintz, Annalen, 1879, 198, 91) and $[\text{CO}(\text{NH}_2)_2]_2 \cdot \text{H}_2\text{PtCl}_6$, m.p. 119° - 120° , red prismatic crystals (Pickard and Kenyon, Chem. Soc. Trans. 1907, 91, 902); the *aurichlorides* $2\text{CO}(\text{NH}_2)_2 \cdot \text{HCl} \cdot \text{AuCl}_3$ and $\text{CO}(\text{NH}_2)_2 \cdot \text{HCl} \cdot \text{AuCl}_3 \cdot \text{H}_2\text{O}$; the *quinine hydrochloride* $\text{C}_{20}\text{H}_{24}\text{N}_2\text{O}_2 \cdot \text{HCl} \cdot \text{CO}(\text{NH}_2)_2 \cdot \text{HCl} \cdot 5\text{H}_2\text{O}$, and similar compounds containing quinidine and cinchonidine (Drygin, Chem. Zentr. 1881, 245); the double hydrobromide

m.p. 70° - 75° , decomposes at 130° - 140° ; the corresponding double hydrochloride is employed as a local anæsthetic (Golubev, J. Russ. Phys. Chem. Soc. 1914, 46, 189); *cotarnine carbamide*, m.p. 180° , possesses therapeutic properties (Knoll & Co., D. R. P. 232785). The compounds with *mercuric nitrate* $2\text{CO}(\text{NH}_2)_2 \cdot \text{Hg}(\text{NO}_3)_2 \cdot 3\text{HgO}$, $2\text{CO}(\text{NH}_2)_2 \cdot \text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgO}$ and

are obtained by precipitation between urea and mercuric nitrate under different conditions of concentration. Urea also combines with mercuric salts to form salts of the divalent radicle $\text{CO}(\text{NHHg})_2$, 'mercuroidcarbamide'; the *hydroxide*

the *chloride* $\text{CO}(\text{NH} \cdot \text{HgCl})_2$, and

the *nitrate*

and the *acetate* $\text{CO}(\text{NH} \cdot \text{HgOAc})_2$ (Ruspaggiari, Gazz. chim. ital. 1897, 27, i. 1). Salts containing chromium complexes and urea have been described by Sell (Proc. Roy. Soc. 1882, 33, 267; 1889, 45, 321).

Acyl derivatives of urea, v. UREIMIDES.

Chloro and nitro derivatives.—*Chlorourea*

decomposes at 71° , dissolves in five parts of water at ordinary temperature, giving a neutral solution that loses nitrogen and forms biuret. It reacts slowly in aqueous solution with aliphatic ketones, yielding the monochloroketone (Béhal and Detoef, Compt. rend. 1911, 153, 681 1229); and with ethylenic hydrocarbons, giving the corresponding chlorohydrin (Detoef, Bull. Soc. chim. 1922, [iv.] 31, 102). *Dichlorourea* $\text{CO}(\text{NHCl})_2$, prepared by passing a rapid stream of chlorine into a well-cooled solution

of urea in water, forms colourless plates that melt with decomposition at 82° when cautiously heated and detonate when rapidly heated, forming nitrogen chloride; on decomposition with ammonia in strong aqueous solution *p*-urazine $\text{CO} \begin{smallmatrix} \text{NH} \cdot \text{NH} \\ \text{NH} \cdot \text{NH} \end{smallmatrix} \text{CO}$ is formed (Chattaway, Proc. Roy. Soc. 1908, A. 81, 381; Chem. Soc. Trans. 1909, 95, 236; compare Datta, *ibid.* 1912, 101, 166; Dowell, J. Amer. Chem. Soc. 1919, 41, 124).

Nitrourea $\text{NO}_2 \cdot \text{NH} \cdot \text{CO} \cdot \text{NH}_2$, prepared by the action of concentrated sulphuric acid on urea nitrate, forms sparingly soluble crystals that decompose on melting; it is a strong acid, liberating acetic acid from its salts. The potassium, sodium and mercury salts have been prepared. On reduction with zinc dust and sodium hydroxide, it forms *nitrosourea* $\text{NH}_2 \cdot \text{CO} \cdot \text{NH} \cdot \text{NO}$, and this develops a purple colour with ferrous sulphate (Thiele and Lachmann, Annalen, 1895, 288, 281). On further reduction it yields semicarbazide

See Backer (Rec. trav. chim. 1912, 31, 1) for the electrolytic reduction of nitrourea. *Carbaminoazoisimide* $\text{NH}_2 \cdot \text{CO} \cdot \text{N}_2$, from sodium nitrite and semicarbazide has m.p. 92°–93° (Thiele and Stange, Annalen, 1894, 283, 1); *cyanocarbamide* $\text{CN} \cdot \text{NH} \cdot \text{CO} \cdot \text{NH}_2$ (Mauguin and Simon, Compt. rend. 1920, 170, 998).

The *alkyl* and *aryl* derivatives of urea are prepared by Wöhler's method from the corresponding mono- or di-substituted ammonium cyanate; by the action of ammonia on the *isocyanic* ester, and by the action of carbonyl chloride on the amine. For a description of these derivatives, see Michler, Ber. 1875, 8, 1664; Schiff, Annalen, 1877, 189, 157; Michler and Escherich, Ber. 1879, 12, 1162; Hemmelmayr, Monatsh. 1891, 12, 89; Chancel, Compt. rend. 1892, 115, 242; Schneegans, Arch. Pharm. 1894, 231, 675; A. E. Dixon, Chem. Soc. Trans. 1895, 47, 559; Diels and Golimann, Ber. 1911, 44, 3158; Cannizzaro, Gazz. chim. ital. 1871, 1, 41; Letts, Chem. Soc. Trans. 1872, 25, 448; Paternó and Spica, Gazz. chim. ital. 1875, 5, 388; Michler, Ber. 1876, 9, 396, 710; Claus, *ibid.* 693; Weith, *ibid.* 821; Pagliani, Gazz. chim. ital. 1879, 9, 28; Cosack, Ber. 1879, 12, 1449; 1880, 13, 1088; Michler and Zimmermann, *ibid.* 1881, 14, 2177; Michler and Keller, *ibid.* 2181; Traube, *ibid.* 1882, 15, 2122; Kym, *ibid.* 1890, 23, 424; Kühn and Landau, *ibid.* 811; Manuelli and Comanducci, Gazz. chim. ital. 1899, 29, ii. 136; Davis, Roberts, Brewster, J. Amer. Chem. Soc. 1916, 38, 731). For a summary of the alkyl substituted ureas, see Abderhalden's Biochemisches Handlexikon, 1911, vol. i. part 2, pp. 772, 773. For ureas of the naphthalene series, v. Bayer & Co., D. R. PP. 278122, 284938, 289107, 289163, and for the di-*aryl*-urea chlorides v. D. R. P. 285134.

Urea forms condensation derivatives with *formaldehyde* (Goldschmidt, Ber. 1896, 29, 2438; Chem. Zeit. 1897, 21, 460; Di Palma, Boll. Chim. Farm. 1912, 51, 78; Einfeld and Hamburger, Ber. 1908, 41, 24; Dixon, Chem. Soc. Trans. 1918, 113, 238; Van Laer, Bull. Soc. chim. Belg. 1919, 28, 381); with β -*diketones* (Evans, J. pr. Chem. 1892, [ii.] 45, 499); with

maleic anhydride (Dunlap and Phelps, Amer. Chem. J. 1897, 19, 492); with *acetone* (Weinschenk, Ber. 1901, 34, 2185); with *ethyl oxalacetate* (Müller, J. pr. Chem. 1897, [ii.] 55, 505); with *hydrazine* (Curtius and Heidenreich, Ber. 1894, 27, 55) with *phenylhydrazine* (Edeleanu, Chem. Zentr. 1892, i. 628); with *chloral hydrate* (Coppin and Titherley, Chem. Soc. Trans. 1914, 105, 32); and with *alloxan* (Biltz, Annalen, 1921, 423, 282). For the condensation derivatives of ureas with acid esters, v. Roeder, Ber. 1913, 46, 2560.

*iso*Ureas, ψ -*carbamides*. The tautomeric form of urea $\text{HN} : \text{C}(\text{OH})\text{NH}_2$ is not known in the free state, but certain of its ethers have been prepared by the action of hydrogen chloride on cyanamide and the corresponding alcohol at 60°–70°. *Methyl-isourea* $\text{HN} : \text{C}(\text{OMe})\text{NH}_2$ has m.p. 44°–45°, b.p. 82°/9 mm.; the *hydrochloride* melts at 130°; *ethylisourea* $\text{HN} : \text{C}(\text{OEt})\text{NH}_2$ has m.p. 42°, b.p. 95°–96°/15 mm.; asym. *phenylmethylethylisourea* $\text{HN} : \text{C}(\text{OEt})\text{NMePh}$ has b.p. 137°/21 mm., the isomeric asym. *phenylethylmethylethylisourea* $\text{HN} : \text{C}(\text{OMe})\text{NEtPh}$ has b.p. 126°/15 mm. (Stieglitz and McKee, Ber. 1900, 33, 807); *propylisourea hydrochloride* melts at 64° and decomposes at 121° (Stieglitz and Noble, *ibid.* 1905, 38, 2243); sym. *m-nitrobenzoylphenylisourea methyl ether*

has m.p. 124° (Bruce, J. Amer. Chem. Soc. 1904, 26, 419).

Thiourea. Isomerism amongst the derivatives of the sulphur analogue of urea is much more general than is the case with the derivatives of urea, and the convention has been adopted of limiting the term *thiocarbamides* to derivatives of the true thiocarbamide

derivatives of the isomeric form $\text{HN} : \text{C}(\text{SH})\text{NH}_2$, being called *thioureas*¹ (Reynolds, Chem. Soc. Trans. 1891, 59, 395).

Thiourea is prepared by heating ammonium thiocyanate at 160°–170°, the reaction is a balanced one; equilibrium is reached in about an hour, when the mixture contains about 25 p.c. of thiourea (Reynolds, Annalen, 1869, 150, 224; Reynolds and Werner, Chem. Soc. Trans. 1903, 83, 1; Findlay, *ibid.* 1904, 85, 403). Thiourea can also be obtained by the action of hydrogen sulphide on cyanamide

(Baumann, Ber. 1875, 8, 26).

Thiourea crystallises in needles that melt at about 172° if rapidly heated; the true melting-point cannot be determined, owing to tautomeric change; it is probably above 177° (Findlay, *l.c.*).

Derivatives. The *nitrate* $\text{OSN}_2\text{H}_4 \cdot \text{HNO}_3$, the *hydrochloride* $\text{CSN}_2\text{H}_4 \cdot \text{HCl}$, and the *silver*

¹ To distinguish between the three isomeric forms of substituted derivatives of thiourea, Dixon (Chem. Soc. Trans. 1895, 67, 564) proposes to designate the NH and NH_2 attachments as α and ν , whilst if the sulphur attachment is occupied by the substituent the compound is designated a *pseudothiourea*. Thus, for example, the systematic names of $\text{EtN} : \text{C}(\text{SH})\text{NMe}_2$, $\text{NH} : \text{C}(\text{SMe})\text{NH}_2$, and $\text{EtN} : \text{C}(\text{SMe})\text{NHMe}$ would be, respectively, α -ethyl- ν -dimethylthiourea, methyl- ν -thiourea, and methyl- α - ν -diethylthiourea.

nitrate derivative $\text{CSN}_2\text{H}_4\cdot\text{AgNO}_3$ are crystalline (Stevens, Chem. Soc. Proc. 1902, 17, 210; Kurnakow, Ber. 1891, 24, 3956). Dithiocarbamide dichloride $(\text{CSN}_2\text{H}_4)_2\text{Cl}_2$ can be crystallised from concentrated hydrochloric acid, and forms the dinitrate $(\text{CSN}_2\text{H}_4)_2(\text{NO}_3)_2$ by the action of dilute nitric acid; the dibromide

and di-iodide $(\text{CSN}_2\text{H}_4)_2\text{I}_2$ are colourless and decompose on warming or by the action of solvents (Claus, Annalen, 1875, 179, 135; McGowan, Chem. Soc. Trans. 1886, 49, 190). The potassium compound $\text{CSN}_2\text{H}_4\cdot\text{K}(\text{CSN}_2\text{H}_4)_2$ forms needles, m.p. 145° (Werner, Chem. Soc. Trans. 1916, 109, 1120); acetylthiocarbamide, m.p. 165° ; diacetylthiocarbamide, m.p. 151° – 152° (Hohmam, J. Amer. Chem. Soc. 1915, 37, 2130; Werner, l.c.).

For the alkyl and aryl substituted derivatives of thiourea and thiocarbamide, see Arzruni, Ber. 1871, 4, 406; Miguel, Bull. Soc. chim. 1877, [ii.] 28, 104; de Clermont, Compt. rend. 1876, 82, 512; Blankenhorn, J. pr. Chem. 1877, [ii.] 16, 358; A. E. Dixon, Chem. Soc. Trans. 1891, 59, 562; 1892, 61, 536; 1893, 63, 318, 538; 1895, 67, 556; 1899, 75, 373; 1906, 89, 892; 1907, 91, 912; 1908, 93, 18; Werner, Chem. Soc. Trans. 1919, 115, 1168. M. W. A.

UREASE v. FERMENTATION.

Urease is produced more profusely by pure cultures of *Bacterium radicum* than by the nodules, particularly by *viciae*, *trifolii*, and *pisiformis*. Urease is also, in certain cases, a product of normal papilionaceous plants (M. W. Beijerinck, Chem. Soc. Abstr. 1923, 124, i. 1157).

From dried cultures of *Bacillus proteus* a soluble urease has been extracted by the use of various phosphate solutions (Tetsugora Takahata, Chem. Soc. Abstr. 1923, 124, i. 1157).

The presence of two constituents in urease has been confirmed by N. Katô (Biochem. Zeitsch. 1923, 139, 352–365). The urease system consists of a thermo-labile constituent which possesses fermentative properties, and a thermo-stable constituent with no fermentative action which N. Katô calls 'stable component X.' This last, at urea concentrations above the 'equivalent urea concentration' (l.c.), increases the activity of the urease, but has no influence at substrate concentrations below this value; its action resembles that of glycine. The action of 'stable component X' is not due to alteration of the hydrogen ion concentration nor to the presence of mineral salts (J. Chem. Soc. Ind. 1923, 42, 993 A).

Urease effects complete conversions of urea into ammonium carbonate. The sample of urea, in aqueous solution, is brought to exact neutrality, a neutral urease solution (freshly extracted from jack-bean flower by means of water, the mixture being exactly neutralised with hydrochloric acid) added, and the mixture kept at room temperature for one hour. A known excess of N/10 hydrochloric acid is then added and the carbon dioxide removed by aeration. The excess of acid is titrated with N/10 sodium hydroxide; each c.c. of N/10 acid consumed is equivalent to 3 mg. of urea originally present. The results are accurate to within a few hundredths of 1 p.c. The method can be used for determining urea in cyanamide and in

phosphate mixtures (after precipitating the phosphate with baryta), and appears to be of quite general application. Most salts have a depressant effect on the action of urease, and barium and calcium chlorides must be removed prior to its addition (E. J. Fox and W. J. Geldard, Ind. Eng. Chem. 1923, 15, 743–745; J. Soc. Chem. Ind. 1923, 42, 901 A).

UREIDES or acyl derivatives of urea are formed by condensation between urea and the acid with the elimination of water; in the case of a monocarboxylic acid the product may be a monoureide $\text{RCONH}\cdot\text{CO}\cdot\text{NH}_2$ or a diureide $\text{CO}(\text{NH}\cdot\text{COR})_2$, according as one or two molecules of the acid condense with one molecule of urea. Similar products may be obtained in the cases of the hydroxy acids and the di-carboxylic acids, but usually condensation occurs between one molecule of the acid and one of urea with the elimination of two molecules of a water and the formation of a cyclic ureide. The more important cyclic ureides have already been described; they include glycolylurea

v. HYDANTOIN. β -Lactylurea, hydracrylurea, hydrouaril $\text{CO} \begin{array}{l} \text{NH}\cdot\text{CH}_2 \\ | \\ \text{NH}\cdot\text{CO} \end{array} \text{CH}_2$ v. PYRIMIDINES.

tribromacetylurea, m.p. 158° (Baeyer, Annalen, 1864, 130, 149); *cyanacetylurea*

m.p. 200°–210°; *isovalerylurea*

m.p. 191°; *monobromoisovalerylurea*

(*bromoura*), m.p. 149°, is a narcotic (van der Eekhout, Arch. exp. Path. Pharm. 1907, 57, 338); it yields two *cotarnine* derivatives, m.p. 125°–127° and 105°–110° respectively, and these have therapeutic values (Knoll & Co., D. R. P. 232785); *butyrylurea*

m.p. 176°; *succinylurea* $\text{C}_4\text{H}_5\text{O}_2(\text{NH}\cdot\text{CO}\cdot\text{NH})_{1/2}$; *benzoylurea* $\text{NH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{COPh}$, m.p. 200°; *adibenzoylurea* $\text{CO}(\text{NH}\cdot\text{COPh})_2$, m.p. 210°; *aa-dibenzoylurea* $\text{NH}_2\cdot\text{CO}\cdot\text{N}(\text{COPh})_2$, m.p. 197°; *p-nitrobenzoylurea*, m.p. 243°–245° (evolution of gas); *o-chloroacetylaminobenzoylurea*, m.p. 222°–223° (effervesces); the *meta*-derivative melts at 252°–253° (decomp.) (Jacobs and Heidelberger, J. Amer. Chem. Soc. 1917, 39, 2418).

Carbonyldiurea $\text{CO}(\text{NH}\cdot\text{CO}\cdot\text{NH}_2)_2$ decomposes on heating (Schmidt, J. pr. Chem. 1872, [ii.] 5, 39); *carboxylurea*, *allophanic acid* $\text{H}_2\text{N}\cdot\text{CO}\cdot\text{NH}\cdot\text{COOH}$ does not exist in the free state; the *esters* can be obtained by the action of phosphoric oxide on the corresponding urethane (Billmann and Bjerrum, Ber. 1917, 50, 503); the *methyl ester* has m.p. 208° (Ephraim, Ber. 1893, 26, 2172), the *ethyl ester*, m.p. 191° (Liebig and Wöhler, Annalen, 20, 396; 59, 291); the *amide* $\text{NH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{CONH}_2\cdot\text{H}_2\text{O}$ is *biuret*, m.p. 190°; it gives a purplish-violet colour with copper sulphate and potassium hydroxide, due to the formation of the double salt

A similar reaction is given by proteids which contain two amino groups in the molecule, these groups being joined directly together or through a single atom of nitrogen or carbon. The amino groups must be either two $\cdot\text{CONH}_2$ groups or one $\cdot\text{CONH}_2$ group and one $\cdot\text{CSNH}_2$, $\text{Q}(\text{NH})\text{NH}_2$, or $\cdot\text{CH}_2\text{NH}_2$ group. Substances that are non-proteid in character but which contain the necessary groups will also give the biuret reaction, for example, *oxamide* and *malonamide*.

The *ureides of substituted aminonaphthol sulphonic acids* form dyes when coupled with diazotised aniline or similar compounds, and may be employed as therapeutic agents for destroying blood parasites. They form metallic salts, which also possess therapeutic properties (Heymann, Dresel, Kothe, Ossenbeck, U.S. Pat. 1308071).

Carbonyldiurethane, m.p. 108°, is produced by the action of urethane on carbonyl chloride; for the action of ammonia and amines on this compound, see Dains, Greder and Kidwell (J. Amer. Chem. Soc. 1919, 41, 1004); Dains and Werthein (*ibid.* 1920, 42, 2303).

Ureides of Sugar. The term *ureide* is also

applied to certain condensation products of urea with aldehydes; these are of the type $\text{RCH}\cdot\text{N}\cdot\text{CO}\cdot\text{NH}_2$ and the most important are those derived from the aldoses. *Glucoseureide* $\text{CH}_2\text{OH}[\text{CH}\cdot\text{OH}]_4\text{CH}\cdot\text{N}\cdot\text{CO}\cdot\text{NH}_2$, thick rhombic crystals, m.p. 207° (decomp.), $[\alpha]_D^{15} = -23.5^\circ$ in 10 p.c. aqueous solution; the *penta-acetyl derivative* $\text{C}_7\text{H}_5\text{O}_5\text{N}_2(\text{CH}_2\text{CO})_5$ has m.p. 200°, and the *tetrabenzoyl* m.p. 117°. *Galactoseureide* is a white amorphous powder $[\alpha]_D + 15^\circ$; *mannoseureide*, m.p. 188°, $[\alpha]_D^{20} = -45.8^\circ$; *lactoseureide* ($\text{C}_{12}\text{H}_{22}\text{O}_{10}\text{N}_2$) $\text{N}\cdot\text{CO}\cdot\text{NH}_2$ decomposes at 240°, $[\alpha]_D^{20} + 2.1^\circ$ (Schoorl, Rec. trav. chim. 1903, 22, 31; Mayer, Biochem. Zeitsch. 1909, 17, 1345). M. A. W.

URETHANE v. SYNTHETIC DRUGS.

URETHANES are the esters of *carbamic acid* (*aminoformic acid*) $\text{H}_2\text{N}\cdot\text{COOH}$; the free acid is not known, but it is said to occur in blood-serum (Drechsel, J. pr. Chem. 1875, [ii.] 12, 417; cp. Hofmeister, Archiv. Physiol. 1876, 12, 337), and in urine (Abel and Drechsel, Chem. Zentr. 1891, ii. 713; Hahn and Nencki, Arch. Sc. biol. Petersb. 1892, 1, 467; Abel and Muirhead, Arch. exp. Path. Pharm. 1893, 31, 15; 32, 467). The *ammonium salt*

is produced by the direct action of carbon dioxide on ammonia in cooled absolute alcohol. It is a white crystalline powder. The *sodium* $\text{NaCH}_2\text{NO}_2\cdot\text{H}_2\text{O}$ and *potassium* KCH_2NO_2 salts are also crystalline; the *calcium salt*

is insoluble in alcohol and crystallises from concentrated ammonia solution in four-sided prisms.

Carbamyl chloride (chloroformamide)

prepared by passing hydrogen chloride over heated metallic cyanates, or carbonyl chloride over heated ammonium chloride, forms long, broad needles, m.p. 50°, b.p. 61°–62° (Gattermann and Schmidt, Ber. 1887, 20, 858).

Urethane, *ethyl carbamate* $\text{NH}_2\cdot\text{COOEt}$, prepared by the action of ammonia on ethyl carbonate or ethyl chlorocarbonate; by heating urea nitrate with alcohol; or by the action of alcohol on carbamyl chloride, crystallises in large pliable plates or prisms that break with a fibrous fracture, sublime readily, melt at 50° and boil at 184°. The system urethane-benzene forms a eutectic containing 97 mols. p.c. at 4.2°, and solid solutions in the interval from 97 to 100 mols. p.c. of benzene (Puschin and Mazarovitch, J. Russ. Phys. Chem. Soc. 1914, 46, 1366). For the use of urethane as a cryoscopic solvent, see Bruni (Atti R. Accad. Lincei, 1918, [v.] 27, i. 321). When heated with water or ammonia, urethane yields a small quantity of urea; for the explanation of this reaction, see Werner (Chem. Soc. Trans. 1918, 113, 622).

Urethane has therapeutic properties, being employed as a hypnotic. Certain of its substituted derivatives have similar properties; for example, *phenylurethane* or *euphorine*

methylpropylcarbinol urethane or *hedonal*

and *cotarnine-urethane*, m.p. 110° (Knoll & Co., D. R. P. 232785).

Urethanes when heated with calcium or strontium bromide yield double compounds of the urethane and the metallic bromide;

is a powerful hypnotic (v. J. Soc. Chem. Ind. 1915, 34, 1166; and Gebe & Co., D. R. P. 284734).

p-Benzylphenyl carbamate, m.p. 144°, *p*-isomylphenyl carbamate, m.p. 73°–74°, *p*-butylphenyl carbamate, m.p. 123°–124°, *p*-isopropylphenyl carbamate, m.p. 93°–95°, *p*-butylphenyl *N*-dimethylcarbamate, m.p. 92°, *o*-allylphenyl carbamate, m.p. 122°–123°, are white powders, sparingly soluble in water, and possess anthelmintic properties (Synthetic Patents Co., U.S. Pat. 1252452, and Farbenfabriken vorm. Friedr. Bayer & Co., D. R. P. 296889, from Chem. Zentr. 1917, i. 714).

4-Hydroxy-3-urethano-phenylarsine

is a white powder, (Farbwerke vorm. Meister, Lucius and Brüning, D. R. P. 275216, addition to D. R. P. 268220).

Nitrourethane $\text{NO}_2 \cdot \text{NH} \cdot \text{COOEt}$ melts at 64°, is readily soluble in water and alcohol and forms metallic salts, the *potassium*, *mercury*, and *silver* salts having been prepared (Thiele and Lachmann, Annalen, 1895, 288, 304). From spectrochemical considerations Brühl assigns the formula

physikal. Chem. 1898, 26, 47; 25, 577). *Nitroso-urethane* $\text{NO} \cdot \text{NH} \cdot \text{COOEt}$ melts and decomposes at 51°–52° and does not develop a purple colour with ferrous sulphate and potassium hydroxide: the *silver*, *potassium* and *ammonium* derivatives are yellow (Thiele and Lachmann, l.c.). From index of refraction values, Brühl regards nitro-

sourethane as diazourethane $\text{N} \begin{array}{c} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{array} \text{NH} \cdot \text{COOEt}$

(Ber. 1902, 35, 1148), whilst Hantzsch formulates it as an *antidiazohydrate* $\text{HO} \cdot \text{N} : \text{N} \cdot \text{COOEt}$ (*ibid.* 1899, 32, 575). *Dibromourethane* $\text{NBr}_2 \cdot \text{COOEt}$ has b.p. 100°–104°/10–11 mm. (Diels and Ochs, Ber. 1907, 40, 4571). *Ethylchlorocarbamate* $\text{NHCl} \cdot \text{CO}_2\text{Et}$ is obtained by the action of chlorine on ethyl carbamate if the solution is kept well cooled; it is a pale yellow viscous oil, b.p. near 99° (decomp.) (Datta and Gupta, J. Amer. Chem. Soc. 1914, 36, 386); it is slowly hydrolysed by water, yielding ethyl 4-chloromethylcyclomethylenhydrazineimide 1:3-dicarboxylate $\text{CH}_2\text{Cl} \cdot \text{CH} \begin{array}{c} \text{N}(\text{CO}_2\text{Et}) \\ \diagdown \text{N}(\text{CO}_2\text{Et}) \end{array} \text{NH}$, colourless needles, m.p. 143°, which forms a crystalline *acetyl* derivative, m.p. 117°–118°, and *imide chloride*, m.p. 75°–76° (Datta and Chatterjee, *ibid.* 1922, 44, 1538).

Urethane forms condensation products with aldehydes and keto acids. *Chloralurethane* $\text{OCl} \cdot \text{CH}(\text{OH})\text{NH} \cdot \text{COOEt}$ has m.p. 103°; *bromalurethane* $\text{CBr}_2 \cdot \text{CH}(\text{OH})\text{NH} \cdot \text{COOEt}$ has m.p. 132° (Bischoff, Ber. 1874, 7, 628, 1078; Conrad and Hoek, *ibid.* 1903, 36, 2306; Simon, Compt. rend. 1901, 133, 536; Simon and Chavanne, *ibid.* 1904, 143, 51).

Thiourethane, a mixture of the isomeric thiourethanes, is obtained by acting on an alcoholic solution of potassium thiocyanate with concentrated hydrochloric acid; these correspond with two of the isomeric forms of the hypothetical thiocarbamic acid, *ethyl xanthamide* $\text{NH}_2 \cdot \text{CS} \cdot \text{OEt}$, m.p. 38°, and *carbonylthioethylamine* $\text{NH}_2 \cdot \text{CO} \cdot \text{SEt}$ (Blankenhorn, J. pr. Chem. 1877, [ii.] 16, 358).

M. A. W.

URGINEA. v. SQUILL.

URIC ACID, 2:6:8-trioxypurine

was discovered in human urine by Scheele in 1776 (Opuscula, 1776, 2, 73), independently by Bergmann in urinary calculi (*ibid.* 1776, 4, 232), and in 'chalk-stones' by Pearson in 1798 (Trans. Roy. Soc. 1798, 15).

Uric acid occurs in the urine of all animals, though only to a small extent in the case of herbivorous animals; the average daily excretion in normal man being 0.597 grm. (Hanzlik and Hawk, J. Biol. Chem. 1908, 5, 355). It occurs in the excrement of birds, reptiles, scaly amphibians, snails and insects; the wing scales of the group of butterflies known as the white *Pieridae* contain uric acid, those of the yellow *Pieridae* contain, as their pigment, a yellow derivative of uric acid, which can be obtained synthetically by heating uric acid with water in sealed tubes at a high temperature (Hopkins, Proc. Roy. Soc. 1894, 57, 5). Uric acid is a normal constituent of the organs and blood of birds, but only occurs in human blood under certain pathological conditions. For its occurrence in blood, v. Bass (Amer. Chem. Abs. 1914, 1602).

Preparation.—Uric acid can be isolated from serpent's excrement, bird's excrement or guano by boiling the material with dilute alkali hydroxide or milk of lime, filtering the hot liquid and precipitating the uric acid by adding excess of hydrochloric acid to the filtrate. Uric acid can also be obtained from the yellow acid urates deposited from urine; this is boiled with sodium hydroxide until it ceases to evolve ammonia, the liquid is filtered and the acid sodium urate precipitated from the filtrate by means of carbon dioxide; this is redissolved in sodium hydroxide and the solution decomposed by acetic acid, or the hot solution of the alkali salt may be purified by boiling with a little potassium permanganate or dichromate and the filtrate decomposed by hydrochloric acid.

Synthesis.—Uric acid was first synthesised by Horbaczewski by carefully fusing glycine with 10 to 15 times its weight of urea in small quantities at a time, until a considerable quantity of precipitate had formed in the molten mass; the uric acid was precipitated in the form of its sparingly soluble silver magnesium salt, which on treatment firstly with potassium sulphide and subsequently with hydrochloric acid, yielded pure uric acid (Monatsh. 1882, 3, 796; 1885, 6, 366). Compare, however, Behrend (Annalen, 1925, 441, 2159; Chem. Soc. Abstr. 1925, i. 441). Further syntheses were effected by Horbaczewski

(*ibid.* 1887, 8, 201) by fusing trichlorolactamide with 10 parts of urea

and by fusing trichlorolactic acid with urea (*ibid.* 1887, 8, 584).

In 1863, Baeyer (Annalen, 1863, 127, 3, 234) synthesised *pseudouric acid*, starting with malonic acid and urea; but it was not until 1895 that Fischer and Ach (Ber. 1895, 28, 2473) showed that uric acid could be readily obtained from pseudouric acid by fusion with oxalic acid, or by boiling with hot dilute mineral acids (Fischer, *ibid.* 1897, 30, 559); a complete synthesis of uric acid from malonic acid and urea is therefore represented by the following equations:

Traube's synthesis of uric acid, starting with cyanacetic acid and urea, is also important, and by substituting alkyl ureas for urea, the method can be extended to the preparation of substituted uric acids. Cyanacetylurea, prepared by the condensation of urea with cyanacetic acid, is converted by the action of alkali into 4-amino-

This is the most important synthetic method of preparing uric acid, and by replacing urea by its alkyl or aryl substituted derivatives, it is possible to prepare the corresponding alkyl or aryl substituted uric acids.

The synthesis of uric acid effected by Behrend and Roosen (Annalen, 1888, 251, 235), starting with ethyl acetoacetate and urea, is represented in the following series of equations:

2:6-dioxypyrimidine, from which 4:5-diamino-2:6-dioxypyrimidine is obtained by reducing its isonitroso derivative; this diamine condenses with ethyl chloroformate to form a urethane derivative, from the sodium derivative of which uric acid is produced by heating at 180°-190° (Ber. 1900, 33, 1375, 3035).

Properties. Pure uric acid forms a colourless microcrystalline powder consisting of rhombic transparent plates or prisms; as precipitated from urine or guano extracts, the crystals are yellowish red or brown. These exhibit, under the microscope, characteristic irregularities in form, due to the rounding of the obtuse angles of the rhombic prisms, and the interpenetration of the crystals, and present the form of dumb-bells, whetstones, rosettes of

prismatic crystals, six-sided irregular plates or rectangular plates with partly jagged sides.

Uric acid is odourless and tasteless; it is sparingly soluble in water, one part dissolving in 39,480 parts at 18° (His and Paul, Zeitsch. physiol. Chem. 1900, 31, 41), or 15,505 parts at 37° (Gudzent, *ibid.* 1909, 60, 27). When shaken with water, uric acid decomposes so that the solubility tends to increase with the time; the increase is only noticeable at the end of 24 hours

and then rises rapidly until at the end of 10 days the solubility is 11 times as great as at the end of a few hours, and in the same time the electrical conductivity has increased 55 times (Gudzent, *l.c.*; cf. Biltz and Herrmann, *Annalen*, 1923, 104). The supersaturation which occurs when a warm aqueous solution of uric acid is allowed to cool to a room temperature in contact with solid uric acid is probably the cause of the high values for the solubility found by Bensch (*Annalen*, 1845, 54, 190); Behrend and Roosen (*Annalen*, 1889, 251, 250). The molecular electrical conductivity of a saturated solution of uric acid is 32.24 at 18° (His and Paul, *l.c.*) or 33.92 at 37° (Gudzent, *l.c.*); the dissociation constant $k=0.000151$ at 18° or 0.000233 at 37°. See also Kanitz (*Zeitsch. physiol. Chem.* 1921, 116, 96). Uric acid has the power of adsorbing precipitated colloids from their solutions. If a trace of dye is added to a hot saturated solution of uric acid, coloured crystals of the latter are deposited from the cold solution (Benoit, *Compt. rend. soc. biol.* 1919, 82, 1051, 1052). Uric acid is fairly readily soluble in lactic acid, acetic acid (see Rossi, *Biochem. Zeitsch.* 1913, 54, 297) or warm concentrated sulphuric acid. For the influence of hydrogen-ion concentration on its solubility, see Jung (*Helv. Chim. Acta*, 1922, 5, 688). It dissolves in glycerol, but is insoluble in alcohol or ether; it dissolves readily in aqueous solutions of alkali hydroxides, of lithium carbonate, and of certain bases such as ethylamine, propylamine, piperazine, but is only sparingly soluble in solutions of *urotropine* (hexamethylenetetramine), *lycetol* (piperazine tartrate) or ammonia (Stevens and May, *J. Amer. Chem. Soc.* 1911, 33, 434; v. also Hanzlik, *Amer. Chem. Abs.* 1916, 1226). The solubility of uric acid in a 1 p.c. solution of sodium salicylate is twice as great, and in a 0.1 p.c. solution of sodium 2-phenylquinoline 4-carboxylate three times as great as in water (Stern, *Biochem. Zeitsch.* 1924, 151, 268; 1925, 159, 192).

Uric acid is not volatile: on being strongly heated it breaks up into urea, hydrocyanic acid, cyanuric acid and ammonia (Wöhler, *Pogg. Ann.* 1839, 15, 529, 619). When oxidised by strong nitric acid or potassium chlorate and hydrochloric acid, or by chlorine or bromine water in the cold, uric acid is broken down into alloxan (mesoxalylurea (*q.v.*) and urea. For cyanuric acid as oxidation product of uric acid, v. Venable and Moore (*J. Amer. Chem. Soc.* 1917, 39, 7750). Warm dilute nitric acid produces parabanic acid (oxalylurea) (*q.v.*). By the action of such oxidising agents as potassium permanganate, or ferricyanide, lead peroxide, mercuric oxide or ozone in neutral or alkaline media, uric acid yields carbon dioxide and allantoin (glyoxyldiureide) (*q.v.*). According to Behrend (*Annalen*, 1904, 333, 141) and Behrend and Schultz (*ibid.* 1909, 365, 21), the first product of oxidation of uric acid in alkaline media is *hydroxyglycoluril carboxylic acid*

which on treating (a) with an excess of alkali hydroxide takes up the elements of water, forming *urosonic acid* (dicarbaminomalonic acid)

(COOH), $\text{C}(\text{NH} \cdot \text{CO} \cdot \text{NH}_2)_2$ (*q.v.*; see also Behrend and Zieger, *Annalen*, 1915, 410, 337; Biltz and Max, *Ber.* 1920, 53, 1964; Biltz and Robl, *ibid.* 1967); (b) with acetic acid yields potassium hydrogen *oxonate* (Strecker, *Chem. Soc. Trans.* 1875, 555); Biltz and Robl (*Ber.* 1920, 53, 1967), have shown *oxonic acid* to be identical with

When oxidised by hydrogen peroxide in alkaline solution, uric acid yields *tetracarbonimide* $\text{CO} \begin{array}{c} \text{NH} \cdot \text{CO} \cdot \text{NH} \\ | \\ \text{NH} \cdot \text{CO} \cdot \text{NH} \end{array} \text{CO}$ (Scholtz, *Ber.* 1901, 34, 4130), *carbonyldiurea* $\text{CO}(\text{NH} \cdot \text{CO} \cdot \text{NH}_2)_2$, and *urea* (Schittenhelm and Wiener, *Zeitsch. physiol. Chem.* 1909, 62, 100; cf. Venable and Moore, *l.c.*; Venable, *ibid.* 1918, 40, 1099; Moore and Thomas, *ibid.* 1120; see also Ohta, *Biochem. Zeitsch.* 1913, 54, 439).

Uric acid is decomposed when fused with potassium hydroxide, yielding the potassium salts of prussic, cyanic, carbonic and oxalic acids. When heated under pressure at 160°–170° with concentrated hydrochloric or hydriodic acid, it yields carbon dioxide, ammonia and glycocholl; it is oxidised by a solution of copper oxide in ammonia (Schweizer's reagent) in the presence of potassium hydroxide to urea and oxalic acid, and a similar oxidation is effected by boiling with ferric chloride. It is decomposed by certain moulds (Kossowicz, *Bied. Zentr.* 1912, 41, 791; *Chem. Zentr.* 1912, ii, 1300, 1482; 1913, i, 640).

For the physiological properties of uric acid, its origin, and the rôle it plays in the animal economy, see Article URINE; also *Biochemisches Handlexikon von Abderhalden*, vol. iv. 1095–1106; and *Oxidations and Reductions in the Animal Body*, by H. D. Dakin, 92. For the influence of drugs on the elimination of uric acid from the blood, v. Abl (*Arch. Expt. Path. Pharm.* 1913, 74, 119); Denis (*J. Pharmacol.* 1915, 7, 255, 601); Folin and Lyman (*J. Pharmacol. Expt. Ther.* 1913, 4, 539); Impens (*Chem. Zentr.* 1914, 563).

Detection.—Uric acid is readily identified by the appearance of the crystals under the microscope. The most characteristic and delicate test for uric acid is the 'murexide test,' which is applied as follows: a few drops of strong nitric acid is added to the uric acid or urate and the solution evaporated to dryness on the water bath, preferably in a porcelain basin; a yellowish-red residue of alloxantin is obtained which acquires the rich purple colour of ammonium purpurate (*murexide*, *q.v.*) on moistening with ammonia, the colour changing to blue on the addition of sodium hydroxide. The nitric acid employed in the test may be replaced by chlorine or bromine water, or by a few drops of concentrated hydrochloric acid and a small crystal of potassium chlorate. Other colour reactions of uric acid are described by (1) Denigès (*J. Pharm. Chim.* 1888, [v.] 18, 161), the uric acid is oxidised to alloxan by evaporating a solution in dilute nitric acid; on adding successively to the residue a few drops of concentrated sulphuric acid and of benzene containing thiophen, a bluish coloration is obtained; (2) Ganaassini (*Boll. chim. farm.* 1908, 47, 714), the uric acid or urate is suspended in water and

dissolved in 10 p.c. sodium hydroxide; subsequent saturation of the solution with potassium persulphate and the gradual addition of 10 p.c. zinc sulphate solution, until the precipitate formed no longer redissolves, causes the precipitate to assume a bluish-green colour. This test is not disturbed by the presence of proteins, other purines or pyrimidines, and may be applied for the detection of uric acid in urine or in blood. According to Vitali (*ibid.* 1911, 50, 799), sodium peroxide is the only oxidising agent that can replace the potassium persulphate in the above test, and no other metallic salt can be used instead of the zinc salt. (3) Folin and Denis (J. Biol. Chem. 1912, 12, 239), a blue coloration is developed when a solution containing 1 mg. of uric acid is mixed with 2 c.c. of a solution prepared by boiling for two hours a mixture of 100 grms. sodium tungstate, 80 c.c. of 85 p.c. phosphoric acid, and 750 grms. of water, cooling and diluting to a litre (compare Leturc, Ann. Chim. anal. 1907, 12, 194; Bass and Wiechowski, Chem. Zentr. 1913, i. 331 Obermayer, Popper and Zak, *ibid.* 658). Tests based upon the reducing properties of uric acid are the formation of a yellow, brown, or black stain of silver, when filter paper previously moistened with silver carbonate is treated with a drop of a solution of uric acid in sodium carbonate; and the reduction of Fehling solution on boiling an alkaline solution of uric acid with excess of the reagent. For the detection of uric acid in blood, Weber (Pharm. Zeit. 1912, 57, 252) recommends the following method: the blood is treated with sodium chloride and potassium phosphate to remove the proteins, the filtrate evaporated to a small bulk and saturated with ammonium chloride, the uric acid is thus precipitated as ammonium urate, which is collected and treated with a few drops of hydrochloric acid and the crystals of uric acid identified under the microscope or by the murexide test.

Estimation.—The methods of estimating uric acid in urine are based upon the precipitation of the uric acid in the form of the sparingly soluble ammonium or the double silver magnesium salt, and the subsequent determination of the uric acid in the carefully washed precipitate. Hopkins' method (Proc. Roy. Soc. 1892, 52, 93; J. Path. and Bacteriology, 1893, 1, 451), 30 grms. of ammonium chloride are added to 150 c.c. of the filtered urine previously warmed to 40° to 45°, after about an hour the precipitate of ammonium urate is collected on a small filter, washed with a 10 p.c. solution of ammonium sulphate until free from chlorine, and transferred to a beaker by means of a jet of hot water, the solution cooled and diluted with water to 100 c.c., 20 c.c. of pure concentrated sulphuric acid are added, and N/20 potassium permanganate run into the acid liquid at 60° until it acquires a pink tint permanent for some seconds and not changed by stirring. Each c.c. of N/20 permanganate solution decolorised represents 0.00375 gm. of uric acid. See Herles (Eighth Inter. Cong. App. Chem. 1912, 19, 141); Telle (Bull. Sci. Pharmacol. 1918, 25, 208).

Wörner (Zeitsch. physiol. Chem. 1900, 29, 70) recommends decomposing the washed ammonium urate with 1-2 p.c. sodium hydroxide solution, heating the solution on the water-bath

until it ceases to evolve ammonia and then determining the nitrogen in the residue by the Kjeldahl method: 1 c.c. N/10 sulphuric acid corresponds with 0.0042 gm. uric acid; Kowarsky (Berlin, Klin. Woch. 1917, 54, 987) recommends the estimation of the ammonia in the ammonium urate by the formalin method.

Folin and Shaffer's modification of Hopkins' method (Zeitsch. physiol. Chem. 1901, 32, 552) is as follows: A solution containing 500 grms. of ammonium sulphate, 5 grms. uranium acetate, and 10 p.c. acetic acid, 60 c.c. per litre is prepared, and 75 c.c. of this solution are mixed with 300 c.c. of the urine, kept for five minutes, passed through a double filter and two quantities of 125 c.c. each collected. Five c.c. of concentrated ammonia are added to each and after about 12 hours the precipitates of ammonium urate are collected and washed and the uric acid in each estimated by the permanganate method. The addition of uranium acetate is made in order to precipitate a small quantity of protein material which is otherwise thrown down on the addition of the ammonia, and which reduces permanganate. Ganassini (Boll. Chim. Farm. 1914, 53, 257) uses a modification of this method for precipitating the uric acid, which is then estimated by means of standard iodine solution, the uric acid being oxidised to alloxan, see Curtman and Lehmann (J. Biol. Chem. 1918, 26, 187).

Salkowski's method modified by Ludwig (Chem. Zentr. 1891, 390) consists in precipitating the uric acid in the urine (100 to 200 c.c.) with a mixture of ammoniacal silver solution and magnesia mixture (cf. Salkowski, Zeitsch. physiol. Chem. 1913, 83, 152); the precipitate containing all the uric and phosphoric acids is filtered and washed with very dilute ammonia. It is then decomposed by a warm dilute solution of potassium sulphide forming potassium urate which passes into solution, the filtrate is acidified with hydrochloric acid, evaporated to a small bulk, and the uric acid that separates on cooling is collected on a tared filter, washed with water, alcohol, ether, carbon disulphide, and again with ether, dried at 110° and weighed, see Salkowski (Zeitsch. physiol. Chem. 1913, 83, 152); Kretschmer (Biochem. Zeitsch. 1913, 50, 223); Graves and Kober (J. Biol. Chem. 1915, 20, xx.); (v. Bernard (Chem. Zentr. 1913, 1, 1364; from Bull. Sci. Pharmacol. 1913, 20, 65, for a comparative investigation of different methods; he maintains Salkowski's method gives the best results).

Folin and Shaffer (Zeitsch. physiol. Chem. 1901, 32, 552) recommend the following modification of the method in order to facilitate the removal of the silver from the silver magnesium urate; the double salt is decomposed by sulphuretted hydrogen in an acid solution containing 5 to 10 c.c. of 1 p.c. copper sulphate solution and the liquid boiled for a few minutes before filtering (cf. Schneller, Chem. Zentr. 1913, 1234).

Folin and Macallum recommend a colorimetric method for estimating uric acid in dilute solution based upon the blue colour produced when phosphotungstic acid and an alkali are added to uric acid (J. Biol. Chem. 1912, 11, 305; Folin and Denis, *ibid.* 1912, 14, 95; Brughsh and Kristeller, Chem. Zentr. 1915, i. 1090;

Benedict and Hitchcock, *J. Biol. Chem.* 1915, 20, 619, 629). The replacement of phosphotungstic by arsenotungstic or arseno-phosphotungstic acid gives a greater depth of colour (Morris and Macleod, *J. Biol. Chem.* 1922, 50, 55; Benedict, *ibid.* 1922, 51, 187; 52, 387). It is claimed that the method as modified by Benedict and Hitchcock (*ibid.* 1915, 20, 624) gives as accurate results as the titration method of Folin and Shaffer (*v. Morris, ibid.* 1916, 25, 205; *Proc. Amer. Soc. Biol.* 1916, xiii.; 1917, 29), who recommends precipitating the uric acid with zinc acetate in alkaline solution as a preliminary to the application of Benedict's method. See Salkowski (*Zeitsch. physiol. Chem.* 1913, 85, 346); Kaschiwabara, (*ibid.* 1913, 84, 223); Hüst (*Zeitsch. physiol. Chem.* 1915, 95, 88); Bogert (*J. Biol. Chem.* 1917, 31, 165); Morris (*Proc. Amer. Soc. Biol. Chem.* 1917, xxi.; *J. Biol. Chem.* 1918, 33; 1919, 37, 231); Cohen Tervaert (*Arch. Néerland. physiol.* 1918, 2, 337); Zaleski and Sachnovska (Russ. *Physiol. J.* 1919, 2, 14); Folin and Wu (*J. Biol. Chem.* 1919, 38, 81, 459); *cf.* Brown and Raiziss (*J. Lab. Clin. Med.* 1922, 8, 129); and Rogers (*J. Biol. Chem.* 1923, 55, 325); Guillaumin (*J. Pharm. Chim.* 1922, [vii.] 25, 5); Thiéry (*ibid.* 87); Jackson and Palmer (*J. Biol. Chem.* 1922, 50, 89; 53, 373).

For the rapid estimation of uric acid in urine, Vaillant (*Ann. Chim. Anal.* 1922, [ii.] 4, 178) titrates the liquid with a standard iodine solution made by dissolving 3·78 grms. of iodine and 15 grms. of potassium iodide in 1 litre of water. Two c.c. of this solution oxidise 0·005 gm. of uric acid to alloxan and urea. The analysis is carried out by measuring into a small tube 2 c.c. of iodine solution and 1 c.c. of carbon disulphide, and allowing the urine to fall a drop at a time from a burette, shaking the tube after each addition, until the carbon disulphide becomes first pale rose and then colourless. The uric acid content per litre of urine is calculated by dividing the number of c.c. used into 5. Sugar and small amounts of albumin do not interfere; larger amounts should be removed by heating to coagulate and then filtering. If the urine is alkaline a few drops of acetic acid are added (*Chem. Soc. Abstr.* 1922, ii. 668).

For the separation of and estimation of uric acid and xanthine bases by means of potassium-zinc ferrocyanide, *see* Thiéry (J. Pharm. Chim. 1921, 23, 494).

A colorimetric method, based on the action of uric acid on iodic acid, whereby iodine is liberated, is recommended by Autenrieth and Funk (Chem. Zentr. 1915, 1, 1918 from Münch. med. Wchschr. 1914, 61, 457); Maase and Zondek (Chem. Zentr. 1915, ii. 858). For a critical review of methods for estimating uric acid and xantho-uric substances, v. Sauzéat (J. Pharm. Chem. 5, 164, 445, 485).

Derivatives. *Salts.*—All four hydrogen atoms of uric acid are acidic and can be replaced by metals, as is shown by the formation of salts from each of the four trimethyl uric acids; the hydrogen atom 3 is the most acidic, then hydrogen 9, the hydrogen atoms 1 and 7 are much weaker in their acidity; hence uric acid behaves as a feeble dibasic acid (Biltz and Herrmann, Ber. 1921, 54, 1676), and forms three

series of salts, the *normal* urates of the type $\text{Na}_2\text{C}_4\text{H}_3\text{O}_6\text{N}_4$ are readily soluble in water and are never found in the animal system; the *acid* or *diurates* $\text{NaC}_4\text{H}_2\text{O}_6\text{N}_4$ are sparingly soluble and occur pathologically in gouty concretions; and the *quadr- or hemi-urates*

are more readily soluble than the diurates and are the common form in which uric acid occurs physiologically.

Normal urates may be obtained by dissolving uric acid in the theoretical quantity of alkali. They are alkaline in reaction and are decomposed by carbon dioxide, forming the acid salt. The *potassium* salt $K_2C_5H_2O_3N_4$ is crystalline; it dissolves with partial decomposition into the acid salt in about 36 parts of cold water; the *sodium* salt $Na_2C_5H_2O_3N_4 \cdot H_2O$ is less soluble than the potassium salt, and is stated to be rendered more soluble by radium D (Gudzent, Zeitsch. f. klin. Med. 71, 3-6), and to be decomposed by the α -rays from radium emanation (Mesernitzky, Compt. rend. 1912, 154, 770); according to Knaff-Lenz and Wiechowski (Zeitsch. physiol. Chem. 1912, 77, 303), and to Kerb and Lazarus (Biochem. Zeitsch. 1912, 42 82), radium has no action on the salt under sterile conditions, but accelerates the degradation of the compound in the presence of enzymes or moulds; the *calcium* $CaC_5H_2O_3N_4$, *strontium* $SrC_5H_2O_3N_4 \cdot 2H_2O$, *barium* $BaC_5H_2O_3N_4 \cdot H_2O$, and *lead* $PbC_5H_2O_3N_4$ salts are sparingly soluble. The *mercury* salt $HgC_5H_2O_3N_4$ is a white amorphous precipitate; it does not give mercuric oxide with sodium hydroxide solution and is therefore probably a lactam salt (Auld, Chem. Soc. Trans. 1907, 1046). *Zinc*, *nickel*, and *copper* salts are described by Curtman and Hart (J. Biol. Chem. 1921, 46, 599).

Acid or di-urates.—According to Gudzent (Zeitsch. physiol. Chem. 1909, 60, 38), uric acid forms two series of primary metallic salts (mono-sodium, potassium and ammonium urates), which differ as regards solubility. The salts of the *a*-series cannot be obtained pure, as at the moment of formation in water they tend to pass into the salts of the *b*-series. The probable cause of the change is an intramolecular rearrangement, so that the two series correspond with the two tautomeric forms of uric acid

The unstable α -salts are probably the *lactam* urates, and the stable δ -salts the *lactim* urates. The α -salts have solubilities and specific conductivities that at 18° are some 33-4 p.c., or at 37° some 33-9 p.c. greater than the corresponding values for the more stable δ -salts.

The sodium salt $\text{NaC}_2\text{H}_3\text{O}_2 \cdot \text{N}_2 \cdot 11\text{H}_2\text{O}$ forms a crystalline powder soluble in 1200 parts of cold or 120 parts of boiling water, forming a neutral solution. The solubility of freshly percolated sodium urate at 18° is 2.03 grms. or 9.8×10^{-3} grms. molecules per litre. On keeping, or more particularly on stirring in contact with the solution, the solubility decreases and approaches that of the crystalline form. The potassium salt $\text{KC}_2\text{H}_3\text{O}_2 \cdot \text{N}_2$ is amorphous.

and dissolves in 800 parts of cold or 70–80 parts of boiling water; *lithium* salt $\text{LiC}_5\text{H}_3\text{O}_2\text{N}_4$ forms crystalline grains and is soluble in 370 parts of cold or 39 parts of boiling water; the *ammonium* salt $\text{NH}_4\text{C}_5\text{H}_3\text{O}_2\text{N}_4$ is soluble in 1500 parts of cold water and quite insoluble in saturated solutions of ammonium chloride or sulphate; and the *magnesium*

calcium $(\text{C}_5\text{H}_3\text{O}_2\text{N}_4)_2 \cdot \text{Ca} \cdot 2\text{H}_2\text{O}$, *strontium*

barium $(\text{C}_5\text{H}_3\text{O}_2\text{N}_4)_2 \cdot \text{Ba} \cdot 3\text{H}_2\text{O}$, and *lead*

salts are described. For the formation of *colloidal uric acid* in the presence of alkalis, see Schade and Boden (Zeitsch. physiol. Chem. 1913, 83, 347); compare, however, Lichtwitz (*ibid.* 1913, 84, 416); Schade and Boden (*ibid.* 1913, 86, 238); Gudzent (*ibid.* 1914, 89, 352); Haskins (J. Biol. Chem. 1916, 26, 205); Kohler (Z. Klin. Med. 1919, 88, 14); Schade (*ibid.* 1922, 23, 1).

The *quadri-urates* are difficult to obtain pure as they readily break down into diurates and uric acid; according to Rosenheim (Lancet, 1900; Zeitsch. physiol. Chem. 1911, 71, 272) and Kohler (*ibid.* 70, 360) the quadri-urates are only mixtures, in molecular proportions, of primary urates and uric acid; they are stated to exist normally in the urine and constitute the whole of the urinary excretion of birds and reptiles (v. URINE).

Adrenaline urate $\text{C}_9\text{H}_{13}\text{O}_3\text{N} \cdot \text{C}_5\text{H}_3\text{O}_2\text{N}_4$ forms small pointed plates (Pauly, Ber. 1904, 37, 1388). *Piperazine urate* $\text{C}_4\text{H}_{10}\text{N}_2 \cdot \text{C}_5\text{H}_3\text{O}_2\text{N}_4$ is soluble in 50 parts of water at 17°. The *phosphotungstate* of uric acid forms reddish-brown cubical plates (Drummond, Bio-Chem. J. 1918, 12, 5).

Uric acid glycol

crystallises with half a molecule of water of crystallisation; it reddens at 150° and melts 165°–168° (effervesces) (Biltz and Heyn, Ber. 1912, 45, 1677; *ibid.* 1914, 47, 459; Ann. 1916, 413, 7).

4 : 5-Di-methoxy-4 : 5-dihydrouric acid

crystallizes in slender needles, m.p. 202°–203° (decomp.); it is reduced by sodium amalgam to uric acid and by hydriodic acid (D 1.96) on the water bath to ψ -uric acid (Biltz, Annalen 1916, 413, 1; Ber. 1921, 54, 2477).

p-Nitrobenzyl urate $\text{C}_5\text{H}_3\text{O}_2\text{N}_4 \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$ melts above 350° (Lyons and Reid, J. Amer. Chem. Soc. 1917, 39, 1727).

Uric acid forms the following condensation products with formaldehyde:—

Diformaldehyde-uric acid $\text{C}_6\text{H}_4\text{O}_2\text{N}_4 \cdot 2\text{CH}_2\text{O}$ is a crystalline, sparingly soluble compound,

monobasic towards N/3 sodium hydroxide and forms a *barium* and a *calcium* salt (Weber, Pott and Pollens, Ber. 1897, 30, 2514; Annalen, 1898, 299, 340). *Formaldehyde uric acid*

crystallises in needles or prisms, decomposes at 37°, and forms crystalline alkali salts; and *anhydroformaldehyde-uric acid*

formed by dissolving diformaldehyde-uric acid in concentrated sulphuric acid and pouring the solution into ice water (Nicolaier, Chem. Zentr. 1907, i. 949). For other derivatives of uric acid, v. Biltz (*l.c.*). M. A. W.

ψ -URIC ACID v. PYRIMIDINES.

URIDINE v. PYRIMIDINES.

URINE. The kidneys are compound tubular glands, and possess the power of excreting from the blood certain waste products which in aqueous solution constitute the urine. Its most important constituents are the result of the breakdown of nitrogenous materials in the body, but these substances, urea, uric acid, &c., are not actually formed in the kidneys themselves. The liver is the most important organ for their actual formation; the kidney is merely the situation where they find an exit from the body.

The characters of the urine differ greatly in different parts of the animal kingdom, according to the character of the food ingested, and the different metabolic habits of animals. The most striking difference is seen when one compares the liquid urine of mammals (in which urea is the main substance in solution) and the semi-solid urine of birds and snakes, in which urates form the preponderant constituents. In the following account attention will be in the main directed to the urine which is most familiar, namely that of man and other mammals.

A man of average weight and height, taking a normal mixed diet, passes from 1400 to 1600 c.c. (about 50 oz.) daily, and this contains about 50 grms. (1½ oz.) of solids. Its yellow colour varies considerably with the concentration of the urine, and is due to the presence of a number of pigments, of which *urochrome* (an amorphous nitrogenous substance of doubtful composition, originally so named by Thudichum) is the most abundant. Another named *urobilin*, a derivative of the bile pigment, is present in health in small quantities, but may be considerably increased in certain diseases.

The reaction of urine is acid; this is partly due to free acid, but mainly to acid salts, of which acid sodium phosphate is the most abundant. During digestion, however, there is a formation of free hydrochloric acid in the stomach, and a corresponding liberation of bases in the blood causes the urine to be less acid, or even alkaline. Alkaline urine is also seen in herbivorous animals and vegetarians; here the food contains excess of alkaline salts of acids such as tartaric, citric, malic, &c. These acids in the body are oxidised into carbonates which, passing into the urine, give it an alkaline reaction.

The specific gravity varies inversely as the quantity of urine passed; the quantity depends on the amount of water ingested, and also on

the amount of water that leaves the body by other channels, such as the skin. It varies normally from 1.015 to 1.025. A sp.gr. below 1.010 should excite suspicion of hydruria; one over 1.030 of a febrile condition, or of diabetes, in which disease it may rise to 1.050. The sp.gr. has, however, been known to sink as low as 1.002 (after large potations, *urina potus*), or to rise as high as 1.035 (after great sweating) in perfectly healthy people.

When a normal urine is distilled, an unknown, or imperfectly known, substance begins to volatilise at 60°–70°C., but does not completely leave the urine until the boiling-point is reached. The distillation is carried out on the urine which has been acidified with phosphoric acid: at least one-quarter of the urine should distil over. This distillate is a limpid colourless liquid of intense urinous odour, and is neutral to all reagents. It is not precipitated by alkalis or acids, nor with the bicarbonate and sublimate mixture; it does not react with Fehling's solution, nor give the diazo reaction in neutral or acid media; no apparent change takes place with salts of silver, cadmium, iron, lead, mercury, or zinc. With Nessler's reagent it gives a greenish-yellow precipitate similar to that given with many other substances, such as alkaloids, amides, all amines, organic ammonias, aldehyde and methylene derivatives. It is concluded that there is a volatile body in normal urine resembling ketone, but different from ordinary acetone, precipitated by Nessler's reagent, and that it is to this substance that the characteristic odour of the urine is due (E. Pittarelli, *La Riforma Med.* May 14th, 1923, through *Lancet*, June 9th, 1923, 1172).

The following table gives the average amounts of the urinary constituents passed by a man taking an ordinary diet containing about 100 grms. of protein in the 24 hours—

Total quantity of urine	1500	grms.
Water	1400	
Solids	60	
Urea	35	
Creatinine	0.9	
Uric acid	0.75	
Hippuric acid	1.0	
Ammonia	0.65	
Sodium chloride	16.5	
Phosphoric acid	3.5	
Sulphuric acid	2.0	
Chlorine	11.0	
Potassium	2.5	
Sodium	5.5	
Calcium	0.26	
Magnesium	0.21	

The most abundant constituents are, therefore, water, urea, and sodium chloride. We will take the most important individual constituents one by one.

Urea. The time-honoured formula of urea as carbamide $\text{CO} \begin{smallmatrix} \text{NH}_2 \\ \text{NH}_2 \end{smallmatrix}$ must be replaced

according to Werner by the cyclic formula $\text{H} \cdot \text{N} : \text{C} \begin{smallmatrix} \text{NH}_2 \\ \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix}$. This offers a satisfactory explanation for the behaviour of urea during hydrolysis. It was first prepared synthetically

by Wöhler (1828) from its isomeride ammonium cyanate.

It crystallises in the dimetric system, and is readily soluble in water and in alcohol; it has a faint saltish taste, and is neutral to litmus. When treated with nitric acid, octahedra, or lozenge-shaped tablets are formed of urea nitrate ($\text{CON}_2\text{H}_4 \cdot \text{HNO}_3$); when treated with oxalic acid prismatic crystals of urea oxalate

are formed.

Under the influence of certain micro-organisms which grow readily in stale urine, it is converted into ammonium carbonate

Hence the ammoniacal odour of putrid urine. In the soil the urinary ammonia is converted into nitrates by nitrifying organisms (*see SOILS*).

By means of nitrous acid, urea is broken up, as shown in the following equation:

Sodium hypobromite decomposes urea as follows:

A critical examination of this reaction shows that there is always a deficit in the quantity of urea found, whether it is calculated from the volume of the nitrogen liberated, the carbon dioxide formed, or the hypobromite used. Side reactions of a complex nature also occur under usual conditions, giving rise to a small amount of CO. Moreover, other urinary constituents (uric acid, creatinine, &c.) also yield nitrogen under the conditions of the experiment. Hence the method which was formerly much used for the estimation of urea is now abandoned when accuracy is required. The methods at present in use are those in which the urea is decomposed into ammonia and carbon dioxide; the ammonia formed is estimated, but as the urine contains a small amount of preformed ammonia this has to be previously estimated and deducted from the total. The methods of Möerner and Sjöquist, Folin and others (*v. UREA*) are examples of this type of estimation, but the enzymatic method depending on the action of the enzyme urease contained in soy-beans promises to replace all other methods. It was introduced by Marshall. Urease is a specific enzyme, which rapidly and quantitatively decomposes urea at 35°–40°C. into ammonia and carbon dioxide. The ammonia formed is driven off in a suitable apparatus by a current of air, absorbed with standard acid, and estimated by titration, alizarin-red or methyl-orange being used as indicator.

The quantity of urea is practically uninfluenced by muscular work, but depends mainly on the amount of protein ingested. The amino acid fragments formed by the digestion of protein are utilised in two ways. A small portion is used by the tissue cells to repair their waste. In time this will be catabolised and the waste products discharged as urea, ammonia, creatinine, &c. The amount of such *endogenous* metabolism is constant. The other and larger part of the cleavage products of the food proteins are deaminised and converted into urea by the liver, the non-nitrogenous fatty residue being

burnt, and so utilised as a source of heat and other forms of energy. This part of metabolism is termed *exogenous*. Urea excretion is usually at a maximum about 3 hours after a meal. The conversion of amino acids into urea is, in part at any rate, due to enzymic action; e.g. arginase is an enzyme which converts arginine (one of the more complex amino acids resulting from protein disintegration) quantitatively into urea and ornithine (di-amino-valeric acid). There is also no doubt that ammonia is an important intermediate between such amino acids as glycine (amino-acetic acid), leucine (amino caproic acid), &c., and the final product urea. Ammonia so liberated unites with the carbon dioxide of the blood, and ammonium carbonate and carbamate are thus formed. The close relationship of these two salts to urea is apparent from their formulae—

This view, though simple, must be modified if Werner's conception of the structure of urea is accepted.

A small quantity of ammonia always slips through into the urine, because a small quantity of the ammonia-containing blood passes through the kidney before reaching the organ (the liver), which is capable of converting it into urea. Acids are very toxic to the body, and the defence of the body against acids (administered as such, or produced in pathological metabolism, e.g. fatty acids in diabetes) is an increase of ammonia formation, or to put it more correctly, less of the ammonia formed is converted into urea.

Creatine and creatinine.—Creatine is an abundant constituent of muscular tissue; *in vitro* by boiling it with baryta it takes up water and splits up into urea and methyl-glycine, as shown in the following equation—

Creatine, however, is absent from normal urine, and only occurs in starvation and in other conditions, in which there is a rapid loss of muscular tissue. Its normal fate in the body is unknown, since creatine injected into the circulation leaves the body in the urine unchanged, and leads to no increase of urea.

It also is not converted into creatinine, which was formerly held to be its fate. Here, again, we have an instance of reactions, which occur *in vitro*, but not *in vivo*. Creatinine is a crystalline, strongly basic substance, which chemically is creatine *minus* a molecule of water. It is always present in the urine, and next to urea, is its most abundant nitrogenous constituent. Mellanby believes that certain products of protein catabolism, the nature of which is uncertain, are carried to the liver, and from these the liver forms creatinine; this is transported to the muscles, and there stored as creatine, excess being then eliminated in the urine. The small amount of creatinine excreted in liver disease favours the view that the liver is the great agent in its production, as it is in that of urea and uric acid. In health the amount of creatinine is very constant, and is not influenced by diet or muscular exercise.

Uric acid ($\text{C}_5\text{H}_4\text{N}_4\text{O}_6$) is excreted as urates in mammals in small quantities only, but in birds and serpents is the principal nitrogenous constituent of their urine. It can be readily prepared from the latter urine, in which it is mainly present as the acid ammonium urate, by dissolving it in sodium hydroxide and precipitating with hydrochloric acid. It crystallises in rectangular plates and prisms. Uric acid dissolves in pure water in the proportion 1 : 15,000 (Gudzent), and at 18° in the proportion 1 : 39,500 (His and Paul). On oxidation it yields urea and oxalic acid, alloxan ($\text{C}_4\text{H}_2\text{N}_4\text{O}_4$) or allantoin ($\text{C}_4\text{H}_6\text{N}_4\text{O}_3$), being intermediate products, according to the oxidising agent employed. It can be best identified by the *murexide* reaction, which consists in evaporating to dryness with nitric acid; the yellowish-red residue gives, on the addition of ammonia, the violet ammonium purpurate.

Uric acid does not contain the COOH group which is typical of organic acids, and in aqueous solution its reaction is neutral. Nevertheless one of its hydrogen atoms is replaceable by a metallic radicle, and it acts therefore as a monobasic acid, and forms *primary* salts (mono- or acid urates). In the presence of strong bases it forms *secondary* salts (di-urates); these only exist in the solid condition or in the presence of strong alkali. By water they are at once decomposed forming primary salt and alkali. A third series of salts (quadri-urates) was formerly assumed to exist, but these are merely mixtures of uric acid and primary urate.

In water, urine and blood, we have therefore only to deal with primary urates. It has been shown that the primary sodium urate

occurs in two modifications, the α - and the β -forms. The unstable α salt is gradually transformed in aqueous solution into the stable β salt, owing to an intramolecular change. These two salts correspond to two tautomeric modifications of uric acid, the lactam form (formula I) giving rise to the unstable, and the lactim form (formula II) to the stable salt.

These facts have a bearing on gouty conditions; normally the small amount of urate in the blood is held in solution. In gout the amount is increased, and the excess is probably in the unstable α -form. The conversion of this into the β -form gives rise to the deposition of urates in the tissues which occurs during the course of the attack.

The quantity of uric acid excreted by an adult varies from 0.5 to 0.75 gm. daily. The method used for estimation is based on Hopkins' discovery, that when the urine is saturated with an ammonium salt (chloride or sulphate), all the uric acid is precipitated as ammonium urate; this is collected and the uric acid in it determined. The Folin-Shaffer method is founded on this reaction. Folin has also introduced a colorimetric method, which depends on the

blue colour uric acid strikes with phosphotungstic acid (v. URIC ACID).

In birds uric acid originates from the combination of ammonia and lactic acid. In mammals it mainly arises from the purine bases of the food, which are cleavage products of nucleic acid, the main constituent of the nuclei of the body cells. In this process several tissue enzymes come into play; first nuclease liberates adenine (amino-purine $C_5H_7N_5NH_2$) and guanine (amino-oxypurine $C_5H_7N_5O.NH_2$) from nucleic acid; then 'deaminising' enzymes convert adenine into hypoxanthine (monoxypurine $C_5H_7N_4O$) and guanine into xanthine (dioxypurine $C_5H_7N_4O_2$); oxidases step in next and convert hypoxanthine into xanthine, and xanthine into uric acid (trioxypurine $C_5H_4N_4O_6$). The liver is the principal seat of these transformations, and in some animals some of the uric acid so formed is destroyed in the same organ, and appears as allantoin and urea. So far as tissue extracts can give a true picture of metabolism *in vivo* the human tissues are destitute of the uricolytic (uric acid destroying) enzyme)

Small quantities of purine bases are found in the urine in addition to uric acid.

Hippuric acid ($C_9H_9NO_3$) in the form of hippurates is present in small quantities in the urine of man, but is specially characteristic of herbivorous urine. This is due to the food of herbivora containing substances of the benzoic acid group. The condensation of benzoic acid with glycine to form hippuric acid appears to occur in the kidney itself, and may be represented by the following equation—

For the estimation of hippuric acid in urine, see Snapper and Laquer, Archives Néerlandaises de Physiologie, 1921, 6, 48, which contains further references to the literature of the subject.

Kynurenic and urocanic acids are present in small quantities in dog's urine. Kynurenic acid $C_{10}H_9NO_3$ is hydroxyquinoline carboxylic acid ($HO \cdot C_6H_4 \cdot N \cdot COOH$) and originates from one of the decomposition products of protein called tryptophan (indole-amino-propionic acid). Urocanic acid ($C_{11}H_{12}N_4O_4$) is a rarer constituent, and its origin in the body is not clear.

Inorganic constituents of urine. The principal salt is *sodium chloride*, and its amount varies with that in the food. The *sulphates* present are principally those of sodium and potassium. They are derived from the metabolism of protein, and their excretion, although it occurs earlier than that of urea, runs parallel with it. About one-tenth of the total sulphates are etheral sulphates, such as potassium phenyl sulphate and potassium indoxyl sulphate (urinary indican); the organic radicles originate from protein putrefaction in the alimentary canal, and abnormally great putrefactive processes there lead to an increase in the excretion of such sulphates. Sulphur is also present in the form of less highly oxidised organic compounds, usually spoken of as 'neutral sulphur,' a term which includes thiocyanic acid and its salts, taurine, cystine, methyl mercaptan.

Carbonates are only present in alkaline urine. Alkaline and earthy *phosphates* are also present and small quantities of organic phosphates, for instance, glycerophosphates. They arise partly from the food, but chiefly from the metabolism of organic phosphorised constituents of the body, such as nucleic acid, lecithin, and other phosphorised fats (phosphatides).

According to Amberg and Mayer (Amer. J. Physiol. 1922, 60, 564) minute quantities of citric acid occur in normal human urine.

Abnormal constituents of urine. The most commonly occurring of these are albumin (in Bright's disease) and other proteins, dextrose, acetone, aceto-acetic acid, and β -hydroxybutyric acid in diabetes, lactose in nursing mothers, bile in jaundice, blood when hæmorrhage occurs in any part of the urinary tract, hæmoglobin, and certain derivatives of hæmoglobin in black water fever and other pathological states, and pus as the result of suppuration in any part of the urinary tract.

Urinary deposits. Normal urine is clear except for a faint cloud of mucus. Formed or anatomical elements such as blood corpuscles, pus corpuscles, bacteria, entozoa, &c., may be present in various pathological conditions, and are identified by microscopic examination. A special chemical interest attaches, however, to crystalline deposits, and without entering into any discussion of the medical reasons that lead to their appearance, these may be briefly enumerated as follows:—

A. In acid urine may be found—

1. Uric acid, as whetstone, dumb-bell, or sheaf-like aggregations of crystals deeply tinged with urinary pigment, looking like cayenne pepper.

2. Urates. These are generally amorphous. The acid urate of sodium and ammonium may sometimes occur in star-shaped clusters of needles or spheroidal clumps with projecting spines. The deposit has the appearance of brick-dust, as it is coloured by one of the urinary pigments (uroerythrin). This deposit dissolves on warming the urine.

3. Calcium oxalate in the form of octahedral crystals insoluble in acid.

4. Cystine (diamino-dithio-lactic acid $C_6H_{12}N_2S_2O_4$)

in colourless hexagons; a rare condition often hereditary.

5. Calcium phosphate $CaHPO_4 \cdot 2H_2O$, rare.

6. Leucine (*amino-caproic acid*) and tyrosine β -p-hydroxyphenyl- α -aminopropionic acid, rare.

B. In alkaline urine we may find—

1. Phosphates; calcium phosphate $Ca_3(PO_4)_2$

which is amorphous; triple phosphate $MgNH_4PO_4 \cdot 6H_2O$

in 'coffin lid' crystals or feathery stars; calcium hydrogen phosphate $CaHPO_4$ in rosettes, spherules, or dumb-bells; magnesium phosphate $Mg_3(PO_4)_2$ in long plates. All are soluble in acetic acid without effervescence.

2. Calcium carbonate $CaCO_3$, biscuit-shaped crystals, common in herbivorous urine, soluble in acetic acid with effervescence.

3. Ammonium urate $C_6H_5(NH_4)_2N^+O_2$ 'thorn apple' spherules.

4. Leucine and tyrosine, very rare.

Of these deposits, urates in acid urine, and phosphates in alkaline urine are the commonest; these are not necessarily pathological; thus urates may form in the urine when it cools, especially if that secretion is concentrated, e.g. after sweating profusely. Urine, when it becomes alkaline, always deposits phosphates, and the alkaline urine of herbivora is always thick for that reason.

Urinary calculi. Concretions called sand, gravel, and stones, according to their size, may form in the kidney, the ureter, or in the bladder. They result from the conglomeration of urinary deposits, the deposition occurring in concentric layers. The substances deposited in acid urine are most frequently uric acid, urates or calcium oxalate, or a mixture of these materials; in alkaline urine, phosphates. If the reaction of the urine changes during the formation of the calculus alternate layers of these two sets of materials will be found. The uric acid calculus is generally regarded as the commonest form of stone in the bladder, but in renal calculi, as B. Moore has shown, the most abundant constituent is calcium oxalate, frequently mixed with calcium phosphate, the second constituent in frequency and abundance. Calcium is practically the only base associated with oxalic acid, phosphoric acid, and in less amount with uric acid. All these acids form highly insoluble salts with calcium. Oxalic and uric acids are associated products in metabolism, and occur in cases of incomplete oxidation.

The physical properties of a calculus—colour, hardness, smoothness, or roughness, &c.—give little or no clue to its chemical nature. A chemical analysis is always necessary, and this gives valuable indications for after treatment; for instance, in renal calculi, consisting of calcium oxalate, the treatment should be designed to diminish alkalinity, to avoid calcium-rich foods, and to induce the taking of exercise to promote oxidation in the body.

There are, in addition to these common forms of stone, others of a rarer kind, and a list of the different varieties of calculus is as follows—

1. Those composed of uric acid or urates with little or no admixture with phosphates.

2. Mixed calculi, like the preceding, but containing often in alternate layers a large quantity of phosphate.

3. Calcium oxalate calculi, often containing small quantities of phosphates and urates.

4. Phosphate calculi: a stone composed of pure calcium phosphate is rare; a nucleus of uric acid is generally present.

5. Calcium carbonate calculi are those generally found in the prostate.

6. Cystine calculi are mostly small, smooth, and have a yellow tinge, turning to green on exposure to air. These are rare.

7. Xanthine calculi are still rarer.

8. Fibrinous calculi composed of fibrin or inspissated albumin, have a glassy appearance on fracture; blood calculi have been described in cases of renal hamaturia; 'urostealith' calculi have been described, and consist of fatty acid with more or less cholesterol. One case of 'isidig' calculus has been described.

No attempt has been made in the foregoing outline sketch of the chemical properties of the

urine in health and disease to give complete bibliographical references. The literature of urine is enormous, and those interested in it should consult standard works on physiology, physiological chemistry, pathology, and medicine. One of the most trustworthy handbooks on the urine only, and containing abundant references to literature, is Neubauer and Vogel's *Analyse des Harns*, edited by Huppert, Wiesbaden, C. W. Kreidel.

W. D. H.

URINOD C_6H_8O , a pale yellow oil, obtained from urine, slightly heavier than water, b.p. $108^\circ/28$ mm.; possessing a very penetrating, persistent and disagreeable odour and to which the characteristic smell of urine is due. Is readily volatile with steam, reduces potassium permanganate and ammoniacal silver nitrate in the cold, and reacts with Millon's reagent, but not with Barreswil's (Fehling's) solution, or solution of alkali picrate. The dinitro-derivative, m.p. 78° forms golden needles. Urinod acts with ser carbazide with production of a compound m.p. 254° , which crystallises in thin, hexagonal leaflets. When urinod is treated with bromine, two compounds are produced; one of these has m.p. about 110° , whilst the other is not melted at 250° . The compound probably has the structure of cyclohexene-4-one

or the quinonoid constitution

Urinod does not occur in the free state in urine, but exists in a conjugated form, and is liberated by fermentation, or by the action of dilute sulphuric acid. It is very toxic, and may have some connection with uramia (Dehn and Hartman, J. Amer. Chem. Soc. 1914, 36, 2136).

URISOL. Syn. for hexamethylenetetramine.

URITONE (hexamine). Syn. for hexamethylenetetramine.

UROCITRAL, UROPHENIN, v. SYNTHETIC DRUGS.

URODONAL. Trade name for a preparation of hexamethylenetetramine, piperazine quinate and methylglyoxalidine.

UROGENIN. Trade name for an addition product of theobromine and lithium hippurate.

UROL. Trade name for urea quinate.

UROPHERIN v. SALICYLIC ACID.

UROPURGOL (helmitol, neurotine, formamol). The hexamethylenetetramine salt of anhydromethylene-citric acid.

UROSIN. Trade name for lithium quinate.

UROTROPIN. Hexamethylenetetramine, v. SYNTHETIC DRUGS.

UROXANIC ACID, dicarbaminomalonic acid $(CO_2H)_2C(NH-CO-NH)_2$, is prepared by the gradual oxidation of uric acid in alkaline solution by the oxygen of the air (Städeler, Annalen, 1851, 78, 286; Strecker, *ibid.* 1870, 155, 177; Biltz and Robl, Ber. 1920, 53, 1950); by oxidising an alkaline solution of uric acid with 5 p.c. potassium permanganate solution (1 atom of oxygen to 1 mol. of uric acid) (Behrend, *ibid.* 1904, 333, 152; Sundvik, Zeitsch. physiol. Chem. 1904, 41, 343; Behrend and Schultz, *ibid.* 1909, 365, 21; Biltz and Robl, *l.c.*).

For the mechanism of the formation of uroxanic acid from uric acid, see Biltz and

VALERIAN.

Max (Ber. 1920, 53, 1964). The two carbamido groups in uroxanic acid can be quantitatively eliminated by sodium nitrite with the formation of mesoxalic acid (Biltz and Robl, l.c.).

Uroxanic acid crystallises in indistinct tetrahedra (decomp. 162°); it is sparingly soluble in cold water and insoluble in alcohol; it is a strong dibasic acid and its normal alkali salts are neutral towards litmus and phenolphthalein. It readily loses CO_2 and yields allantonic acid when shaken for several days with cold 95 p.c. methyl alcohol. When heated with water it breaks down into allanturic acid

mesoxalic acid and urea. The aniline and hydroxylamine salts are sparingly soluble; the latter, melts at 155° ; the normal phenylhydrazine salt, $\text{C}_6\text{H}_5\text{O}_4\text{N}_4 \cdot 2(\text{C}_6\text{H}_5\text{N}_2)$, crystallises in colourless plates, m.p. 130° – 132° (decomp.), when boiled with water it is decomposed, yielding the phenylhydrazine salt of mesoxalic acid phenylhydrazone $\text{C}_{18}\text{H}_{18}\text{O}_4\text{N}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, this forms yellow needles that melt at 154° – 158° , solidify at 160° and then decompose at 183° . The normal silver, sodium, barium, and calcium salts of uroxanic acid are crystalline.

The potassium salt forms colourless crystals, $a:b:c=0.88576:1:1.2044$, and gives hydrates containing 3.5, 3, and probably 0.5, H_2O ; the ammonium salt decomposes at 182° . The methyl ester decomposes at 213° , and is converted by boiling water into spirodihydantoin, which yields the di-silver salt $\text{C}_6\text{H}_2\text{O}_4\text{N}_4\text{Ag}_2 \cdot 2\text{H}_2\text{O}$ and the diammine copper salt

(Biltz and Robl, l.c.).

For the physiological action of uroxanic acid, see Saiki (J. Biol. Chem. 1910, 7, 263).

M. A. W.

URSAL. Urea salicylate. A uric acid eliminant.

URSOL v. p- PHENYLENEDIAMINE.

URSOL P v. p- AMINOPHENOL.

URSONE. Urson. A white crystalline optically active substance $\text{C}_{22}\text{H}_{47}\text{O} \cdot \text{COOH} \cdot 2\text{H}_2\text{O}$, m.p. 273° , $[\alpha]_D^{15} = +58^{\circ}$, found in holly, maté, and other species of *Ilex*, and in many ericaceous plants. With sulphuric acid it gives an orange-yellow colour with green fluorescence; an acetic anhydride solution gives with sulphuric acid a red coloration passing to violet, green, and blue; a chloroform solution shaken with an equal volume of sulphuric acid colours the latter

yellow. Soluble in ethyl and methyl alcohols, chloroform, carbon disulphide, ether, and ethylene bromide. Yields a readily crystallisable methyl ester (Dodge, J. Amer. Chem. Soc. 40, 12; Nooyen, Pharm. Weekblad. 1920, 57, 1128). According to van Der Harr (Rec. trav. chim. 1924, 43, 367) urson has the formula $\text{C}_{21}\text{H}_{40}\text{O}_8$, m.p. 279° – 280° , and gives sesquiterpene and CO_2 on distillation with zinc dust. It forms an acetyl derivative, m.p. 201° , a methyl ester, m.p. 165° , and an acetyl derivative of the methyl ester, m.p. 245° . It thus appears to contain a hydroxyl and a carboxyl group.

URUSHIOL v. LACQUER; RESINS. Cf. Majima, Ber. 1922, 55 [B.] 172; Levin, J. Amer. Med. Assoc. 1924, 465; Pharm. J. 1924, 112, 236.

USNIC ACID $\text{C}_{18}\text{H}_{18}\text{O}_7$ (Stenhouse, Proc. Roy. Soc. 18, 222), $\text{C}_{18}\text{H}_{18}\text{O}_8$ (Paterno, Ber. 9, 345). An acid found in certain lichens (v. LICHENS).

UVANITE. Hydrated uranium vanadate $2\text{UO}_2 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{H}_2\text{O}$, crystallised in the orthorhombic system. It occurs as a brownish-yellow powder disseminated in sandstone at Temple Rock in Emery Co., Utah. In appearance and mode of occurrence it thus resembles carnotite (q.v.), but it has not the clear yellow colour characteristic of carnotite. The mineral dissolves readily in a solution of ammonium carbonate. The name uvanite is a contraction of the words uranium and vanadium with the mineralogical termination *ite*. (F. L. Hess and W. T. Schaller, 1914.) L. J. S.

UVAROVITE v. GARNET.

UVITONIC ACID v. BONE OIL.

UZARA. The root of a species of *Gomphocarpus* (N.O. *Asclepiadaceae*) is used by medicine men in the region of the great African lakes against diarrhoea. The action of an extract was first described by Gürber (Muench. Med. Wochenschr. 1911, 58, 2100) and was found to be specific on the intestine, resembling that of opium, but without the undesirable after effects of the latter drug. A dried alcoholic extract has been placed on the market in Germany under the name uzaron. According to Hennig (Arch. Pharm. 1917, 255, 382) the active principle is the glucoside *uzarin* (5 p.c. of the root) $\text{C}_{25}\text{H}_{108}\text{O}_{30} + 9\text{H}_2\text{O}$, relatively well soluble in water and hydrolysed by acids into one molecule of propyl alcohol, three of dextrose and three of *uzaridin* $\text{C}_{18}\text{H}_{22}\text{O}_6$, which is strongly bitter. The glucoside is only slightly bitter. Cf. Kofler, Arch. Pharm. 1917, 255, 550; and Holmes, Pharm. J. 1920, 507. G. B.

V

VALAMIN. Trade name for the *isovaleric* ester of tertiary amyl alcohol.

VAL D'ARNO SUPERIORE RESIN v. RESINS.

VALEARIN. Trade name for valeryl trimethylammonium chloride.

VALENTINITE. Antimony trioxide Sb_2O_3 , crystallised in the orthorhombic system and dimorphous with senarmontite (q.v.). The small tabular or prismatic crystals are often arranged in fan-shaped groups. They have perfect cleavages in three plane directions (the unit prism and the brachypinacoid) parallel to the

vertical axis, and consequently broken surfaces present a fibrous aspect with pearly lustre. They are white or greyish, translucent, adamantine in lustre, very soft (H. 2), and readily distorted. Sp.gr. 5.76. The mineral occurs in the upper oxidised portions of lodes, having resulted by the alteration of stibnite and other antimony minerals. It is found at Bräunsdorf in Saxony, Příbram in Bohemia, Malaczka in Hungary, Algeria, Bolivia, &c. L. J. S.

VALERIAN. The root of *Valeriana officinalis* (Linn.) yields on distillation with water an essential oil of a pale yellow or greenish colour,

having a strong smell of valerian, an aromatic taste, and acid reaction; sp.gr. 0.90-0.93. Thickens at -15° , and begins to boil at about 200° . Consists of a mixture of valeric acid, a camphene, a stearoptene, and a resin (Pierlot, Ann. Chim. [iii.] 56, 291; Gerhardt, *ibid.* [iii.] 7, 275).

Valerian root contains two alkaloids: *chatinine* and *valerine*. One kilo of the fresh root yielded only 0.10 grm. of mixed alkaloids, chatinine predominating (Goris and Vischniac, Compt. rend. 1921, 172, 1059).

For the assay of Valerian Root, see Bullock, Pharm. J. 1924, 113, 109.

VALERIC or PENTOIC ACIDS C_4H_8COOH .

Four isomerides are known.

1. *n*-Valeric acid $CH_3[CH_2]_3COOH$, is found in pyroligneous acid, and occurs free and as esters in the animal and vegetable kingdoms, chiefly in the roots of *Valeriana officinalis* (Linn.) and of *Archangelica officinalis* (Hoffm.), from which it may be isolated by boiling with water or sodium hydroxide. It may be obtained by boiling *n*-butyl cyanide with potash (Lieben and Rossi, Annalen, 159, 58); by oxidation of α -hydroxycaproic acid (Erlenmeyer, Ber. 1876, 1840); by reduction of levulic acid (β -acetylpropionic acid) with phosphorus iodide or sodium amalgam (Kehrer and Tollens, Annalen, 206, 233; Fittig and Wolff, *ibid.* 208, 109); by heating propylmalonic acid (Juslin, Ber. 1885, 2504); by the fermentation of calcium lactate (Fitz, *ibid.* 1880, 1309); and by the action of CO_2 on magnesium *n*-butyl bromide (Gilman and Parker, J. Amer. Chem. Soc. 1924, 46, 2816; Chem. Soc. Abstr. 1925, 128, i, 228). A colourless oil having a disagreeable smell, b.p. 186° - 186.4° (Fürth, Monatsh. 9, 310); sp.gr. 0.9415 at $20^{\circ}/4^{\circ}$ (Lieben and Rossi); 1 vol. of acid dissolves in 27 vols. of water at 16° .

Methyl valerate boils at 127.3° , *ethyl valerate* at 144.6° (736.5 mm.), and *isobutyl valerate* at 167.0° - 168.5° ; sp.gr. 0.8544 $20^{\circ}/4^{\circ}$.

2. isoValeric acid, β -methylbutyric acid

Discovered in 1817 by Chevreul in dolphin oil from *Delphinus globiceps* and *D. phocaena*, and termed by him *phocenic acid* (cf. André, Compt. rend. 1924, 178, 1188; J. Soc. Chem. Ind. 1924, 43, 479). Found in other fish oils and in perspiration. In the roots of *Valeriana officinalis* (Linn.), *Archangelica officinalis* (Hoffm.), and in the berries of *Viburnum Opulus* (Linn.). Formed in the putrefaction of albuminoids; by the oxidation of glue, oleic acid, fats, and fusel oil (Lawkrow and Jazukowitsch. J. 1864, 337; Pierre and Pouchet, Ann. Chim. [iv.] 29, 229; Koizami and Ichinose, Japan. Pat. 41910; Chem. Soc. Abstr. 1924, 126, i, 259). Prepared by the action of alcoholic potash on isopropyl cyanide, and by long boiling of amyl alcohol with sodium methoxide (Guerbet, Compt. rend. 128, 512). Colourless oily liquid, smelling like valerian root and putrid cheese; b.p. 173.7° (Kahlbaum, Ber. 1883, 2480), sp.gr. 0.931 at 20° . Soluble in 23.6 parts of water at 20° . The valeric acid of pharmacy is prepared from valerian root or from amyl alcohol. The ammonium and zinc valerates are also used in medicine.

For quantitative estimation of isovaleric acid

in the presence of acetic acid, v. Chapman, Annalen, 1899, 114.

Methyl isovalerate boils at 116.7° , and *Ethyl isovalerate* at 134.3° .

isoAmyl isovalerate $C_8H_{17}O(C_2H_5)_2O$; b.p. 194° ; dissolved in spirits of wine is used in confectionery as *essence of apples*.

3. α -Methylbutyric acid $CH_3\cdot CH(C_2H_5)\cdot COOH$ is found in the oil of *Archangelica officinalis* (Hoffm.) (Ciamician and Silber, Ber. 1896, 1815), and may be obtained by heating methyl-crotonic acid (tiglic acid) with hydriodic acid (Schmidt and Berendes, Annalen, 191, 117); by the action of sodium amalgam on bromomethyl-ethylacetic acid in a sulphuric acid solution (Pagenstecher, *ibid.* 195, 109); and by heating methyl ethyl-malonic acid (Conrad and Bischoff, *ibid.* 204, 151). On oxidising optically active amyl alcohol, a mixture of isovaleric and α -methylbutyric acids is obtained which can be separated by converting them into their silver salts, silver isovalerate being six times less soluble in water than silver α -methylbutyrate (Erlenmeyer and Hell, Annalen, 160, 301; Conrad and Bischoff, *ibid.* 204, 157). A colourless somewhat mobile liquid; b.p. 173° - 174° , sp.gr. 0.938 at $20^{\circ}/20^{\circ}$ (Schütz and Marckwald, Ber. 1896, 26).

4. $\alpha\alpha$ -Dimethylpropionic acid $(CH_3)_2C\cdot COOH$. Obtained by heating trimethyl-acetonitrile with strong hydrochloric acid (Butlerow, Annalen, 170, 151; 173, 355); or by the oxidation of pinacolin (Butlerow, *l.c.*; Friedel and Silva, Ber. 6, 146, and 816). Crystallises in the regular system; m.p. 34° - 35° , b.p. 163° (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 475), sp.gr. 0.905 at 50° ; soluble in 45 parts of water at 20° .

VALEROBROMINE $(CH_3)_2CH\cdot CHBr\cdot COONa$. Obtained by hydrolysing and neutralising the product formed by the action of bromine on valerianic acid. Used as a sedative.

VALEROPHEN. Methyl ester of phenolphthalein.

VALERYDIN, VALIDOL, VALISAN, VALYL, v. SYNTHETIC DRUGS.

VALINE, α -aminoisovaleric acid

was isolated first by Gorup-Besanez (Annalen, 1856, 98, 1) from the pancreas of the ox, and occurs in the young seedlings of *Lupinus luteus* (L.), *Lupinus albus* (L.), *Lupinus angustifolius* (L.), *Vicia sativa* (L.), the etiolated seedlings containing more than the green plants (Schulze and Barbieri, J. pr. Chem. 1883, [i.] 27, 337; Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 308; Schulze, *ibid.* 1894, 20, 306; 1896, 22, 423; Schulze and Castoro, *ibid.* 1903, 38, 199; Wassilieff, Landw. Versuchstat. 1901, 55, 45; Schulze, Zeitsch. physiol. Chem. 1893, 17, 193; Menozzi, Ber. 1888, 21, 619); in zein (Osborne and Clapp, Amer. J. Physiol. 1908, 20, 470); Dakin (J. Biol. Chem. 1924, 61, 137); in Emmenthaler cheese (Winterstein, Zeitsch. physiol. Chem. 1904, 41, 500). Valine is one of the products of hydrolysis of such proteins as horn, keratin, edestin, etc., and occurs together with leucine and proline in the fraction of esters, b.p. 60° - $90^{\circ}/10$ mm.; it is formed in the autolysis of the pancreas and liver, and in peptic and tryptic digestion (Fischer and Dörpinghaus, *ibid.* 1902, 36, 462; Abderhalden and Voitino-

vici, *ibid.* 1907, 52, 348; Levene and van Slyke, J. Biol. Chem. 1909, 6, 419; Levene, Zeitsch. physiol. Chem. 1904, 41, 393; Lawrow, *ibid.* 1901, 33, 312). The valine occurring naturally is the dextrorotatory form; the racemic form was prepared first synthetically by Fittig and Clark (Annalen, 1866, 139, 200) by the action of concentrated ammonia on α -bromoisovaleric acid at 100°; and later by Lipp (*ibid.* 1880, 205, 1) by hydrolysing the aminoisovaleronitrile obtained by the condensation of isobutyraldehyde with ammonia and hydrocyanic acid. It is prepared most conveniently, and the yield is 70 p.c. of the theoretical, by Slimmer's modification of Fittig and Clark's method (Ber. 1902, 35, 400); 500 grms. of α -bromoisovaleric acid with 1500 grms. of aqueous ammonia saturated at 15° and 500 grms. of powdered ammonium carbonate are heated in an autoclave at 100° for eight hours; the resulting brownish liquid is filtered and evaporated to one-third its bulk, when most of the amino acid crystallises out. The rest is obtained in the form of its hydrochloride by acidifying the mother liquor with hydrochloric acid, evaporating to dryness and extracting the residue with 80 p.c. alcohol.

Racemic valine can be resolved into its optically active isomerides by the fractional crystallisation of the brucine salt of the formyl derivative; the brucine salt of formyl-*L*-valine being less readily soluble in methyl alcohol than is the corresponding salt of formyl-*D*-valine: *D*-valine and *L*-valine are obtained by hydrolysing with hydrobromic acid the corresponding formyl derivatives (Fischer, Matsubara and Hilpert, Ber. 1906, 39, 2320).

dl-Valine. In addition to the synthetic methods already described for the preparation of *dl*-valine, it can be obtained by racemising the active acids by heating them with baryta water at 180° (Fischer, Zeitsch. physiol. Chem. 1911, 33, 162).

dl-Valine crystallises in colourless plates from alcohol, has a sweet taste, and melts in a closed tube at 298° (corr.) with decomposition; it is readily soluble in water, 1 part dissolving in 11.7 parts of water at 15°, is almost insoluble in cold alcohol or ether, sparingly so in boiling alcohol (Slimmer, *l.c.*); when oxidised by hydrogen peroxide it yields isobutyraldehyde, isobutyric acid (part of which is further oxidised to acetone and carbon dioxide), ammonia and carbon dioxide; with lead peroxide or sodium hypochlorite as the oxidising agent, isobutyraldehyde is the product (Dakin, J. Biol. Chem. 1908, 4, 63; Langheld, Ber. 1909, 42, 2360). When *dl*-valine undergoes putrefactive decomposition it yields isovaleric acid and a small quantity of butylamine; the residual aminovaleric acid is laevorotatory indicating an asymmetric attack by the bacteria (Neuberg and Karczag, Biochem. Zeitsch. 1908, 18, 435).

Salts and derivatives of dl-Valine.—The copper salt $(C_5H_{11}O_2N)_2Cu$, blue crystals soluble in 3644 parts of methyl alcohol at 20°, or in 9230 parts of 96 p.c. ethyl alcohol at 21°, and sparingly soluble in cold water (Ehrlich and Wendel, Biochem. Zeitsch. 1908, 8, 399); the silver salt $C_5H_{11}NO_2Ag$ is crystalline and insoluble in cold water. The hydrochloride

crystalline plates, readily soluble in water or in alcohol, insoluble in ether; the nitrate

is a readily soluble crystalline compound. The ethyl ester $CHMe_2.CH(NH_2)CO_2Et$ has b.p. 33.5°/8 mm. or 174° with decomposition under atmospheric pressure, sp.gr. 0.9617 at 15°/4°; it forms a sparingly soluble crystalline picrate, m.p. 139.5° (corr.), and a soluble hydrogen tartrate which on crystallisation suffers partial resolution into its optically active isomerides (Slimmer, *l.c.*). Of the acyl derivatives of *L*-valine, the formyl derivative

obtained by heating *dl*-valine with 1½ times its weight of formic acid crystallises in large rhombic plates from water, sinters at 137° and melts at 140°–145° (corr.), is readily soluble in hot water, alcohol or acetone (Fischer, Ber. 1906, 39, 2322); the benzoyl derivative

crystallises in plates, m.p. 132.5° (corr.), is readily soluble in alcohol or ether, sparingly so in water (Slimmer, *l.c.*); the phenylisocyanate derivative $CHMe_2.CH(CO_2H)NH\cdot CO\cdot NHPh$ forms colourless plates, soluble in 130 parts of hot water, m.p. 163.5° (corr.) with decomposition, is readily soluble in hot alcohol, sparingly so in ether, and is converted into phenylisopropylhydantoin

by boiling with hydrochloric acid; this compound crystallises from ether in long needles, m.p. 124°–125° (corr.), and is sparingly soluble in hot water, readily so in alcohol or ether (Slimmer, *l.c.*); the carbamino derivative

crystallises in needles, m.p. 176°, is soluble in 213 parts of water at 20°, and forms crystalline barium, mercury and silver salts (Lippich, Ber. 1908, 41, 2962); the picryl derivative

forms bright yellow needles, sparingly soluble in cold water, and has m.p. 171° (Hirayama, Zeitsch. physiol. Chem. 1909, 59, 290). *dl*-Valinamide $CHMe_2.CH(NH_2)CONH_2$, obtained by the action of liquid ammonia on the ester prolonged over a period of three months, crystallises from benzene in colourless prisms, m.p. 78°–80° (corr.), and yields a β -naphthalenesulphonic derivative $C_{15}H_{15}O_3N_2S$, m.p. 256°–257° (corr.), a carbethoxy derivative $C_8H_{11}O_2N_2$, m.p. 143°–144° (corr.) (Königs and Mylo, Ber. 1908, 41, 4427), and a hydrochloride

crystallising in the monoclinic system, and forming a crystalline platinumchloride

(Lipp, Annalen, 1880, 205, 1). *dl*-Valine anhydride $C_{10}H_{15}O_2N_2$, obtained by heating *dl*-valine, or by heating the ethyl ester under pressure at 180°–190°, forms long colourless needles, m.p. 303° (corr.) (Fischer and Schenkel, Annalen, 1907, 354, 1).

When α -bromoisovalerylglycinamide is

beated at 120° with alcoholic ammonia, it yields a mixture of *valylglycine anhydride* (*diketiso-propylpyperazine*)

needles from hot water, m.p. 245°, and the *hydrobromide of valylglycinamide*

microscopic needles from alcohol-ether, m.p. 235° (Bergell, Zeitsch. physiol. Chem. 1916, 97, 293). α -Amino- β -hydroxyisovaleric acid has been synthesised from ethyl β -dimethylacrylate, it melts with decomposition at 218°; the *methoxyl derivative* $\text{OMe} \cdot \text{CMe}_2 \cdot \text{CH}(\text{NH}_2) \cdot \text{CO}_2\text{H}$ forms colourless lustrous plates, m.p. 250°–260° (decomp.); the naphthalene β -sulphonyl derivative $\text{C}_{10}\text{H}_7\text{O}_2\text{NS}$ forms small colourless needles, m.p. 281° (Schrauth and Geller, Ber. 1922, 55, 2783).

Valinol $\text{CHMe}_2 \cdot \text{CH}(\text{NH}_2) \cdot \text{CH}_2 \cdot \text{OH}$, prepared by reducing valine ethyl ester, is a colourless oil with a strong odour, b.p. 181°–186°/720 m.m.; the *hydrochloride*, m.p. 114°, is very hygroscopic.

Dimethylvalinol, prepared by reducing ethyl α -dimethylaminoisovalerate (b.p. 160°), gives with methyl iodide *valinecholine* in the form of its iodide, m.p. 195°; the *aurichloride*

forms yellow leaflets, m.p. 225°, the *platinochloride*, brownish-red prisms, m.p. 210°–211° (Karrer, Gisler, Horlacher, Locher, Mäder and Thomann, Helv. chim. Acta, 1922, 5, 469).

d-Valine is most conveniently obtained from the two to three weeks old etiolated seedlings of *Lupinus luteus* and *Lupinus albus*; contamination with leucine, which is very difficult to separate from valine, can be obviated by removing the cotyledons from the young plants before they are dried (Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 312). *d*-Valine is prepared from the synthetic compound by the fractional crystallisation of the brucine salts of the formyl derivative (Fischer, Matsubara and Hilpert, Ber. 1906, 39, 2320).

d-Valine crystallises in colourless, shining six-sided plates. It melts in a closed capillary tube at 315° (corr.); when heated in an open tube it sublimes and decomposes partially with formation of the anhydride. It dissolves in 11 parts of water at 16.5°. The taste is first slightly sweet, then bitter (Fischer, Matsubara and Hilpert, l.c.). The natural compound obtained from *Lupinus luteus* has $[\alpha]_D^{16} + 28.2^\circ$ in 20 p.c. hydrochloric acid (0.5 grm. in 10 c.c.); from *Lupinus albus* $[\alpha]_D^{16} + 27.9^\circ$ in 20 p.c. hydrochloric acid (0.5012 grm. in 10 c.c.) (Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 299). The synthetic compound prepared by hydrolysing the formyl derivative has $[\alpha]_D^{20} + 28.75^\circ$ in 20 p.c. hydrochloric acid, or $[\alpha]_D^{20} + 6.42^\circ$ in aqueous solution (Fischer, Matsubara and Hilpert, l.c.). For the practically quantitative separation of *d*-valine and *d*-alanine by the alternate crystallisation of valine as the free amino acid and of alanine as the phospho-

193).

Salts and derivatives of d-valine.—The *copper salt* $(\text{C}_6\text{H}_{11}\text{O}_2\text{N})_2\text{Cu}$, blue crystalline plates, soluble in 52 parts of methyl alcohol at 18°. The *hydrochloride* $\text{C}_6\text{H}_{11}\text{O}_2\text{N} \cdot \text{HCl}$, small prismatic crystals readily soluble in water or alcohol, the *platinochloride* is also readily soluble (Schulze and Barbieri, J. pr. Chem. 1883, 27, 337); the *picrolonate* has m.p. 170°–180°, and $[\alpha]_D^{20} + 23.4^\circ$ (Levene and van Slyke, J. Biol. Chem. 1912, 12, 127).

Formyl d-valine

obtained by the resolution of *dl*-formyl-valine through the brucine salt, forms small prisms, sinters at 150° and melts at 156° (corr.), and has $[\alpha]_D^{20} + 12.8^\circ$ to 13.27° in alcoholic solution *d*-valine *phenylcarbimide*

forms small microscopic prisms, m.p. 147° (corr.) with decomposition (Fischer, Matsubara and Hilpert, l.c.), m.p. 154° (Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 303), and yields the *d*-phenylisopropylhydantoin

on treatment with concentrated hydrochloric acid. This forms colourless thin prisms, m.p. 131°–133° (corr.), and has $[\alpha]_D^{20} - 97.5^\circ$ in alcoholic solution (Fischer, Matsubara and Hilpert, l.c.); m.p. 124° (Schulze and Winterstein, l.c.); *chloroacetyl-d-valine*

has m.p. 113°–115° (corr.) $[\alpha]_D^{20} + 15.8^\circ$; *glycyl-d-valine* $\text{NH}_2 \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NH} \cdot \text{CHPr}^s \cdot \text{CO}_2\text{H}$ has m.p. 254° (corr.), $[\alpha]_D^{20} - 19.7^\circ$ in aqueous, -10.5° in hydrochloric acid or -6.9° in sodium hydroxide solution; it forms a crystalline *hydrochloride* and a *copper salt*. The *hydrochloride* of the *methyl ester* $\text{C}_6\text{H}_{11}\text{O}_2\text{N}_2 \cdot \text{HCl}$ is converted by methyl alcoholic ammonia into *glycyl-d-valine-anhydride* $\text{CH}_2 < \begin{array}{c} \text{NH} \cdot \text{CO} \\ \text{CO} \cdot \text{NH} \end{array} > \text{CHPr}^s$, m.p. 266°

(corr.), $[\alpha]_D^{20} + 20.8^\circ$ in glacial acetic, $+32.7^\circ$ in aqueous or $+41^\circ$ in alcoholic solution; 1-*valyl-d-valine* $\text{C}_{10}\text{H}_{18}\text{O}_4\text{N}_2 \cdot 1\frac{1}{2}\text{H}_2\text{O}$ becomes anhydrous at 95°/12–15 mm. over phosphoric oxide; has m.p. 308° (corr.), and $[\alpha]_D^{20} - 70.6^\circ$ to -74° ; the *hydrochloride* of the *methyl ester* yields on treatment with methyl alcoholic ammonia the *trans-valine-anhydride* $\text{CHPr}^s < \begin{array}{c} \text{NH} \cdot \text{CO} \\ \text{CO} \cdot \text{NH} \end{array} > \text{CHPr}^s$ prisms, m.p. 316°–318° (corr.), which is optically inactive (Fischer and Scheibler, Annalen, 1906, 363, 136).

l-Valine is obtained by the resolution of the racemic formyl derivative through the brucine salt (Fischer, Matsubara and Hilpert, l.c.); by the action of ammonia on *d*- α -bromoisovaleric acid (Fischer and Scheibler, Ber. 1906, 41, 2891); and by the selective action of yeast on *dl*-valine (Ehrlich, Biochem. Zeitsch. 1906, 1, 8; 1908, 8, 438).

l-Valine is soluble in 17.1 parts of water at 5°, possesses a markedly sweet taste, and has $[\alpha]_D^{20} - 6.06^\circ$ in 24 p.c. aqueous solution.

—29.04° in 20 p.c. hydrochloric acid solution (Fischer, Matsubara and Hilpert, l.c.). A specimen obtained from yeast had $[\alpha]_D^{20}$ —27.62° in a 4.61 p.c. solution of 20 p.c. hydrochloric acid.

1-Formylvaline $\text{CHMe}_2\cdot\text{CH}(\text{CO}_2\text{H})\cdot\text{NH}\cdot\text{CHO}$ crystallises in small prisms, sinters at 150° and melts at 156° (corr.); it has $[\alpha]_D^{20}$ —12.93° to 13.07° in alcoholic solution, or +16.9° in aqueous solution; 1-valine phenylisocyanate $\text{C}_{11}\text{H}_{15}\text{O}_2\text{N}_2$ has m.p. 147° (corr.) decomp., and $[\alpha]_D^{20}$ —19.02° in absolute alcoholic solution, and yields 1-phenylisopropylhydantoin $\text{C}_{12}\text{H}_{14}\text{O}_2\text{N}_2$ on treatment with hydrochloric acid. It has m.p. 131°–133° (corr.) and $[\alpha]_D^{20}$ +97.22° in absolute alcoholic solution. For iso-valine, α -amino- α -methylbutyric acid, v. Gadamer and Rukop (J. pr. Chem. 1914, [ii.] 90, 405). M. A. W.

VALONIA (Valonée, Fr.; Valonea, Acker-doppen, Orientalische Knoppfern, Ger.). An important tanning material. Is the acorn cup of certain species of oak, usually *Quercus Aegilops* (Linn.), and probably *Q. macrolepis*, *Q. graeca*, *Q. Ungeri*, and *Q. coccifera* (Linn.). The former is most prolific in the highlands of Morea, Roumelia, Greek Archipelago, Asia Minor, and Palestine, whereas the *Q. macrolepis* forms great forests in Greece. These acorn cups have a diameter up to about 1½ ins., and in good condition possess a bright colour.

The fruit ripens in Asia Minor about July or August, and the trees are then shaken, and the material left on the ground to dry; this is subsequently collected into heaps, and allowed to ferment for some weeks, until the acorn contracts and falls from the cup. The acorn, which contains but little tannin, is employed for feeding purposes.

In Greece distinct qualities of valonia are known, the best (*chamada*) collected about April before the fruit is ripe, a second (*rhabdisto*) in September or October, and a third little used inferior variety (*charcola*).

Smyrna valonia may contain 40 p.c., Greek 19–30, and Candia valonia 41 p.c. of tannin matter, which consists of a mixture of a gallo-tannin and an ellagitannin. Valonia is, indeed, an excellent source for the preparation of ellagic acid, because it so readily yields a product easy to purify. Extract of valonia frequently undergoes fermentation with deposition of ellagic acid, and to avoid this the employment of antiseptics is to be recommended.

Valonia is especially suited for the manufacture of sole leather, and together with gambier and other materials for dressing leather, but is little employed for dyeing purposes (cf. Procter, Principles of Leather Manufacture, 259). A. G. P.

VANADINITE. A mineral consisting of lead chloro-vanadate $(\text{PbCl})\text{Pb}_4(\text{VO}_4)_3$, crystallised in the hexagonal system and isomorphous with apatite and pyromorphite (q.v.). The formula requires 19.4 p.c. V_2O_5 , but this is often partly replaced by phosphoric and arsenic oxides; and the variety *endlicheite* forms a passage to the species *milneite* (lead chloro-arsenate). The mineral forms small hexagonal prisms usually terminated simply by the basal plane; at times the crystals are curved and barrel-shaped. Cleavage, warty, and cauliflower-like mass

occur. The colour is usually yellowish or brownish, but crystals from Arizona are bright scarlet. Sp.gr. 6.6–7.2. When touched with a drop of nitric acid a yellow coating of vanadic oxide is formed on the crystals; this affords an easy test for recognising the mineral.

Vanadinite is a mineral of secondary origin in the upper portions of lodes of lead ore, and it sometimes occurs in association with gold. It was formerly found in some quantity at Wanlockhead in Dumfriesshire and near Klagenfurt in Carinthia; and now abundantly in several of the mining districts of Arizona and New Mexico. It has been met with at Broken Hill in Northern Rhodesia, and in Morocco. Important localities in Arizona are the Red Cloud mine in Yuma Co., the Mammoth gold mine in Pinal Co., the Globe district in Gila Co., and in Pima Co. and Yavapai Co., &c. In New Mexico at the Sierra de los Caballos near Lake Valley in Sierra Co., Magdalena in Socorro Co., Georgetown in Grant Co., &c. It is also of abundant occurrence at Santa Marta in Badajoz, Spain.

In New Mexico and Arizona, and also in Spain, the mineral is mined as a source of vanadium. The concentrate containing the vanadinite, together with descloizite, is treated in lead-lined vats with dilute sulphuric acid heated by steam, and the vanadium obtained in solution as sulphate, the lead remaining in the insoluble residue. The solution is decanted and evaporated, and the vanadium salt heated to give vanadic oxide. The bulk of this product appears to be used in the manufacture of vanadium-steel, and to a limited extent also as a pigment. Other minerals that have been worked for vanadium are carnotite, descloizite, patronite, and roscoelite (q.v.). L. J. S.

VANADIUM. Sym. V. At.wt. 51.0. This element was discovered by Del Rio (Gilbert's Ann. 1801, 71, 7) in a lead ore, *vanadinite*, from Zimapan in Mexico; the discovery was confirmed by Sefström (Pogg. Ann. 1830, 21, 48), and by Wöhler and Berzelius (*ibid.* 1831, 22, 1; cf. Collet-Descotils, Ann. Chim. 1805, [i.] 53, 260). Upon the work of Berzelius was based the view that vanadium was allied to chromium and molybdenum and, like them, yielded an acidic trioxide, and this idea was current till Roscoe, in 1867, showed that the substance believed to be the metal in earlier investigations had been either an oxide or a nitride, and that the compounds of vanadium in general showed that the element belonged to the phosphorus group. According to Aston, vanadium is simple with an atomic weight of 51.

Occurrence.—Minerals containing a large proportion of vanadium are rare, but the metal is very widely distributed in small quantities. Vanadium occurs as vanadic acid in *vanadine* with the native copper of Lake Superior, and in *alaite* (Nenadkevitch, Bull. Acad. Sci. St. Petersburg, 1909, 185); as lead vanadate, with lead chloride, in *vanadinite*; as *descloizite*, a basic lead and zinc vanadate; as hydrated vanadate of lead and copper in *mottramite* and *peitavite*; as vanadate of copper in *turnite* (Nenadkevitch, l.c.); as lead vanadate containing zinc and manganese in *degehenite*, *arconite*, and *eusynelite*; as vanadate of lead and arsenic in *endlicheite*; as bismuth vanadate in *pucheris*; as the basic

oxide V_2O_5 in the vanadium muscovite *roscoelite* (Hillebrand, Turner and Clarke, Amer. J. Sci. 1899, [iv.] 7, 451); as vanadate of copper, barium, and calcium in *volborthite*; and as vanadium sulphide V_2S_5 with sulphur, in *patronite* (Hillebrand, *ibid.* 1907, [iv.] 24, 141; Hewett, Eng. & Min. J. 1906, 82, 385; Trans. Amer. Inst. Min. Eng. 1910, 40). See also Vanadium Ores [Monographs on Mineral Resources prepared under the direction of the Imperial Institute], John Murray, London, 1924.

Vanadium is present in magnetites and in most other iron ores (Pope, Chem. Soc. Abstr. 1900, ii. 409), and becomes concentrated in the residues from their treatment, especially by the Thomas-Gilchrist process. It is said to be diffused, with titanium, through all primitive granite rocks (Dieulaufait; Hillebrand, Amer. J. Sci. 1898, 6, 209; 7, 294), and has been found by Deville in *bauxite*, *rutile*, and many other minerals, and by Bechi and others in the ashes of plants and in argillaceous limestones, schists, and sands. Jorissen has found vanadium in the coal of Liège (Bull. Acad. Roy. Belg. 1905, 178). Scacchi has observed its presence in incrustations on the Vesuvian lava of 1631, and Donath has found as much as 0.16 p.c. of vanadic acid in a sample of commercial caustic soda (Dingl. poly. J. 240, 318). It occurs in the sun and has been found in stony meteorites (Hasselberg, Vetensk. Akad. Svenska. 1899, 56, 131).

Extraction.—Ammonium metavanadate was formerly prepared on a commercial scale by the Magnesium Metal Co. at Patricroft near Manchester.

The mineral employed was *mottramite* $(PbCu)_3(VO_4)_2 \cdot 2PbCu(HO)_2$, which occurs in the copper-bearing Keuper beds at Alderley Edge and Mottram St. Andrew's, in Cheshire, as a film on the grains of sandstone. The sand is digested in concentrated hydrochloric acid, and the acid liquid is withdrawn. The solution, with the washings of the residue, is concentrated and evaporated with an excess of ammonium chloride, forming ammonium metavanadate, which, being insoluble in a concentrated solution of ammonium chloride, is precipitated. After being freed from copper and iron by repeated crystallisation, it is gently roasted in a porcelain vessel, with production of vanadium pentoxide. This is suspended in water and subjected to a current of ammonia gas, with formation of ammonium metavanadate, the solution being separated from the silica, phosphates, &c., which are not affected by ammonia, is crystallised until free from phosphates, and gently ignited to produce pure vanadium pentoxide (v. Roscoe, Phil. Trans. 1867, 158, 1).

The chief ores from which vanadium is or may be derived are patronite, carnotite, roscoelite, vanadinite and asphaltite. The chief deposits of vanadium ores, mainly carnotite, in the United States are in South-Eastern Utah and North-Western Colorado, but at present the only vanadium produced from native ore is obtained as a by-product from carnotite worked for its radium content. The principal source of supply at present is in Peru, where deposits occur at *Uchire* *Passo*, about 30 miles to the north-west of the Cerro de Pasco copper mines; here it is found in the coal deposits as a

black mineral resembling slaty coal; it contains about 30 p.c. of free sulphur, with 40 p.c. vanadium sulphide (patronite). After burning out the free sulphur the ore contains from 30 to 52 p.c. of vanadium oxide (V_2O_5). The asphaltite deposits of Peru frequently contain considerable amounts of vanadium, the ash yielding from 25 to 40 p.c. of vanadium oxide.

Vanadium ores are also worked in New Mexico, and carnotite, roscoelite, and vanadinite deposits are found in Colorado, Utah, Nevada, Arizona, and Oklahoma, mainly for the production of ferro-vanadium and vanadium steel. Small quantities of vanadium are also obtained from Argentina (*rafaelite*), Chile (*chileite*), South-West Africa (*mottramite*), and Spain (*vanadinite*).

Two consignments of 25 and 30 tons, respectively, of vanadinite concentrate, averaging 13 p.c. V_2O_5 , from the Kafir's Krall mine in the Transvaal, constitute the first important shipment of this ore from the Union.

To extract it from vanadinite the mineral is fused with potassium nitrate, alone or mixed with sodium carbonate, the mass is lixiviated, and the solution acidified, or, better, evaporated with ammonium chloride in order to precipitate alumina and silica. From the clear solution barium chloride and ammonia precipitate the barium salts of vanadic, chromic, and molybdic acids, &c., and on treating the product with sulphuric acid, followed by ammonia and water, the vanadium goes into solution as ammonium metavanadate, which is finally precipitated by the addition of ammonium chloride. Vanadic acid may also be separated from mixtures of sodium vanadate and silicate by the addition of more vanadic acid. This precipitates the silica and leaves only fairly pure sodium vanadate in solution (Herrenschmidt, Compt. rend. 1904, 139, 862).

Gin (Proc. Seventh Int. Cong. Appl. Chem. London, 1909) smelts the vanadinite in the electric furnace with 6 p.c. of its weight of carbon, which is sufficient to reduce the base metals, leaving the vanadium in the slag in the form of trioxide. The slag is pulverised and gently heated in a current of air until the trioxide is oxidised to tetroxide; at this stage sodium carbonate and a little nitrate are added to complete the oxidation to vanadic anhydride; the mass is then fused, cooled, pulverised and treated with boiling water, which dissolves the sodium metavanadate together with the phosphate, silicate and aluminate. The cooled solution is treated with carbon dioxide to precipitate silica, and then ammonium carbonate is added and the solution concentrated until ammonium metavanadate is precipitated. This is washed, dried, again washed with water acidified with nitric acid, and calcined to obtain vanadic acid. When electric-furnace treatment is inadmissible, it may be replaced by treatment in a water-jacket furnace, in which case the lead and copper are separated, and the slag is oxidised on the hearth of a reverberatory furnace and mixed with sodium carbonate and nitrate. Or, alternatively, the vanadiferous slag is melted with sodium bisulphate in an iron or steel pan; when the reaction has ceased, the mass is run off on to plates of silicon-steel, pulverised, digested with water in a water-jacketed

with an agitator, steam being introduced during the process. The copper, silver, and arsenic are precipitated from the solution by hydrogen sulphide, ammonia added and the iron and alumina removed. The solution now contains the vanadium in the form of thiovanadate, which is converted into vanadium sulphide by neutralising with dilute acid, and the sulphide is converted into vanadic acid by roasting (J. Soc. Chem. Ind. 1911, 30, 218).

Vanadium can be separated from arsenic or phosphorus by precipitation of vanadic acid from an acidified vanadate solution. A vanadinite concentrate containing 10.24 p.c. V_2O_5 , 0.28 p.c. As, and 0.27 p.c. P, was fused with sodium carbonate, sodium hydroxide, and charcoal. The lead present was reduced to the metallic state and the slag extracted with hot water. After acidifying with sulphuric acid the solution was boiled with live steam for several hours. A 97 p.c. recovery of vanadic acid free from arsenic and phosphorus was obtained (H. A. Doerner, J. Ind. Eng. Chem. 1923, 15, 1014; J. Soc. Chem. Ind. 1923, 42, 1182 A.).

Determination of phosphorus in vanadium ores.—Precipitation of the phosphorus as ammonium phosphomolybdate from a solution containing relatively large quantities of vanadic acid yields an orange-brown precipitate which contains considerable amounts of vanadic acid. The method recommended by Treadwell (Kurzes, Lehrbuch der Analytischen Chemie, 6th ed.), involving previous reduction of vanadic acid to vanadyl sulphate, is also unsatisfactory for determining small quantities of phosphorus in vanadium ores; the precipitate is greenish-yellow, and the results are too high. The most satisfactory of several procedures tested was found to be the following: 10 grms. of finely-divided ore is dissolved in 75 c.c. of hydrochloric acid and 25 c.c. of water, and the solution is oxidised with nitric acid and evaporated with 30 c.c. of sulphuric acid (1 : 1) until strong, white fumes are evolved. The cold mass is dissolved in 100 c.c. of water, and the sand and lead sulphate are removed by filtration. To the filtrate 50 c.c. of strong nitric acid and 1 gm. of fine tin powder are added, and the mixture is shaken till the latter has dissolved, then set aside overnight in a hot place. The liquid is diluted with 400 c.c. of hot water and filtered. The precipitate is heated in a nickel crucible, and the residue fused with 5 grms. of potassium cyanide, which reduces tin and arsenic to the metallic form. The fused mass is dissolved in water, the solution filtered, and the filtrate boiled with hydrochloric acid to expel all hydrocyanic acid. It is transferred to a graduated flask, treated with potassium ferrocyanide until a spot test gives a brown colour with uranium acetate, when it is diluted to 500 c.c. 450 c.c. is filtered through a dry paper, treated with a solution of an aluminium salt containing about 0.1 gm. of metal, then with a slight excess of ammonia. The precipitate, which contains all the phosphoric acid, is collected, washed free from chloride and ferrocyanide, and dissolved in hydrochloric acid. The solution is evaporated to remove silica, and the filtrate is evaporated with nitric acid to expel chlorine compounds. The phosphoric acid is eventually precipitated as ammonium molybdate and determined in

the usual manner (Kriesel, Chem. Zeit. 1923, 47, 177; J. Soc. Chem. Ind. 1923, 314A).

According to Wits and Osmond (Bull. Soc. chim. 1882, [ii.] 38, 49; Compt. rend. 95, 42), the slags produced while working the Thomas-Gilchrist process at the Crenot ironworks contain nearly 1.5 p.c. of vanadium, the quantity of that metal thus concentrated amounting to 60,000 kilos (nearly 59 tons) annually. They recommend the following process for the separation: 1 kilo of the roughly broken slag is treated with a quantity of hydrochloric acid insufficient to attack the whole (about 1 litre of acid of 21°–22°Bé.) without stirring, 3 litres of water being added, and the whole remaining at rest for 2 days. The solution, having a sp.gr. of about 27°Bé. at 36°, is decanted and diluted to 15°Bé., and the silica is removed. The solution contains the vanadium in the hypovanadic condition, and may be used at once for the production of aniline black. If it is desired to produce hypovanadic phosphate, the solution is nearly neutralised and about 250 c.c. of saturated ammonium acetate solution is added. The bluish-grey precipitate produced, containing phosphates of iron, aluminium, and vanadium, is re-dissolved and again treated with ammonium acetate, the precipitate containing about 20 p.c. of vanadium.

If the slag contains less than 1.5 p.c. of vanadium, the hydrochloric acid solution is neutralised by the addition of a further quantity of finely-powdered slag. The solution becomes colourless, and a greyish granular precipitate separates, containing the whole of the vanadium and smaller proportions of the other less soluble phosphates. The precipitate is re-dissolved and re-precipitated as before. For the preparation of ammonium metavanadate, the phosphatic precipitate is roasted at incipient redness, and the ochreous-yellow mass of impure pentoxide is dissolved with the aid of ammonia, boiled until colourless and filtered, the ammonium metavanadate being precipitated by the addition of excess of ammonium chloride. From 4 kilos. of slag containing 1.5 p.c. of vanadium, about 250 grms. of ammonium metavanadate may be produced. It is a colourless transparent salt, or white powder, difficultly soluble in water, insoluble in a concentrated solution of ammonium chloride and in ether. It was formerly used, in conjunction with sodium chlorate, as an oxygen-carrier in the formation of the finest aniline black, only an extremely small quantity of the salt being required for a large amount of aniline.

Später attempted (1896) to employ the ash of an anthracite from Yauli (Peru) containing 28 p.c. of vanadium, but was unsuccessful.

From minerals in which it occurs with uranium, vanadium may be extracted by fusing with potassium hydrogen sulphate, lixiviating the mass and concentrating the solution thus obtained. The solution is reduced with zinc and the vanadium precipitated with ammonia and ammonium carbonate (Gin. Elektrochem. Zeit. 1906, 13, 119).

Haynes states (Mines and Minerals, 1900, 30, 139) that vanadium is extracted from carnotite, in West Colorado, by dissolving out the uranium and vanadium with hot sodium carbonate solution, precipitating the uranium with caustic soda, and throwing down the vanadium from the mother liquor as calcium vanadate.

also Barker and Schlundt, *J. Soc. Chem. Ind.* 1916, 35, 175.

Fleok and Haldane recommend that the crushed ore be treated with 15–20 p.c. sulphuric acid, the acid liquid neutralised by the addition of fresh ore, and the clear solution fractionally precipitated with limestone, whereby a complex mixture, rich in vanadium, is obtained, from which the element may be extracted by any ordinary method (U.S. Pat. 880752).

It is probable that in future American carnotite ore will for the most part be delivered to the reduction works as concentrates. The most usual process for dealing with these is as follows. They are first boiled in autoclaves with soda ash and water, with stirring, for 6–10 hours. This converts radium and barium salts into the carbonates, 90 p.c. of the uranium present into sodium uranyl carbonate, and 30 p.c. of the vanadium into sodium vanadate. The treated concentrate is settled, decanted, filter-pressed, and washed free from sulphate. The filtrate and washings contain the uranium and vanadium salts and are evaporated. The cake is acidified with hydrochloric acid and boiled, pressed in wooden filters, and washed. The cake is discarded. The filtrate contains radium and vanadium, and the former is precipitated as radium barium sulphate and removed on vacuum filters. The cake is washed and boiled with soda ash, caustic soda and water, the resulting carbonates are pressed and washed, converted into chlorides, and are then ready for fractional crystallisation. The utmost care must be taken against contamination by sulphates during the stages of this process. The uranium is separated from vanadium by crystallisation as sodium uranyl carbonate, dissolved in water, acidified, and boiled. Any vanadium present is removed by addition of a small quantity of ferrous sulphate, and the uranium precipitated as ammonium uranate. The vanadium in the acid solution from the barium radium sulphate precipitation is precipitated with lime, and the calcium vanadate added to the solution remaining from the sodium uranyl carbonate crystallisation, and the whole boiled with sodium carbonate and a small quantity of manganese dioxide. The solution, containing 95–98 p.c. of the vanadium, is filtered, almost neutralised with sulphuric acid, and freed from phosphate by precipitation with sodium aluminate. The solution is concentrated and vanadic acid precipitated by boiling with a slight excess of sulphuric acid. By this process a minimum yield of 80 p.c. of each product is obtained from carnotite (K. B. Thews and F. J. Heinle, *J. Ind. Eng. Chem.* 1923, 15, 1159–1161; *J. Soc. Chem. Ind.* 1924, 43, 55 B).

Preparation of metallic vanadium.—Roscoe gave two methods for the preparation of the metal; (a) the reduction of vanadium nitride in hydrogen, which never gives a pure product; and (b) the reduction of anhydrous, oxygen-free vanadium chloride in dry hydrogen. For a long time the latter method was the only one known by which the pure metal could be obtained (v. Roscoe and Schorlemmer, *Treatise on Chemistry*), but it can be also prepared by the reduction of vanadium pentoxide with 'mischmetal', a mixture of alkaline earth metals extracted from the residues from the manufacture

of thorium (Weiss and Aichel, *Annalen*, 1904, 337, 380). The mixture of mischmetal and pentoxide is placed in a magnesia crucible and fired; the heat of reaction is sufficient to melt the reduced metal, which is afterwards found as a compact mass in the crucible (Muthmann, Weiss and Riedelbauch, *ibid.* 1907, 355, 58).

It was formerly supposed that Goldschmidt's aluminium reduction method would not give pure vanadium from the pentoxide (Koppel and Kaufmann, *Zeitsch. anorg. Chem.* 1905, 45, 352), but under certain conditions Vogel and Tamman have, by this method, obtained a regulus containing 99 p.c. vanadium, with a little silicon and aluminium (*ibid.* 1909, 44, 225).

According to Ruff and Martin (*Zeitsch. anorg. Chem.* 1912, 25, 49), vanadium trioxide melting at about 2000°, gives better results than the pentoxide.

Reduction of the oxide with metallic calcium according to Muthmann's method, gives product containing only 91–93 p.c. of vanadium. A purer regulus is obtained by reducing with a mixture of calcium and aluminium (Prandtl and Bleyer, *ibid.* 1909, 64, 217).

Vanadium produced by the reduction of the pentoxide in the electric furnace contains 10–25 p.c. of carbon and consists chiefly of vanadium carbide VC, a silvery-white, highly crystalline and extremely hard substance of sp.gr. 5.405 and m.p. 2705°. A product containing less carbon can be obtained by conducting the operation in an atmosphere of hydrogen (Moissan, *Compt. rend.* 116, 1225; 122, 1297; *Zeitsch. anorg. Chem.* 14, 174).

The pure metal can also be obtained by the electrolysis of a solution of sodium vanadate in hydrochloric acid, using carbon electrodes and a current density of 0.018–0.020 amp. per sq. m., and maintaining the temperature about 80° (Cowper-Coles, *Eng. and Min. J.* 67, 744; von Bolton, *Zeitsch. Elektrochem.* 1905, 11, 45).

On the small scale it can be obtained by passing a mixture of hydrogen and vanadyl chloride vapour over incandescent platinum wire, when metallic vanadium is deposited as a silver-grey coating, or by passing the chloride over sodium hydride. The reduction of vanadium trichloride with sodium yields a product containing about 96 p.c. of metal and of D₄, 5.819.

Properties.—Pure vanadium is a silver-white metal, similar in appearance to cast iron, and crystallises in hexagonal rhombohedra, like the other elements of its group. Its hardness is 7.5 on Mohr's scale, and it is as brittle as glass. Its sp.gr. is 5.688 at 18.7° (sp.gr. 5.5 at 15°/15°, Roscoe), and its specific heat is 0.124 (Matignon and Monnet, *Compt. rend.* 134, 542; Muthmann, Weiss and Riedelbauch, *l.c.*), which, assuming the atomic heat to be 6.4, confirms the atomic weight of 51. Heat of combustion of 1 gram. (to V₂O₅) is 2456 cal.

The melting-point is very high, but the data given by various investigators are not in agreement. Werner von Bolton, using the photometric method of Lammer, found it to be 1880°. Vogel and Tamman give it as 1780°, and 1790° (*Zeitsch. anorg. Chem.* 1908, 33, 73); Ruff and Martin 1715°. The melted metal readily dissolves both the trioxide and the pentoxide, and the

mixtures melt at higher temperatures than the metal.

It is stable in moist or dry air at ordinary temperatures, and a polished surface retains its lustre for weeks. It is unacted upon by bromine water, aqueous alkali solutions, hydrochloric acid, or cold sulphuric acid. It is dissolved by hydrofluoric acid or hot sulphuric acid forming green solutions, and is attacked by nitric acid or *aqua regia*. Melted potash or saltpetre rapidly dissolve the metal with formation of an alkali vanadate. Metallic vanadium reduces solutions of mercuric chloride and bromide, cupric chloride and bromide, and ferric chloride to the lower haloid salts, and it precipitates the metal from solutions of auric chloride, silver nitrate, platonic chloride, iridium tetrachloride, &c.

Alloys of vanadium can be prepared in the electric furnace by the reduction of the pentoxide in presence of a second metal or its oxide (Moissan, *Compt. rend.* 1896, 122, 1297). By fusing vanadic acid with aluminium in the necessary proportions, Czako (*Compt. rend.* 1913, 156, 140) has prepared alloys of aluminium and vanadium, and has isolated crystals of Al_3V and AlV . The hardness of the alloys increases with the vanadium content up to 60 p.c., after which it diminishes. The chief industrial use of vanadium is in the preparation of special steels, which are largely used for motor-car work; it is introduced into the molten steel as *ferro-vanadium*, an alloy prepared by electric-furnace methods. The addition of 0.1–0.25 p.c. of vanadium to chromium, manganese, or other open-hearth or crucible steels greatly increases the elastic limit and the ultimate tensile stress without reducing the ductility (J. Kent Smith, *J. Soc. Chem. Ind.* 1906, 291; cf. Auchy, *J. Ind. and Eng. Chem.* 1909, 1, 455).

Colloidal solutions of vanadium have been prepared by Svedberg (*Ber.* 1906, 39, 1712). According to Prandtl and Hess (*Zeitsch. anorg. Chem.* 1913, 82, 103) they are best obtained from the solutions of the vanadic esters, especially *tert.* butyl orthovanadate, as the alcohol is easily removed by boiling. Riedel (*Chem. Zentr.* 1914, i. 1738) found that *iso-amyl* orthovanadate ($C_5H_{11}VO_4$, b.p. $161^\circ/19$ mm.) is the most convenient ester. This is boiled in water until a homogeneous dark red solution is obtained. After removing the amylene hydrate by ether the deep red solution contains about 8 p.c. vanadic acid.

OXIDES OF VANADIUM.

There are five oxides of vanadium, analogous to the oxides of nitrogen—

- Vanadium suboxide, V_2O ;
- “ monoxide, hypovanadious oxide, V_2O_3 ;
- “ sesquioxide or trioxide, V_2O_5 ;
- “ dioxide, hypovanadic oxide, V_2O_4 (VO_2);
- “ pentoxide, vanadic anhydride, V_2O_5 .

The first three of these act as basic oxides, forming salts with acids; the last two behave both as weak basic oxides and acid-forming oxides.

Vanadium suboxide V_2O is obtained as a brown powder by the exposure of finely divided

metallic vanadium to the air. No salts of this oxide have been prepared.

Vanadium monoxide V_2O_3 , or VO (*vanadyl*) is obtained as a lustrous grey solid by reducing the higher oxides with metallic potassium, or by passing the vapour of vanadyl trichloride with hydrogen over red-hot carbon, or by heating the solid oxychloride $VOCl$ to a red heat in hydrogen. It has sp.gr. 3.64, is brittle and conducts electricity. At a red heat it burns in air to form the trioxide, and it combines directly with chlorine to form the oxytrichloride. This oxide was supposed by Berzelius to be the metal. It is a black amorphous powder D¹⁴ 5.758.

Vanadium monoxide dissolves in acids to form the corresponding salts, which have a blue or violet colour and act as powerful reducing agents. The solution in hydrochloric acid has been suggested as a reagent for the removal of arsenic from hydrochloric acid gas in the process of manufacture, the arsenic being reduced to the free state and remaining suspended in the liquid (D. R. P. 164355).

Vanadium trioxide V_2O_3 , obtained by reducing the pentoxide with hydrogen or carbon at a red heat, is a black powder of sp.gr. 4.7, m.p. 2000° . Heat of formation 302 ± 10 cal. (Ruff and Friedrich). In air it oxidises, slowly at the ordinary temperature, quickly when heated, forming the dioxide V_2O_4 . It is insoluble in most acids.

Vanadium dioxide V_2O_4 , or VO_2 , is prepared by the oxidation of the trioxide or by the partial reduction of the pentoxide. It is a steel-coloured powder composed of dark indigo-coloured crystals. It dissolves in acids to form solutions of vanadyl salts of a bright blue colour, and in alkalis to form *vanadites* (v.i.). A hydrate, $V_2O_4 \cdot 7H_2O$, or $V_2O_4(OH)_4 \cdot 5H_2O$, is obtained as a greyish-white precipitate by adding sodium carbonate to a solution of a vanadyl salt. At 100° it loses 4 molecules of water, forming $V_2O_4 \cdot 3H_2O$.

Hypovanadic acid (*vanadious acid*) $H_4V_2O_6$ has been prepared by boiling a solution of the dioxide VO_2 in aqueous sulphurous acid. It is a pink crystalline powder (Gain, *Compt. rend.* 1906, 143, 823; see also *ibid.* 1154), and can exist in a green isomeric form (Gain, *ibid.* 1907, 146, 403; *Ann. Chim.* 1908, [viii.] 14, 224).

The salts in which VO_2 is the acidic oxide are derived from the partial anhydrides $H_2V_2O_6$ and $H_4V_2O_6$.

Potassium and sodium vanadites

are prepared by adding excess of caustic alkali to a solution of vanadyl sulphate or chloride (v. Koppel and Goldmann, *Zeitsch. anorg. Chem.* 1903, 36, 281). They form reddish-brown crystalline scales and dissolve in water to dark-brown solutions.

Vanadium pentoxide V_2O_5 is the final product of most commercial processes for the extraction of vanadium from its ores. The pure oxide is best prepared by decomposing vanadyltrichloride with water and fusing the product, or by the decomposition of ammonium metavanadate by

(Matignon, *Chem. Zeit.* 1906, 29, 266; also Beard, *Ann. Chim. anal.* 1906, 1 of formation 427 ± 7 cal. (Gibbs)

Friedrich, *Zeitsch. anorg. Chem.* 1914, 39, 273.

Vanadium pentoxide forms large rhombic prisms, of a fine ruby-red colour by transmitted light, of sp.gr. 3.85, soluble in about 1000 parts of water with formation of a yellowish, tasteless solution which reddens litmus; this appears to be a colloidal modification of vanadic acid. At 668° (Carnelley) it fuses, forming a red liquid, which recrystallises in needles, with incandescence, on cooling. When the molten acid is poured into water it yields a solution of the colloidal modification (Müller, *Zeitsch. Chem. Ind. Kolloide*, 1911, 8, 302).

When prepared by heating ammonium metavanadate, treating the residue with nitric acid and drying at a gentle heat, it is a yellow, hygroscopic powder which forms hydrates with 1, 2, and 8 molecules of water, and is soluble in water to the extent of 8 parts in 1000. When the oxide is heated at 440°, or fused, two different sparingly soluble modifications are formed (Ditte, *Compt. rend.* 1885, 101, 698).

The properties of colloidal vanadium pentoxide have been studied by Dumanski (*J. Russ. Phys. Chem. Soc.* 1924, 54 703; *Chem. Soc. Abstr.* 1924, ii, 195).

Vanadium pentoxide is reduced to V_2O_4 by the action of SO_2 , or by evaporation with hydrochloric acid or hydriodic acid in absence of air; to V_2O_3 by magnesium and hydrochloric acid, or by hydrogen in the dry way; to V_2O_2 by zinc and hydrochloric acid (Glasmann, *Ber.* 1905, 38, 600; Chapman, *Analyst*, 1907, 32, 250); or by shaking with mercury in presence of sulphuric or hydrochloric acid:

If a sufficiency of sodium chloride is present the whole of the mercury is precipitated as mercurous chloride, and a blue solution is obtained which may be quantitatively titrated with permanganate:

(McCay and Anderson, *J. Amer. Chem. Soc.* 1922, 44, 1018). The determination of vanadium by reduction with hydrogen peroxide and titration with permanganate has been studied by Hotherhall (*J. Soc. Chem. Ind.* 1924, 43, 270 T, 853 B). Vanadic acid volatilises with hydrochloric acid or to a slight extent when heated with alkaline chlorides.

The pentoxide was formerly used in the preparation of aniline black, and it acts as a carrier of oxygen in many reactions, e.g. the electrolytic oxidation of organic compounds in acid solution (Meister, Lucius and Brüning, *D. B. P.* 172654), and the oxidation of sugar to oxalic acid or of stannous to stannic chloride (Ludwig, Mooser and Lindenbaum, *J. pr. Chem.* 1907, [ii.] 75, 146; *D. B. P.* 183022).

For the analysis of commercial vanadic acid, see Cheneau (8th Internat. Cong. Appl. Chem. 1913, 1, 123; *J. Soc. Chem. Ind.* 1912, 31, 921).

The Vanadic Acids and their Salts.

Orthovanadic acid H_3VO_4 has not been prepared.

Metavanadic acid HVO_3 may be obtained by boiling copper metavanadate with aqueous sulphurous acid. A mixture of brown and yellow

crystals is first produced, the former being redissolved on continued boiling with excess of sulphurous acid. The remaining yellow crystals consist of metavanadic acid. The acid may also be prepared by addition of a solution of ammonium metavanadate to one of copper sulphate containing excess of ammonium chloride, until a permanent precipitate is produced, and heating for a few hours at 75°. The whole of the vanadium is slowly precipitated, the colour being finer when precipitation is slow (Gerland, *Ber.* 1876, 9, 874). Metavanadic acid forms brilliant golden or orange-coloured scales, which are used as a pigment in place of gold bronze under the name 'vanadium bronze.'

Pyrovanadic acid $H_2V_2O_7$, prepared by the action of nitric acid on an acid vanadate, is a brown precipitate which when air-dried has above composition (von Hauer, *v.i.*).

Hexavanadic acid $H_4V_6O_{17}$, formed when a solution of pervanadic acid is allowed to stand, is known only in solution (Düllberg, *Zeitsch. physikal. Chem.* 1903, 45, 170).

The following sodium vanadates are known, and may be taken as typical of the vanadates in general—

- Sodium metavanadate, $NaVO_3$;
- " orthovanadate, Na_2VO_4 ;
- " pyrovanadate, $Na_2V_2O_7$;
- " tetravanadate, $Na_4H_2V_4O_{17}$;
- " hexavanadate, $Na_4H_4V_6O_{17}$.

(v. also von Hauer, *J. pr. Chem.* 1856, [i.] 69, 385; 1859, 76, 156 and 929; 1860, 80, 324; Carnelley, *Chem. Soc. Trans.* 1873, 323). In solution the metavanadates are most stable, and the orthovanadates least stable, the pyrovanadates being intermediate. This is the reverse of the order of stability of the phosphates. At high temperatures orthovanadates are the most stable salts, being produced, e.g., by fusing alkali carbonates with vanadium pentoxide. The alkali pyrovanadates, prepared by fusing the pentoxide with excess of alkali carbonate and crystallising from water, are soluble, whilst the pyrovanadates of heavy metals are mostly insoluble.

The alkali metavanadates are obtained by boiling a solution of alkali carbonate with the pentoxide, and are colourless salts which give yellowish-red anhydro-salts on treatment with acid. The metavanadates of heavier metals are usually yellow. Pure silver metavanadate is precipitated on addition of silver nitrate to a neutral solution of an alkali vanadate (Browning and Palmer, *Amer. J. Sci.* 1910, 30, 230).

A test which distinguishes between ortho- and meta-vanadates depends on the colour of the copper salts of the acids which are blue-green and light yellow respectively.

A series of double stannates and vanadates of sodium has been described by Prandl and Rosenthal (*Ber.* 1907, 40, 2125). Mixed alkali tungstates and vanadates by Prandl and Hecht (*Zeitsch. anorg. Chem.* 1915, 92, 196). Heteropolyvanadates have also been prepared by Rosenheim and Pieck (*Zeitsch. anorg. Chem.* 1916, 98, 223).

By introducing vanadium pentoxide into a boiling aqueous solution of iodic acid, the salts $V_2O_5 \cdot I_2O_5 \cdot 4H_2O$ and $V_2O_5 \cdot 2I_2O_5 \cdot 16H_2O$ may be formed. By ————— potassium and ammonium salts of the acids

$2R_2O_3 \cdot 2V_2O_5 \cdot 3P_2O_5 \cdot xH_2O$ are produced. Phosphates give rise to such salts as

and $R_2O_3 \cdot 2V_2O_5 \cdot P_2O_5 \cdot xH_2O$ (Rosenheim and Yang, *Zeitsch. anorg. Chem.* 1923, 129, 181; *Chem. Soc. Abstr.* 1924, 126, ii, 54).

A number of molybdeno-vanadates such as $4K_2O \cdot 4MoO_3 \cdot 3V_2O_5 \cdot 7H_2O$ and

have been prepared (Canneri, *Gazz. chim. ital.* 1923, 53, 779; *J. Chem. Soc. Abstr.* 1924, 126, i, 118).

Ammonium metavanadate NH_4VO_3 is the most important salt of vanadic acid. It may be prepared by dissolving vanadium pentoxide in excess of aqueous ammonia and then, by evaporation or by adding alcohol or excess of ammonium chloride, it is thrown out of solution as a white crystalline powder.

Pure ammonium metavanadate (*d* 2.326) is prepared by saturating with ammonia moist vanadium pentoxide and crystallising from a very dilute ammonia solution. One hundred parts of water dissolve 5.18 parts of the salt at 15° and 10.4 parts at 32°; it is only slightly soluble in hot alcohol and in ether. When heated in a vacuum to 135°–210°, the salt yields anhydrous ammonium triivanadate; above 210°, lower oxides of vanadium are formed. On boiling an aqueous solution, soluble ammonium divanadate and the insoluble triivanadate are formed. By the action of 4 p.c. acetic acid on boiling solutions of ammonium metavanadate, the divanadate

is obtained, which on desiccation loses $2H_2O$. Use of 10 p.c. acid gives the triivanadate $3V_2O_5 \cdot (NH_4)_2O \cdot 2H_2O$ (*d* 2.594), desiccation of which gives an anhydrous red salt (*d* 2.163). The previously described yellow anhydrous triivanadate has *d* 3.029. When the acetic acid is replaced by nitric, hydrochloric, or sulphuric acid, indefinite acid ammonium vanadates are formed, the composition varying with the concentration of the acid added. With a large excess of hydrochloric acid, reduction of the vanadate also takes place (*M. Lachartre, Bull. Soc. chim.* 1924, [iv.] 35, 321; *Chem. Soc. Abstr.* 1924, 126, ii, 409).

A 'vanadium ink' is produced by the addition of gallic acid to a mixture of neutral ammonium metavanadate and gum water. This ink is not destroyed by acids, alkalis, or chlorine but does not appear to be permanent. Soerensen (*J. Soc. Chem. Ind.* 1, 185) recommends the use of a solution of 1 lb. neutral ammonium metavanadate in 10 gals. of water for producing a permanent black dye on leather which has been tanned with nut galls.

A 'drier' for linseed oil may be prepared by ammonium metavanadate with rosin or oil. Vanadium is said to be superior to lead in drying power and gives smoother and tougher films than manganese or cobalt. According to Gardner (*Circ.* 149, *Paint Manufacturers Assoc., U.S.*, April, 1922) the time of drying of linseed oil siccated with vanadium is not markedly different from that of oil siccated with other known driers.

Paravanadic acid HVO_3 , prepared by adding finely powdered vanadium pentoxide to a solution of hydrogen peroxide acidified with sulphuric acid, forms yellow crystals soluble in water, giving a deep-red solution (Werther, *J. pr. Chem.* 1861, 83, 195; Pissarjewsky, *Zeitsch. physikal. Chem.* 1903, 43, 173). The potassium salt KVO_3 forms a yellow microcrystalline precipitate (see also Melikoff and Pissarjewsky, *Zeitsch. anorg. Chem.* 1899, 19, 504; Pissarjewsky, *ibid.* 1903, 32, 341; Melikoff and Kasanezky, *ibid.* 1901, 28, 242; Melikoff and Jelchmaninoff, *Ber.* 1909, 42, 2291; Anger, *Compt. rend.* 1921, 172, 1355).

Vanadiselenious acid $3V_2O_5 \cdot 4SeO_3 \cdot 4H_2O$ and its salts have been described by Frandl (*Ber.* 1905, 38, 1305).

Vanadium trifluoride $VF_3 \cdot 3H_2O$ crystallises in dark-green octahedra from a solution of the trioxide in hydrofluoric acid. Addition of potassium fluoride precipitates the double potassium salt $2KF \cdot VF_3 \cdot H_2O$ as a bright green crystalline powder.

Vanadium tetrafluoride VF_4 , a brownish-yellow hygroscopic powder, deliquescent to a blue liquid, is produced by the action of hydrogen fluoride on the tetrachloride.

Vanadyl difluoride VOF_2 is prepared by heating vanadyl dibromide in a current of hydrogen fluoride. It is a yellow powder of sp.gr. 3.396 at 19°.

Vanadyl trifluoride VOF_3 is formed by the action of hydrogen fluoride on vanadyl trichloride. It forms yellowish-white hygroscopic crusts of sp.gr. 2.459, deliquescent to a brownish-yellow solution. Melts at 300° and boils at 480°. May be sublimed in a current of oxygen.

Vanadium pentafluoride VF_5 , obtained as a white sublimate by heating the tetrafluoride in nitrogen. Is readily soluble in water, alcohol, chloroform, acetone and light petroleum. Sp.gr. 2.177; b.p. 111.2°/758 mm (Ruff and Lickfett, *Ber.* 1911, 44, 2539).

Numerous double fluorides have been described (see Petersen, *J. pr. Chem.* 1889, [ii.] 40, 193, 271; Piccini and Giorgis, *Gazz. chim. ital.* 1888, 18, 186; Baker, *ibid.* 1878, 388; Costăchescu, *Ann. Sci. Univ. Jassy*, 1910, 6, 117).

Vanadium tetrachloride VCl_4 is formed by the action of excess of chlorine on the metal or the mononitride. It is prepared the vapour of vanadyl trichloride with over red-hot sugar charcoal, or by the action of chlorine on the impure metal obtained by Goldschmidt's method (Koppel, Goldmann and Kaufmann, *Zeitsch. anorg. Chem.* 1905, 45, 245), and is separated from admixed oxychloride by fractional distillation. It is readily obtained by the action of chlorine on finely powdered vanadium carbide. It is best prepared by heating the trichloride in a stream of chlorine (Ruff and Lickfett, *Ber.* 1911, 44, 506), or by passing chlorine over heated ferro-vanadium:

(Mertes, *J. Amer. Chem. Soc.* 1913, 35, 671). Heat of formation 165 ± 4 Cal.

It is a deep brown-red, viscous liquid which fumes in air. It boils at 154°, and when heated or exposed to light loses chlorine, forming the trichloride (*v.i.*). It has sp.gr. 1.8384 at 20° and V.D. 8.09 at 205°. Water decomposes it.

with formation of a blue solution of vanadyl chloride. It is soluble in carbon tetrachloride.

The pentachloride does not appear to exist.

Vanadium trichloride VCl_3 is obtained by the decomposition of the tetrachloride, by passing the vapour of the tetrachloride with hydrogen through a red-hot tube, or by heating the trisulphide in chlorine (Halberstadt, Ber. 1882, 15, 1619). It is prepared by passing first the vapour of carbon disulphide and then dry chlorine over heated vanadium pentoxide, or more easily by heating vanadyl trichloride or vanadium tetrachloride with sulphur (Ruff and Lickfett, l.c.). Hydrogen chloride reacts at $300^\circ\text{--}400^\circ$ with vanadium to give the trichloride (Meyer and Backe, Zeitsch. anorg. Chem. 1924, 135, 177). Heat of formation 187 ± 8 Cal.

The trichloride thus obtained forms beautiful purple tabular crystals, resembling chromium trichloride. Heated in air, it decomposes yielding the pentoxide. Heated in nitrogen it is decomposed into the tetrachloride and dichloride. When heated in hydrogen it does not volatilise, but is reduced to the dichloride. Its sp.gr. is 3.0, and it is extremely hygroscopic.

The hydrated salt $\text{VCl}_3 \cdot 6\text{H}_2\text{O}$ is obtained by evaporating *in vacuo* a solution of the trioxide in hydrochloric acid (Locke and Edwards, Amer. Chem. J. 1898, 20, 594), or by reducing electrolytically a solution of the pentoxide in hydrochloric acid and saturating the resulting solution with hydrogen chloride (Piccini and Brizzi, Zeitsch. anorg. Chem. 1899, 19, 394). It is a green crystalline powder, and when heated begins to decompose before all the water has been driven off.

Vanadium dichloride VCl_2 is prepared by reducing the trichloride, by heating to redness a mixture of the tetrachloride and hydrogen, or by heating the silicide VSi_2 in chlorine (Moissan and Holt, Compt. rend. 1902, 135, 78; Ruff and Lickfett, l.c.). Heat of formation 14 ± 74 Cal.

It forms deliquescent, apple-green hexagonal plates having a micaceous lustre; it dissolves in water to form a solution which bleaches strongly, and is a more powerful reducing agent even than chromous chloride (Piccini and Marino, Zeitsch. anorg. Chem. 1902, 32, 68).

When the solid is heated in hydrogen the pure metal is obtained (Roscoe).

Vanadyl trichloride VOCl_3 (vanadium oxytrichloride) is prepared (1) by the action of chlorine on the trioxide, some pentoxide being formed according to the equation

(2) by heating the pentoxide to a dull red heat in a stream of chlorine; (3) by heating a mixture of the pentoxide and carbon in a current of chlorine; (4) by passing dry hydrogen chloride over a mixture of vanadium and phosphorus pentoxides at 60° (Ephraim, Zeitsch. anorg. Chem. 1903, 35, 66); (5) by chlorinating a mixture of the pentoxide and sulphur; (6) by heating the trichloride in a current of oxygen. Heat of formation 200 ± 4 Cal.

The product is usually dark-coloured from the presence of the tetrachloride, and is best purified by distillation over metallic sodium in an atmosphere of carbon dioxide.

A solution in acetic acid may be obtained by the action of dry hydrogen chloride on a solution

of the pentoxide in glacial acetic acid (Koppel and Kaufmann, *ibid.* 1905, 45, 352).

Pure vanadyl trichloride is a lemon-yellow mobile liquid; b.p. 127.2° , sp.gr. 1.86534 at $0^\circ/4^\circ$ (Thorpe). In contact with moist air it evolves dense red fumes. Water decomposes it with formation of vanadic and hydrochloric acids, and with a large quantity of water it yields a yellow solution (see Agafonoff, J. Russ. Phys. Chem. Soc. 1903, 35, 649). Heated in a current of ammonia it yields the mononitride. At 70° it combines with ether yielding the compound $\text{VCl}_3(\text{OC}_2\text{H}_5)_2$, crystallising in red needles (Bedson, Chem. Soc. Trans. 1876, i, 309), and it forms a compound with pyridine.

Vanadium may be quantitatively volatilised as the trichloride by heating its compounds: current of carbon tetrachloride vapour (Jannasch and Harwood, J. pr. Chem. 1909, [ii.] 80, 127).

Vanadyl dichloride VOCl_2 , crystallising deliquescent green tablets, is formed when the oxytrichloride is heated with zinc at (Thorpe), or with hydrogen at a red heat. latter method of reduction yields vanadyl monochloride VOCl , a flocculent brown powder, insoluble in water, and divanadyl monochloride $\text{V}_2\text{O}_2\text{Cl}$, a yellow crystalline powder. Double compounds of VOCl_2 with the hydrochlorides of pyridine and quinoline, have been described (Koppel, Goldmann and Kaufmann, Zeitsch. anorg. Chem. 1905, 45, 345).

Divanadyl tetrachloride $\text{V}_2\text{O}_2\text{Cl}_4 \cdot 5\text{H}_2\text{O}$ is obtained as a brown, amorphous deliquescent mass by the evaporation of a solution of the pentoxide in hot concentrated hydrochloric acid. It dissolves in water to a blue solution which is turned brown by hydrochloric acid or alcohol, possibly owing to the formation of different hydrates (Crow, Chem. Soc. Trans. 1876, ii, 453).

Another oxychloride $\text{V}_2\text{O}_2\text{Cl}_2 \cdot 4\text{H}_2\text{O}$ is obtained by similar methods as a dark-green deliquescent solid (Ditte, Compt. rend. 1886, 102, 1310).

Vanadium tribromide VBr_3 is prepared by the action of dry bromine on the metal on the mononitride, on vanadium carbide V_4C_3 , or a mixture of the trioxide and carbon at a red heat. It is a deliquescent solid which is very unstable and loses bromine even at the ordinary temperature.

The hydrated bromide $\text{VBr}_3 \cdot 6\text{H}_2\text{O}$ is prepared in a similar manner to the corresponding chloride (*q.v.*).

Vanadyl tribromide VOBr_3 , prepared by passing bromine vapour over the heated trioxide, is a dark-red liquid, sp.gr. 2.967 at 0° , b.p. 130° under 100 mm. Heated to 180° it suddenly decomposes into free bromine and vanadyl dibromide VOBr_2 , a brownish-yellow powder. This on further heating yields VOBr , a violet powder, of sp.gr. 4.0, which is eventually decomposed into vanadium tribromide and vanadium trioxide (Ruff and Lickfett, Ber. 1911, 44, 2534).

Vanadium triiodide (hydrated) $\text{VI}_3 \cdot 6\text{H}_2\text{O}$ is prepared in the same manner as the corresponding bromide.

Divanadyl tetriodide $\text{V}_2\text{O}_2\text{I}_4 \cdot 6\text{H}_2\text{O}$ is obtained as a dark-coloured deliquescent solid by the action of hydriodic acid on vanadium pentoxide (Ditte, Compt. rend. 1886, 102, 1310).

Vanadium monosulphide VS, obtained by heating the sesquisulphide in hydrogen, is a brown powder soluble in nitric acid.

Vanadium sesquisulphide (vanadium trisulphide) V_2S_3 , is prepared by heating the trioxide in a current of hydrogen sulphide or the pentoxide in the vapour of carbon disulphide. It is a greenish-black powder (Kay, Chem. Soc. Trans. 1880, 728; cf. Wedekind and Horst, Ber. 1912, 45, 262).

Vanadium pentasulphide V_2S_5 is obtained as a black powder by heating the trisulphide with sulphur. This sulphide is acidic and gives rise to a series of *thiovanadates*, which are best prepared by passing hydrogen sulphide into cooled solutions of the corresponding vanadates.

Vanadyl sulphite $6VO_2 \cdot 4SO_3 \cdot 9H_2O$ is obtained as a dark blue crystalline powder by reducing barium vanadate with sulphur dioxide. Gain has described a sulphite $4VO_2 \cdot 3SO_3 \cdot 10H_2O$, crystallising in silky blue needles (Compt. rend. 1906, 143, 823; see also *ibid.* 1907, 144, 1157).

Vanadous sulphate $VSO_4 \cdot 7H_2O$ is best prepared by acting with sulphur dioxide on a suspension of vanadium pentoxide in sulphuric acid and then reducing the solution electrolytically. On evaporation *in vacuo* the salt is obtained in reddish-violet monoclinic crystals which appear to be isomorphous with ferrous sulphate. The solution of the salt is a powerful reducing agent and bleaches strongly.

Vanadous sulphate forms a series of double salts with the alkali sulphates (see Piccini, Zeitsch. anorg. Chem. 1899, 19, 204; Piccini and Marino, *ibid.* 1902, 32, 55; Marino, *ibid.* 1906, 50, 49; Rutter, *ibid.* 1907, 52, 368; and Zeitsch. Elektrochem. 1906, 12, 230).

Vanadium sesquisulphate $V_2(SO_4)_3$, prepared by reducing a solution of vanadium pentoxide in sulphuric acid with magnesium, or by the electrolytic reduction of vanadyl sulphate, forms a green solution from which green crystals of the acid salt $V_2(SO_4)_3 \cdot H_2SO_4 \cdot 12H_2O$ separate out. By dissolving this salt in water, adding sulphuric acid and heating at 180° in a current of carbon dioxide, the sesquisulphate separates out as a yellow crystalline powder, insoluble in water (Stähler and Wirthwein, Ber. 1905, 38, 3978). Alkali vanadium sulphates of the form $MV(SO_4)_2$ have also been prepared (Rosenheim and Mong, Zeitsch. anorg. Chem. 1925, 148, 25; Chem Soc. Abstr. 1925, 128, i, 1411).

Several *vanadium alums* have been prepared.

Vanadyl sulphate $V_2O_5 \cdot (SO_4)_2$ is prepared (a) in the insoluble form by dissolving the dioxide VO_2 in sulphuric acid and heating the solution at 260° (Gerland, Ber. 1877, 10, 2109; Koppel and Behrendt, Zeitsch. anorg. Chem. 1903, 35, 154); (b) in the soluble form by heating the insoluble form with water at 130° , or by dissolving the dioxide in sulphuric acid, evaporating, and treating the residue with alcohol. Both forms are blue, and by crystallisation of the soluble form under different conditions hydrates with 13, 10, 7, 4, 3, and 2 molecules of water are obtained.

Strongly acid solutions deposit the acid sulphate $(V_2O_5)_2H_2(SO_4)_2$, crystallising with molecules of water. When heated it gradually loses water, yielding various lower hydrates, and, finally, at 190° , the *anhydrous salt*

which forms microscopic green tetragonal crystals, sparingly soluble in water (Koppel and Behrendt, *loc. cit.*; Gain, Compt. rend. 1906, 143, 1154).

Divanadyl trisulphate $(VO_2)_2(SO_4)_3$ is obtained in ruby-red octahedra by boiling the pentoxide with excess of sulphuric acid (see Ditte, *ibid.* 1886, 102, 77). Other basic salts, e.g. $(VO_2)_2O(SO_4)_2$ and $VO(OH)SO_4$, have been described (see Gerland, Ber. 1878, 11, 98).

Vanadium pyrophosphate $V_2(P_2O_5)_3 \cdot 30H_2O$ is formed as a flocculent green precipitate when an alkaline pyrophosphate solution is added to a solution of vanadium ammonium alum (Rosenheim and Triantaphyllides, Ber. 1915, 48, 582).

Vanadium mononitride VN may be obtained by the direct union of its elements or by heating ammonium metavanadate or the pentoxide to whiteness in a current of ammonia. It is a brown powder, oxidised to the blue oxide when heated in air.

Vanadium dinitride VN_2 is a black powder obtained by the action of ammonia on vanadyl trichloride.

Many phosphovanadic and arsenovanadic acids are known, giving rise to numerous derivatives (see Ditte, Compt. rend. 1886, 102, 757; Gibbs, Amer. Chem. J. 1886, 7, 118, 209; Friedheim, Ber. 1890, 23, 1530, 2600; Gain, Compt. rend. 1907, 144, 1271; Mawrow, Zeitsch. Chem. 1907, 55, 147). Blum has described a series of phosphovanadic molybdates (J. Amer. Chem. Soc. 1908, 30, 1858).

Vanadium boride VB is formed by heating a mixture of its constituents in the electric arc. It is a hard metallic looking substance. Stable towards alkalis and acids but readily decomposed by fused alkali hydroxide.

Vanadium carbide VC, obtained by heating the pentoxide with carbon in the electric furnace, forms hard crystals of sp.gr. 5.405; m.p. 3100° Abs.

Vanadium silicides. Two silicides are known: V_2Si , sp.gr. 5.48; and VS_i , sp.gr. 4.42. Both are obtained in the electric furnace from the oxide and silicon. They are hard, crystalline substances, having a metallic lustre (Moissan and Holt, Compt. rend. 1902, 135, 78, 493; Meyer and Backa, Chem. Soc. Abstr. 1924, ii, 558).

A vanadium aluminium silicide V_3 has been described by Manchot and Annalon, 1907, 357, 129).

For *vanadic esters and other organic vanadium compounds*, see Hall, Chem. Soc. Trans. 1887, 51, 751; Prandtl and Hess, Zeitsch. anorg. Chem. 1913, 82, 103; Barbieri, Atti R. Accad. Lincei, 1914, [v.] 23, ii, 408; Mertens and Fleck, J. Ind. Eng. Chem. 1915, 7, 1037.

Detection and estimation of vanadium.—Vanadium may be detected *qualitatively* by the behaviour of its compounds on oxidation and reduction, yellow or red solutions of vanadates yielding blue solutions of vanadyl salts on reduction with zinc and acid. Addition of ammonium chloride to a solution of a vanadate precipitates white ammonium metavanadate. The most delicate test known for vanadium consists in adding hydrogen peroxide and ether to a solution of a vanadate acidified with sulphuric acid; a yellow or red colour is produced in the aqueous layer (G. Werther, J. pr. Chem.

1903, [L.] 88, 195; Campagne, Chem. Zentr. 1904, [L.] 1167). Vanadium may also be detected spectroscopically (see Purvis, Trans. Camb. Soc. 1906, 20, 193; Pollok, Sci. Proc. Roy. Dubl. Soc. 1909, 11, 331).

For the arcspectrum of vanadium, see W. F. Meggers (J. Washington Acad. Sci. 1923, 13, 317-325).

Vanadium is usually estimated volumetrically by oxidation methods after other reducible metals have been eliminated. See art. ANALYSIS, and also Hartmann (Zeitsch. anal. Chem. 1925, 66, 16).

For the volumetric estimation of vanadium in steel, see A. T. Etheridge (Analyst, 1923, 48, 588).

Atomic weight.—The atomic weight of vanadium was estimated by Roscoe (Phil. Trans. 1868, 158, 1) to be 51.23; by Prandtl and Bleyer (Zeitsch. anorg. Chem. 1909, 65, 152; 1910, 67, 257) as 51.07; by McAdam (J. Amer. Chem. Soc. 1910, 32, 1603) as 50.96; and by Briscoe and Little (Chem. Soc. Trans. 1914, 105, 1310) as 50.95.

VANADIUM INK v. VANADIUM.

VANADIUM MICA v. ROSCOELITE.

VANILLA is the dried fermented pod of certain orchids, indigenous to Mexico, but also found in Java, Réunion, the Seychelles, Brazil, Peru, on the banks of the Orinoco, Parahyba and other rivers of South America.

The chief cultivated variety is *V. planifolia* (Andr.), which is grown on a considerable scale in Mexico, Réunion, Mauritius, Madagascar, the Seychelles, and in Java. The long fleshy stem of the plant clings by its aerial rootlets to trees, and bears a greenish-white flower. The fruit is a pulpy pod, about 6-12 ins. long and half an inch thick. In Mexico the plant is cultivated by planting cuttings at the feet of trees left in a clearing of the forest; these root in a few weeks and bear in the third year. In Réunion and in the Seychelles the plants are trained on trellis-work supported by trees, and are fertilised by hand. Care has to be taken to gather the pods at the proper time of maturity, as if over-ripe they split in drying, and if under-ripe they are deficient in flavour.

The fruit is usually gathered in the late autumn when full grown, but just before it ripens.

The curing of the fruits consists essentially of a slow process of drying in warm air, using either artificial or solar heat, but the details vary in different countries; thus in Mexico the gathered pods are allowed to lie in heaps until they begin to shrivel, after which they are heated, either by exposure to the sun or in ovens, when they gradually acquire a dark-brown colour. In Réunion and Madagascar the pods are immersed in boiling water for a few seconds, and then exposed to the sun for a few weeks in woollen cloths until they acquire the proper brown colour. As they become dry, they discharge a viscid liquid from the upper end, and are pressed from time to time to promote its flow. They are usually packed for the market in small bundles of fifty or one hundred in each. The yield of vanilla beans in Madagascar and dependencies for the season 1921-22 was 309,000 lbs., and in Réunion and Mauritius 121,000 and 2000 lb., respectively.

It has also been suggested to use

chloride in the drying of the beans (J. Soc. Chem. Ind. 1898, 180).

For literature on the culture and curing of the vanilla beans, v. *ibid.* 1893, 707; *ibid.* 1896, 679; *ibid.* 1900, 847; *ibid.* 1901, 1048; *ibid.* 1906, 1117; *ibid.* 1909, 1002; Fr. Pat. 367285, 1906.

Those who habitually handle vanilla beans are often subjected to a cutaneous affection in the form of an eruption on the hands, face, or neck, which causes intense irritation; this is probably due to the oily juice which exudes from the beans. To avoid the affection, good ventilation of the factories and thorough washing of the hands are recommended (Claverie, J. Soc. Chem. Ind. 1908, 1082).

Commercial vanilla beans are almost 15-20 cm. long and 6-9 mm. thick. They are of a flattened cylindrical shape, tapering towards each end, wrinkled and flexible. The varieties, chiefly the Mexican, are the largest; they are very dark, glossy, and frost or (i.e. become covered with white crystals) very quickly. The inferior varieties are shorter, lighter in colour, and do not frost much.

Vanillons are the cured fruits of uncultivated vanilla plants; they are usually of poor quality. The unripe beans are said to contain coniferin and two enzymes, one of which converts coniferin into coniferyl alcohol and glucose, and the other oxidises the former to vanillin (Lecomte, Compt. rend. 1901, 133, 745).

Best Mexican vanilla beans contain 1.60-1.86 p.c. vanillin, Bourbon 1.91-2.90, Java 2.75, German East African 2.16, Ceylon 1.48, Tahiti 1.55-2.02, but the flavour of vanilla does not depend merely on the quantity of vanillin it contains (Busse, Zeitsch. Nahr. Genussm. 1899, 2, 519). The best qualities of vanilla beans contain less actual vanillin than the cheaper varieties.

In addition to vanillin, the beans also contain vanillic acid $C_8H_7(OH)(OCH_3)CO_2H$, resins, fat, sugar, and 4-5 p.c. ash (Winton and Silverman, J. Soc. Chem. Ind. 1902, 1300; U.S. Pat. 931805; *ibid.* 1909, 1062; Gautier and Kling, Ann. Falsif. 1910, 3, 200). Anisyl alcohol and anisaldehyde have also been detected (Walbaum, Chem. Zentr. 1909, ii. 2181).

When the green vanilla pods are exposed to ultra-violet rays, they emit a smell of vanillin, the process being accelerated by a rise in temperature and by previous immersion in dilute manganous chloride (Pougnet, Compt. rend. 1911, 152, 1184).

Tincture or essence of vanilla is formed by extracting the ground or cut up vanilla (10 parts) with a mixture of alcohol and water, and mixing the extract with 20 parts of refined sugar, the whole being made up to 100 parts.

The extracts obtained from several varieties of vanilla and tonka beans, using isopropyl alcohol, ether, acetone, and carbon tetrachloride, when compared with that obtained with ethyl alcohol showed that the alcoholic solvents are much superior as regards quality of extract, carbon tetrachloride giving the poorest extract. It is possible, however, that a preliminary extraction with ether or carbon tetrachloride, followed by extraction with a dilute solution of alcohol, may give satisfactory extracts (J. W. Sale, J. Ind. Eng. Chem. 1923, 15, 758-759; J. Soc. Chem. Ind. 1923, 43, 367 A-368 A).

The chief adulterant in vanilla extracts is either artificial or from tonka beans; imitation extracts may be obtained from 3 parts of vanilla, and 1 part of tonka beans, but most commercial imitations contain no vanilla, and are made up of artificial vanilla and coumarin and extract of tonka beans, the whole being coloured with caramel (Winton and Silverman, *l.c.*). In the preparation of inferior extracts weak alcohol and alkali are employed; these can be distinguished from good extracts by shaking a few c.c. with 3 volumes of water, when, if no alkali has been employed, a flocculent red precipitate will be formed. With hydrochloric acid a good extract should give only a slight turbidity (Hess, *J. Amer. Chem. Soc.* 1899, 21, 719).

Vanilla in the form of its tincture, is employed for flavouring chocolate and confectionery. It is also largely used in the manufacture of liqueurs and perfumes. See also Vanille, Vanilline, Vanille-Extraiten. W. L. Utermark, Amsterdam: Kolonial Instituut, 1922.

VANILLIN (4-hydroxy-3-methoxybenzaldehyde $C_8H_8(OH)(CHO)(OCH_3)$) is contained in vanilla beans (*v. VANILLA*); in *Habenaria nigra* (R. Br.) (Lippmann, *Ber.* 1894, 27, 3409); in dahlia tubers (*ibid.* 1906, 39, 4147); in the woody parts of plants (*ibid.* 1904, 37, 4521); in the fruit and roots of *Avena sativa* (L.) (Rawton, *Compt. rend.* 1897, 125, 797). It also occurs in many other plants, in resins, balsams, and other substances (Campani and Grimaldi, *Bull. Soc. chim.* 1890, [iii.] 3, 458; Weld, Tollens and Lindsey, *Ber.* 1890, 23, 2990; Thomas, *Arch. Pharm.* 1899, 237, 271; Knittl, *ibid.* 256; Itallie, *ibid.* 1901, 239, 506). Vanillin may be obtained from vanilla pods by disintegrating the latter with sand and extracting with ether or a mixture of ether and alcohol (Tiemann and Haarmann, *Ber.* 1876, 9, 1287).

Vanillin may be obtained artificially by oxidising coniferin or coniferyl alcohol with chromic acid; by oxidising eugenol or, better, isoeugenol with air (Fr. Pat. 316526, 1902; Eng. Pat. 4909, 1902; *J. Soc. Chem. Ind.* 1902, 722; *ibid.* 1903, 439). According to A. Lowy and Catherine M. Moore (*Am. Electrochem. Soc. Trans.* 1922, 42, 273), contrary to the claim of D. R. P. 92007 (1897), no appreciable proportion of vanillin could be obtained by the electrolytic oxidation of isoeugenol. The latter is highly susceptible to oxidation to a wide variety of possible products and vanillin itself is readily oxidised electrolytically (*Sci. Abstr.* 1924, 27, 575). In the oxidation of the sodium salts of isoeugenol, or of acetyl isoeugenol in presence of aromatic amino carboxylic acids, extracting acetylvanillin from the products of the reaction, converting this into the bisulphite compound and treating successively with acid and sodium hydroxide (Sievers and Givaudan & Co., Swiss Pat. 89063); with ozone or ozonised air (Trillat, *Compt. rend.* 1901, 133, 822; *Bull. Soc. chim.* 1903, 29, 45; Fr. Pat. 326775, 421784, 1909; U.S. Pat. 829300, 1906; *J. Soc. Chem. Ind.* 1903, 819); with peroxides (Eng. Pat. 11952, 1894; 14923, 1896; *J. Soc. Chem. Ind.* 1895, 806; *ibid.* 1897, 633); electrolytically (Eng. Pat. 1624, 1895; *ibid.* 1896, 48, 323).

Ozonised air on a commercial scale have not been uniformly successful, owing to the formation of a resin as a result of the reaction being a very rapid one. In the new process the plant consists of a series of four towers partly filled with splash plates or balls. The first two contain a mixture of isoeugenol and aqueous sodium bisulphite, while the third and fourth are smaller and contain sodium carbonate and hydroxide respectively. Ozonised air is drawn through the towers and the vanillin dissolves in the bisulphite solution as formed. After 8 hours the aqueous layer is run off, the bisulphite compound decomposed with the requisite quantity of sulphuric acid (determined by titration of test sample), rendered slightly alkaline with sodium carbonate, and extracted with benzene. The crude vanillin recovered from the benzene solution is crystallised three times from water, the last crystallisation being from water completely free from iron. The power required for ozonisation is given as $\frac{1}{2}$ kva. per oz. of vanillin (B. G. Wood, *Met. & Chem. Eng.* 1923, 28, 806; *J. Soc. Chem. Ind.* 1923, 42, 626A).

A 95 p.c. yield and a much purer product is said to be obtained by oxidising eugenol, isoeugenol, coniferin, or coniferyl alcohol, simultaneously with air and ultra violet rays at 50°–60° (D. R. P. 224071; *J. Soc. Chem. Ind.* 1910, 1036).

The conversion of isoeugenol to vanillin by ozonised air has been studied by Briner, Patry, and E. De Luserna (*Helv. Chim. Acta*, 1924, 7, 62), by conducting a current of ozonised air at varying concentrations of ozone (5 p.c. to 19 p.c.) into a solution of isoeugenol in carbon tetrachloride, at temperatures from 15°–150°. The highest oxidation efficiency obtained, in terms of ozone consumed, was 20 p.c. at the lowest temperature. At higher temperatures the efficiency falls off rapidly and the quantity of resinous by-product formed increases (*Chem. Soc. Abstr.* 1924, 126, i, 290).

Vanillin may also be prepared by dissolving 14.2 kilos protocatechuic aldehyde in concentrated sodium carbonate solution, and mixing it with 12.6 kilos of dimethyl sulphate. The whole is heated on the water-bath, acidified, and extracted with ether. The latter is evaporated, and the vanillin extracted from the residue with chloroform (*J. Soc. Chem. Ind.* 1902, 274; see also *ibid.* 1897, 633; *ibid.* 1894, 1218; *ibid.* 1895, 1061).

Pure vanillin may be synthesised by the following method, the yield being 70–80 p.c. of the theoretical: 1 gm. molecule of a methyl or ethyl ester of mesoxalic acid or of any α -diketonic acid (or of the free acid) is added to a solution of 250 grms. of zinc chloride in 500 grms. of glacial acetic acid. The whole is kept at the ordinary temperature for 15 hours, after which it is heated at 50° for some hours, and then diluted with water and shaken with ether. The ethereal extract is washed with dilute aqueous sodium carbonate, distilled with steam to remove guaiacol (if present) and oxidised with copper chloride or acetate, vanilloylcarboxylic acid being formed. The latter, when heated with an equal weight of dimethyl-*p*-toluidine at 170°, yields vanillin, which is extracted from the acidified mixture.

and. 1909, 140, 928). Vanillin may also be synthesised by treating guaiacol with hydrocyanic acid, hydrochloric acid, and zinc chloride in the presence of infusorial earth (D. R. P. 189037; Chem. Zentr. 1908, i, 73).

A nearly theoretical yield of vanillin sodium hydrogen sulphite is obtained when dry hydrogen is passed through a boiling mixture of vanilloyl chloride-*p*-toluenesulphonic ester (154 pts.), dry xylene (1000 pts.), and palladised barium sulphate (5 p.c., 30 pts.) until evolution of hydrogen chloride ceases (Eng. Pat. 131161).

Vanillin has also been prepared by other methods.

The process of the Ozone Vanillin Co. (U.S. Pat. 829100) consists in passing ozonised air into a mixture of isoeugenol and sodium bisulphite solution of 30°Bé. The vanillin produced unites with the bisulphite from which it is easily separated. The production in the United States in 1919 was 134,700 lbs., valued at \$1,365,900 (Census of Industrial Products). Gattefossé and Morel describe a method of producing vanillin from phenol which consists in nitrating the phenol, separating the ortho- and para-derivatives by steam distillation, methylating the ortho-nitrophenol by dimethyl sulphate in presence of caustic soda to produce *o*-nitroanisole, which is then reduced by zinc powder in presence of calcium chloride to *o*-aminoanisole. This is converted by diazotisation into guaiacol, which by treatment with formaldehyde and hydroxylaminobenzenesulphonic acid yields vanillin.

These reactions may be thus represented :

Literature.—Tiemann, Ber. 1891, 24, 2877; Augier and Boissien, Bull. Soc. chim. 1895, 13, 519; Bouveault, *ibid.* 1898, [iii.] 19, 75; Verley, *ibid.* 1901, [iii.] 25, 48; J. Soc. Chem. Ind. 1896, 556, 740; *ibid.* 1902, 68; *ibid.* 1908, 644; Stok, Ber. 1904, 37, 4149; Frdl. 1877-87, i, 563-590; 1890-94, iii, 894-900; 1894-97, iv, 1273-1291; 1897-1900, v, 101, 110; 1902-04, vii, 755; 1905-07, viii, 1280, 1281; 1907-10, ix, 162, 1130, 1166.

Vanillin forms white needles having a strong characteristic taste and smell, m.p. 80°-81°, b.p. 285° (without decomposition in a stream of carbon dioxide) or 170°/15 mm. It is soluble in 90-100 parts of water at 14°, and in 20 parts at 75°-80°; it is readily soluble in ether, alcohol, and chloroform. Curves of solubility in aqueous alcohol and aqueous glycerol are given by Mange and Ehler (J. Ind. Eng. Chem. 1924, 16, 1258). The aqueous solution is acid, and gives a blue-violet colour with ferric chloride. When treated with ferrous sulphate and bromine water, vanillin is coloured bluish-green, then yellow (Pharm. J. 1897, 58, 167). Vanillin in hydrochloric acid gives characteristic colour reactions with phenols, ketones, and other substances; thus with acetone and its homologues a rose colour is formed, which becomes green on warming (Rosenthaler, Zeitsch. anal.

Chem. 1905, 44, 292). A nitric acid solution of vanillin on standing yields a small quantity of hydrogen cyanide (Jorissen, J. Soc. Chem. Ind. 1910, 1036).

When oxidised with ferric chloride, nitric acid, or with fungus extract, or with gum arabic solution, vanillin forms *dehydrovanillin*.

white needles, m.p. 303°-304° (Tiemann, Ber. 1885, 18, 3493; v. Lerat, Bull. Soc. chim. 1904, [iii.] 31, 270; Bourquelot and Marchadier, *ibid.* 1248; Bentley, *ibid.* 1900, [iii.] 24, 942).

Vanillin may be estimated by converting it into its hydrazone by treatment with a hydrazide (Hanuš, Zeitsch. Nahr. Genussm. 1900, 531, 657; *ibid.* 1905, 10, 585); or by converting it into its bisulphite derivative, decomposing the latter with sulphuric acid, removing the sulphur dioxide with a stream of carbon dioxide, extracting the vanillin with ether; the ether is evaporated and the residue weighed (Busse, *ibid.* 1899, 2, 519; Doherty, J. Roy. Soc. N.S.W. 1914, 47, 157). For other methods, see J. Soc. Chem. Ind. 1893, 718; *ibid.* 1903, 514. Or it may be estimated colorimetrically by adding a phosphotungstic phosphormolybdic acid solution to an acid solution of vanillin, and comparing the intensity of the blue colour produced with that formed under like conditions by a standard solution of vanillin. For details, see Folin and Denis, J. Ind. Eng. Chem. 1912, 4, 670. Or 1 c.c. of the vanilla essence is extracted with ether, the extract evaporated over the water-bath, and the aqueous solution filtered and diluted to 50 c.c. in a Nessler glass. Ten drops of freshly prepared bromine water and ten drops of 10 p.c. ferrous sulphate are then added, and the green colour matched against a 0.2 p.c. solution of pure vanillin. Methods for determining vanillin are critically reviewed by Radcliffe and Sharples (Perf. Ess. Oil Rec. 1924, 15, 396, 437; 1925, 16, 20, 51, 87, 156, 197, 271, 353, 387).

A refractometric determination of vanillin in vanilla sugar may be made by shaking 3 grms. of the sugar with 3 c.c. of ether for 1 minute, and allowing to settle. The butyro-refractometer readings of the ether used and that of the ethereal solution of vanillin are then taken. The difference multiplied by 0.4 gives the percentage of vanillin in the sugar. The temperature of the prism should be the same for both readings.

A volumetric method of determining vanillin depends on the formation of a hydro-derivative by the interaction of vanillin and *p*-toluidine dissolved in 80 p.c. alcohol. This compound contains the original hydroxyl group of the vanillin, and is therefore soluble in alkali, giving a yellow solution. A measured excess of standard alkali is added, followed by a comparatively large volume of cold water. The addition of standard acid first neutralises the excess of alkali and then liberates the anhydro-derivative from its sodium salt. The first drop of acid which liberates the derivative produces yellow turbidity, the free derivative being practically insoluble in the liquid phase. The volume of alkali required for the titration of the vanillin is thus obtained. Accurate results are obtained when benzoic acid is present as an adulterant in quantities up to 10 p.c. but

with higher percentages of acid it is advisable to use a gravimetric method. No sample of first-class vanillin contains more than 1 p.c. of acid (as vanillic acid), though some of the samples had been kept in cardboard containers for 10 years. The gravimetric method suggested comprises the precipitation of vanillin as the semi-carbazone from dilute acetic acid solution. The precipitate is easy to wash and filter and may be dried in a water oven for 6-8 hours, without losing a weighable quantity by volatilisation. The vanillin may be separated from impurities, such as piperonal, by dissolving the semi-carbazone in ammonia solution. Vanillin semi-carbazone, by virtue of its hydroxyl group, forms a soluble ammonium salt, giving a yellow solution, whilst piperonal semi-carbazone is insoluble. Test analyses in which piperonal was added to vanillin gave results agreeing with the actual percentage to within 1 part in 450. The oxidation of samples of purified vanillin exposed to air, moisture, and light was practically negligible. With vanillin in solution, however, oxidation proceeds much more rapidly, while solutions of vanillin in alkali behave similarly to alkaline pyrogallol solution. The following corrected melting-points are given: vanillin semi-carbazone, 232°C.; piperonal semi-carbazone, 218°C.; vanillin-*p*-nitrophenylhydrazones, 148°C. (S. B. Phillips, *Analyst*, 1923, 48, 367-373; *J. Soc. Chem. Ind.* 1923, 42, 948 A).

Oxidising agents, in particular ferric chloride, convert vanillin into *dehydrodivanillin*

m.p. 302°-305°C., and the precipitation of the latter can be observed from aqueous solutions containing as little as 1 in 10,000 of vanillin. 20 c.c. of the solution to be tested is heated in a bath containing a solution of calcium chloride at 130°-140°C., and two fractions of 10 c.c. of distillate are collected. Further quantities of 10 c.c. of water are added to the residue and distilled off, until nine or ten such fractions have been collected. These fractions are tested with ferric chloride, it being easily possible to detect and characterise 0.01 grm. of vanillin in the 20 c.c. of sample taken (*cf.* *Chem. Soc. Abstr.* 1923, ii. 887; H. Herissey and P. Delauney, *J. Pharm. Chim.* 1923, 28, 257-262; *J. Soc. Chem. Ind.* 1923, 42, 1197 A).

For other methods, see Fellenberg, *Chem. Zentr.* 1916, ii. 391; Dox and Plaisance, *Amer. J. Pharm.* 1916, 88, 481; Estes, *J. Ind. Eng. Chem.* 1917, 9, 142.

Vanillin is frequently adulterated with coumarin, acetanilide, and with acetyl isoeugenol (Heas and Prescott, *J. Amer. Chem. Soc.* 1899, 21, 256; see also *J. Soc. Chem. Ind.* 1898, 1976; *ibid.* 1899, 604).

According to Winton and Lott (*ibid.* 1910, 1268) genuine vanillin may be distinguished from imitations by determining the lead number which, for the former, should lie between 0.29 and 0.34.

DERIVATIVES OF VANILLIN.

Vanillin forms salts with zinc, lead, sodium, and manganous of the type $(C_6H_4O_3)_2M'$ (Tiemann and Haarmann, *Ber.* 1874, 7, 614).

Bromovanillin $C_6H_4Br(OMe)(CHO)(OH)$, m.p. 187°-188°, crystalline yellow leaflets (Tiemann

and Haarmann, *l.c.*); the corresponding iodo compound has m.p. 174° (Bentley, *Amer. Chem. J.* 1900, 24, 172).

2-Nitrovanillin has m.p. 137°, 5-nitrovanillin, m.p. 176° (Bentley, *l.c.*; Paschorr and Sumuleanu, *Ber.* 1899, 32, 3405).

Vanillin forms an *aldoxime*, m.p. 121°-122° (Decker and Klausner, *ibid.* 1904, 37, 520); a *phenylhydrazone*, m.p. 105° (Tiemann and Kees, *ibid.* 1885, 18, 1662); an *azine*, m.p. 174°-176° (Knöpfer, *Monatsh.* 1909, 30, 29); an *acetyl* derivative, m.p. 77° (Paschorr and Sumuleanu, *l.c.*); a *benzoyl* derivative, m.p. 75° (Wörner, *Ber.* 1896, 29, 143); also a *di-* and *trithio* derivative, in which the oxygen of the aldehyde group is replaced by sulphur, m.p. 129°-130°, 235°-237°, respectively (Manchot and Zahn, *Annalen*, 1905, 345, 320; Wörner, *l.c.*). *Vanillinacetic acid* $CHO \cdot C_6H_4(OMe)O \cdot CH_2 \cdot CO_2H$ has m.p. 188° (Gassmann and Krafft, *Ber.* 1895, 28, 1871).

Vanillin-*p*-phenetidine (*eupyrin*)

is formed by the interaction of vanillin and *p*-phenetidine at 140°; m.p. 97°. It is said to have hypnotic and antineuralgic properties (*D. R. P.* 91171, 96342; *Frdl.* 1894-97, iv. 1183, 1185).

Benzaldivanillin forms microscopic needles, m.p. 221.5°-222.5° (Rogoff, *Ber.* 1901, 34, 3881; *ibid.* 1902, 35, 1961).

Methyl ether of vanillin (veratraldehyde) $(CH_3O)_2C_6H_3CHO$ may be obtained by the methylation of vanillin, and by other methods. It is best to dissolve 1 mol. of vanillin in less than the equivalent quantity of 10 p.c. methyl sulphate on the water-bath, 1 mol. of potash in solution is then added in drops. When the reaction is over the solution is made slightly alkaline when it separates into two layers. The upper layer is extracted with ether, and on distilling off the latter, the pure aldehyde is obtained (Decker and Koch, *Ber.* 1907, 40, 4794). It has m.p. 47° (Juliusberg, *ibid.* 119), and possesses hypnotic properties. The corresponding *ethyl* derivative $CH_3O \cdot C_6H_4(OC_2H_5)CHO$ has m.p. 64°-65° (Tiemann, *Ber.* 1875, 8, 1120). Homologues of vanillin have also been prepared (*Eng. Pat.* 10112, 1895; *J. Soc. Chem. Ind.* 1895, 595).

o-Vanillin (*m*-methoxysalicylic aldehyde) $(CHO : OH : OMe = 1 : 2 : 3)$ is, in the pure state, a solid which crystallises from water in pale yellow needles, m.p. 45.5°, b.p. 265°-266°. It dyes wool and silk from an acid bath a golden or lighter yellow, but the shades are not fast to soap (Noelting, *Bull. Soc. Ind. Mulhouse*, 1909, 79, 401; *J. Pharm. chim.* 1908, 28, 173).

It gives a phenyl-hydrazone, m.p. 139°-131° and a large number of other derivatives. *Cf.* Perkin and Robinson, *Chem. Soc. Trans.* 1914, 105, 2376; Mosimann and Tambor, *Ber.* 1916, 49, 1261.

The root of a species of *Chlorocodon* of Uganda, where it is termed *Murundo*, contains an odorous constituent $C_6H_4O_3 \cdot OMe$, m.p. 41°-42°, b.p. 257°-258°, which forms thin, colourless plates, is isomeric with vanillin, and yields an *azine*, m.p. 138°, and a phenyl-hydrazone, m.p. 137°-138° (Goulding and Pelly, *Chem. Soc. Proc.* 1908, 62).

VANTHOFFITE. The presence of this double salt, $3\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4$, in the abraum-salts at Wilhelmshall near Stassfurt, was detected by plotting on curves the results of several analyses of material from an apparently homogeneous specimen, which was found to consist of a mixture of vanthoffite, loewite, apthitalite, halite, &c. Such intimate intermixtures of minerals of different kinds are really of the nature of rocks, and they must be studied by the methods of petrography; namely, by the examination of thin sections in the polarising microscope, and by separating the individual minerals with the help of heavy liquids (e.g. mixtures of methylene iodide and benzene or tetrabromoethane and toluene). Similar mixtures containing vanthoffite have also been found in the Berlepsch mine at Stassfurt. The mineral has also been observed as nodules embedded, with loewite, in bloedite at Hall in the Tyrol. It is colourless with a vitreous lustre, and a flat-conchoidal fracture; sp.gr. 2.7; H. 3½. The mineral is named after J. H. van't Hoff, who, when its occurrence in the salt deposits was discovered, succeeded in preparing it artificially. When crystals of bloedite ($\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 4\text{H}_2\text{O}$) are heated in contact with their mother-liquid to above 70° they are transformed first into loewite ($\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 2\text{H}_2\text{O}$) and then into the anhydrous salt $3\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4$. L. J. S.

VAPOUR DENSITY *v.* SPECIFIC GRAVITY.

VAREC. *Kelp v.* IODINE.

VARIOLARIN *v.* LICHENS.

VARISCITE. One of the many minerals consisting of hydrated aluminum phosphate, here with the formula $\text{AlPO}_4 \cdot 2\text{H}_2\text{O}$. It forms concretionary and compact nodular masses, sometimes with a minutely crystallised (orthorhombic) surface. The colour is bright apple-green (due to chromium); sp.gr. 2.5-2.6; H. 4-5. It was first found in 1837 in Saxon Voigland (the ancient Variscia), and within recent years has been mined in considerable quantities (3½ tons in 1909, and 2½ tons in 1910) at several places in Utah and Nevada. It is used as a gem-stone, taking the place of green turquoise (D. B. Sterrett, Min. Res. U.S. Geol. Survey, Annual Reports for 1910 and earlier). L. J. S.

VARNISH (Syn. *Vernis*, Fr.; *Lac*, *Firniss*, Ger.). A varnish may be described as a homogeneous fluid, which, when applied by any suitable means in a thin layer over the surface of any object, dries either by the evaporation of the volatile solvent, or by the combined evaporation of the volatile solvent and the oxidation of the component oils and resins to a more or less impervious elastic film of varying degrees of hardness and of generally good weather-resisting properties.

Varnishes, in the drying of which heat is applied in a well-ventilated compartment to expel the solvent and to complete the oxidation so that the film is uniform like glass, are termed stoving varnishes. The simplest form of varnish is the spirit varnish, which is merely a solution of a more or less elastic solid in a volatile solvent. Spirit varnishes dry the most rapidly, but are liable to be brittle and eventually to crack and peel off unless plasticised by the addition of suitable soluble elastic substances. Oil varnishes are, to a large extent,

free from this defect;

contain, binding and softening the resin, and although they take longer to dry, they are generally more lustrous and durable. When varnish is used as the vehicle or medium for the application of a pigment or a pitch to an object, an enamel is produced. Such enamels dry with a gloss, and save labour by combining painting and varnishing in one operation. The solvents employed in making the various varnishes are chiefly turpentine, naphtha and petroleum spirit, kerosene and white spirit, methylated spirit and, recently, higher aliphatic alcohols, e.g. isopropyl, butyl and amyl alcohols. Linseed oil is the drying oil in most general use, but tung oil (China wood oil) is coming more into demand. Walnut and poppy oils are artists' media. The solids, i.e. resins, &c., mostly employed in oil varnish making are: 1. Copal, incl. Kauri, Manila and Congo; 2. Rosin, incl. its glyceryl ester; 3. Asphaltum, including the various pitches. Recently synthetic resins have been tried in the form of coumarone resins and phenol formaldehyde resins incorporated with rosin (Albertols). The resins are solid bodies, generally more or less coloured, amorphous usually with a vitreous lustre, which melt as a rule at comparatively low temperatures often with decomposition. They are insoluble in water, but partially or wholly soluble in a number of solvents, e.g. alcohol, ether, acetone, carbon tetrachloride, benzene, light petroleum, turpentine, &c. In practice the varnish maker is more concerned with the properties of the varnish film than of the original resin, and although, generally speaking, the hardest resin gives the hardest film, the properties of the film are greatly affected by the other ingredients of the varnish and the skill with which they are incorporated.

Resins.—The resins have been classified into hard, medium and soft. Among the hard resins appear Zanzibar and Amber. The medium resins include Kauri, West African and Gold Coast copals. Among the soft resins are Manila (East Indian) and South American resins. Among the spirit varnish resins shellac, dammar, sandarac are hard resins, whereas mastic and rosin are medium, and elemi, oleo-resin turpentine and Burgundy pitch are soft. The solubility of a resin may be said to be in inverse proportion to its hardness. The hard resins and semi-hard resins are but very slightly soluble in their original condition at the ordinary temperature, but they are easily dissolved by turpentine, linseed oil, and other solvents, by previously heating them in such a manner as to cause them to lose by destructive distillation 10-25 p.c.

to the resin dealt with. This partial destructive distillation of the harder resins is necessary before they will dissolve in oil or other solvents. The temperature to which the resins must be heated before they become soluble, is higher in the case of the hard resins than of the soft resins.

Oil Varnishes.—The first process in preparing an oil varnish is selection of the gum; the pieces are sorted out by hand and graded according to their colour and general soundness, and so the gum gives the hardening properties to the varnish and is the most expensive constituent, great

case is encountered in its solution. The selected gum is melted or 'run,' whereby depolymerisation occurs, and then caused to unite with the oil. The gum is heated in a pot of copper, or of iron with a copper bottom, or of aluminium over a rapid fire, until it is perfectly liquid at about 260°-300°C.; a hood or lid is placed over the pot, which is connected to large flues in which the varnish 'fumes' are condensed. The drying oil, specially chosen for varnish making and clarified, is heated and added cautiously at the right moment to the 'run' gum, the whole being kept well stirred, and the heating continued until the mixture is perfectly clear. The driers are added in several ways, either in the form of a lead and manganese soap dissolved in oil or as solid lead and manganese compounds, and the mixture boiled with stirring until the driers are incorporated. The pot is then removed from the fire, and when sufficiently cooled, turpentine or white spirit is added gradually, stirring all the while until the whole is thoroughly mixed. Much inflammable vapour is evolved during these operations, and it is necessary that the varnish house should be so constructed that the vapours do not come in contact with fire.

After the addition of the thinners the varnish is strained into a tank, and allowed to stand until clear for use. The time required for this varies, and as all varnishes improve by age, the longer they are tanked the better. In some cases the driers, consisting of litharge and dry white copperas (cryst. ZnSO_4), are churned at the ordinary temperature with the varnish and the excess of undissolved solids is allowed to settle in tanks. Old varnishes produce surfaces of much greater lustre than new ones. The good qualities of a varnish largely depend on the efficient mixing of the gum and oil; if these are thoroughly incorporated the varnish will be free from spots and blemishes on its surface, while, if well boiled, a varnish is said to flow more freely and to dry more rapidly. Excessive boiling, however, causes the varnish to stouten and thus to require more thinners to bring it to a working consistency, and the resulting fluid, being poorer in its non-volatile constituents, yields a thinner and less lustrous coat. No strict rule on this point can be given, as some oils and gums stouten more rapidly than others, and the final result has to be manipulated according to circumstances.

The drying of oil varnishes varies considerably according to composition, and within certain limits to the proportion of metallic driers present as well as to the objects to which they have to be applied; thus a gold size may dry in a few minutes, while body or coach varnishes require 12-24 hours, and even then should be allowed 2 or 3 days to harden.

Of recent years many attempts have been made to prepare oil varnishes without previous fusion of the gum. Only one has led to successful results, viz. that in which naphthalene under pressure is employed. By this process, which was patented in 1894, the copals are dissolved in naphthalene by heating under pressure to 250°-300°C.; linseed oil or other drying oil is added to the solution and the naphthalene is distilled off. The varnishes obtained by this process are satisfactory and of

good hardness. The objections to the autoclave processes are the capital outlay and the length of time taken in rendering the gum soluble. Other special solvents for copals have been suggested, e.g. linseed oil acids, amyl alcohol, terpineol, &c., but they have met with no success. The effect of the solvent materials on the finished product is deleterious, unless they can be completely removed, which is not feasible. The weight of the gum 'run' in one operation has been steadily on the increase, and nowadays the old charge of $\frac{1}{2}$ cwt. is increased to over 1 cwt. and the whole operation can be performed with complete safety, if proper precautions are taken.

The number of varieties of oil varnishes is large; as many as 200 may be listed, each having its own special use. There is no general classification, although long and short oil varnishes, based on the proportion of resin to oil, is the most acceptable. The most important classes are, coachbuilders' varnishes, including those for carriages, motor cars and railway work; boat, marine and spar varnishes; decorators' varnishes for inside and outside work. Other classes include furniture varnishes, clear and black stoving varnishes and black japans containing pitch. Coachbuilders' varnishes (body and carriage varnishes) must give films which are dust dry within 12 hours and do not crack nor show 'bloom'; moreover, they will retain their lustre for several years, if washed from time to time and occasionally polished with wax. Undercoating varnishes, harder than finishing varnishes, must be sufficiently dry in 10-15 hours to admit of being lightly rubbed down previous to the application of an elastic finishing coat. A film of a blooming varnish shows after a time an opacity which may become permanent. Such surfaces have been found to be strongly polar. Blooming is not confined to oil varnish films. The general formulae of coachbuilders' varnishes may be summarised as follows:

	Resin	Oil	Thianox
Finishing body varnish	60 lbs.	15 gals.	15 gals.
Elastic coach varnish	60 "	12 "	12 "
Hard elastic varnish	60 "	10 "	12 "
Quick hard drying varnish	60 "	8 "	12 "

Undercoating varnishes show bloom when not covered by an elastic finish. Boat varnishes should give a water-resisting film and should not become opaque on immersion in water; these, as well as seaplane varnishes, generally contain China wood oil. Whilst a film of linseed oil never attains a degree of hardness to withstand abrasion, China wood oil gives a harder and more weather-resisting coating. Owing to the rapid gelatinisation of wood oil on heating, copals are largely replaced by rosin and rosin glyceride. Decorators' varnishes for inside and outside work differ slightly in the proportions of gum and oil; the inside varnishes must have good flow, be free from bloom, but great weather-resisting power is not required; for outside work, varnishes on the lines of the carriage varieties are employed. The undercoating varnishes are termed *stoving* or *rubbing*

varnishes, drying rapidly so that in 12 hours they may be rubbed down to a flat surface upon which the finishing variety may be applied. The proportions of gum to oil may be 1:1.25. They are liable to bloom and not durable to weathering unless protected by an elastic finishing coat. Other varieties of decorators' varnishes include: church oak, drying with a hard film, not softening appreciably up to 40°C., suitable for church seats; floor varnish, softer than church oak, with a gum and oil proportion of 1:1.4 or 1:1.67; front door varnish, which must combine elasticity with hardness and lustre; furniture varnish containing rosin: oil=1:1.10, in which rosin is often introduced, and thin coats are applied, rubbing down between each coat until the requisite brilliance is obtained.

Black Japans and Bituminous Varnishes occupy a special position, since they have for their characteristic ingredients a bitumen or asphalt. Both gum resin and oil may or may not be present, as the asphaltic substances differ far more widely in their hardness and elasticity than the various gum resins, and their properties can be modified with greater facility. The most important bituminous varnish in the higher branches of the decorative craft is known as black japan. The term "japan," as applied to substances which promote the drying of a paint film, denotes generally liquids which dry to a hard film possessing considerable coherence. Japan driers give a harder film than the oleo-driers, which are elastic and of a drying-oil character, whilst japan driers are of the nature of a resin varnish containing resin, or rosin with lead and manganese. The specific purpose of black japan is in the production of a brownish-black ground of special translucence or depth, thus differing from pigmented preparations (black enamels), which appear to reflect their depth of colour from the surface only. The main use of black japan in the coach-building trade is for panel work. The varnish is obtained by amalgamating specially treated oil of great drying power with suitable bitumens, in the same manner as described in the manufacture of copal varnish. Black japan itself rarely possesses great elasticity or weather resistance, so that it requires a coating of a suitable finishing varnish. The art of the varnish maker consists in the preparation of a mixing of great degree of depth and intensity of colour without employing so high a proportion of bitumen that the solubility of the latter in the ensuing coat takes place, a condition manifesting itself by the appearance on the finished work of a greenish fluorescence. It is difficult to give a general formula for these coatings, as the quality depends on the selection of the materials. The proportions may be roughly stated as equal quantities of hard resin, asphaltum or petroleum pitch, and boiled oil with turpentine, and white spirit thinners.

Air-drying Black Enamels are made on a far plan to the coachmakers' black japans, but consist of materials which are not so carefully selected, e.g. asphaltum, rosin, boiled oil, and petroleum thinners. Some contain only pitch, oil, and turpentine, and are known as **household blacks**, for which the following formula may be considered as fairly represen-

tative: 45 lb. pitch, 6 galls. boiled oil, and 6 lb. litharge, boiled until stringy and then cooled and thinned with 25 galls. turpentine or petroleum. It is evident that the varieties of blacks will be large in number and will have special names according to their requirements. They may be bright or dead; e.g. Berlin black for grates and fenders, in which the introduction of a black pigment such as carbon black produces a matt appearance. Coach and motor builders require a quick black for iron work, drying in about an hour, a black petrol-resisting varnish of brilliant lustre, drying and hardening quickly, and a dead black metal priming, capable of standing great heat, for the exteriors of cylinders of motor cars.

Black Stoving Enamels are of great variety and a similar classification holds, as in the of resin oil varnishes as to elasticity, body viscosity, and temperature of stoving coating, under-coating and finishing, dipping and spraying modifications are use.

The marked difference between clear varnishes and black stoving enamels lies in the presence of bitumen. The remaining components are drying oils with their attendant driers and thinners, chiefly kerosene, since the temperature of stoving is higher than that of resin-oil varnishes, viz. 150°-177°C. Some black stoving enamels contain no resin or rosin, but generally a certain proportion is present; but it is difficult to identify the resins in the presence of a mixture of bitumens, especially if stearine pitches have been used. Flow and surface are important properties. The finishing coat must have a high lustre and hardness, and should show no runs or rivelling at the edges under the conditions of application, dipping, brushing, or spraying. The production of quality coatings demands careful selection of the components and of the proportions in the mixings. If an under-coating be used it must be adherent to the surface and be rust preventative, providing also a grip for the coat. The under-coatings possess small elasticity, great hardness, good hiding power, but no lustre. They may contain a pigment such as carbon black instead of bitumen, whose function is to leave a dull uniform surface for the finishing coat. The composition and mode of preparation is variable. Among the many published formulae a mixing containing asphaltum, resin, and boiled linseed oil in the proportions of 10; 2.5; 50, with petroleum or turpentine may be considered as fairly representative. The proportions will depend on the requirements and on the temperature of stoving. British Specifications for oil, black and shellac varnishes used in the trade have been issued by the British Engineering Standards Association.

Such black stoving enamels, largely used on ironwork, have great weather-resisting power, but recently cellulose air-drying black enamels have been put forward. It is impossible in the space available to consider adequately the great variety of decorative and protective coatings, as well as their advantages and defects.

For further details reference may be made to R. S. Morrell's *Varnishes and Compounds*, 1923; H. M. Langton, *Blacks and*

VARNISH.

Flückiger, 1923; H. Henton, Volatile Solvents and Thinners, 1925; T. H. Barry, A. A. Drummond and R. S. Morrell, Resins, Natural and Synthetic, 1926; The Analysis of Pigments, Paints and Varnishes, J. J. Fox and T. H. Bowles, 1926.

Spirit Varnishes.—The manufacture of spirit varnishes is much less complicated than that of the oil preparations, the former being simply solutions of one or more resins in various solvents. On the evaporation of the solvent a coating of varnish is obtained, consisting practically of the unchanged resins. The resins employed for this purpose are chiefly shellac, sandarac, soluble Manila, dammar, acaroid, elemi, benzoin, mastic and rosin. The solution of the resins is affected either cold or hot, as circumstances require, heat presenting the advantages of rapid solution and clearing, while the palest varnishes are obtained by the cold process. To facilitate solution the gum should be kept continually agitated, thus preventing the particles of gum from forming a mass. It will be readily seen that the larger the surface of the gum exposed to the solvent the quicker will be the solution. A revolving churn is used, and the rotation keeps the particles in motion and prevents them from caking together. When the gum is all dissolved the varnishes are set aside to settle, and are ready for use almost immediately. They dry very rapidly and are, generally speaking, harder and more brittle than oil varnishes, and as their drying is merely dependent on the evaporation of the solvent the addition of driers is not required. Within recent years many forms of artificial or synthetic resins have come into use. They may be broadly classified into (1) condensation resins—e.g. the formaldehyde-phenolic resins; (2) polymerisation resins—e.g. the coumarone resins, which are obtained by the treatment of certain distillates from coal tar naphtha. Condensation resins are such as are made by preliminary interaction of at least two chemical substances, generally involving elimination of water. Resinification may be completed by a polymerising action.

Formaldehyde phenolic resins.—The most important condensation resin is made from formaldehyde and phenolic compounds. Bakelite is the typical example. Amongst other trade products of similar character are—in America, Redmanol, Condensite, Amberite, Phenoform, Sibolite, Nuloid, Amberdeen, Abalac, etc.; in France, Melusite, Cerite; in Great Britain, Elo, Bakelacque. There is a marked difference in the properties of the formaldehyde phenolic resins compared with the natural resins. The natural resins can be melted, but not 'run,' and cooled, without great change in their solubility or fusibility, but the phenol synthetic resins on heating may, under certain conditions, pass more or less rapidly into solid infusible resins, charring at 300°C.; moreover, the resin becomes insoluble in all ordinary solvents and has acquired a remarkable increase in strength.

It is this marked change in properties which has made Bakelite products so valuable as substitutes for wood. The formaldehyde resins are of two distinct types—

analogous to the resins of the natural resins.

form the class of shellac substitutes (called Novolak by Baekeland). They are analogous to shellac in their solubility relationships; they are soluble in alcohol and insoluble in hydrocarbons. The second type of resin is that in which the resin is soluble and fusible only in an intermediate stage and becomes insoluble and infusible on heat treatment, being finally in the *resite* condition, passing through the intermediate *resitol* stage. Bakelite, Elo, and Bakelacque are examples of this latter type. Baekeland terms these latter resins *resinoids*, as they do not possess all the properties common to the natural resins.

For details as to preparation and further application reference must be made to Carleton Ellis, Synthetic Resins and their Plastics, 1923, and to the Chemistry of Natural and Synthetic Resins by Barry, Drummond and Morrell, 1926.

The chemical changes occurring during the manufacture of these substances are not yet understood, although considerable advance has been made during the last few years. The varieties of resin produced is dependent on the amounts of formaldehyde and phenol used and whether the catalyst is acidic or basic in character. Baekeland (J. Ind. Eng. Chem. 1909, 1, 159) uses ammonia as catalyst. An acid catalyst will tend to produce a soluble resin, whereas an alkali favours an insoluble resin. The greatest development of these resins has been in the direction of moulding and insulating compounds.

Formaldehyde-urea Resins.—Condensation products of formaldehyde with urea and thiourea have been used to give viscous products which may be gelatinised in several hours. The reaction takes place in two stages, a condensation phase followed by a polymerisation phase. The solid resins obtained are transparent, colourless, stable, taking a high polish, and may be used as substitutes for glass; Polloplas and the Beetle Products Company resins are examples. In Pollak's Schellan solutions the resin is maintained in water solution by alkali salts of weak acids, e.g. sodium acetate or a borax solution of shellac.

Coumarone Resins are obtained from the fraction of solvent naphtha 150°–200°C., and are polymerised as regards certain of their constituents by sulphuric acid to yield 25–40 p.c. of resin. These resins are not usually soluble in alcohol, and benzene, toluene, solvent naphtha, and turpentine are the best solvents. They are miscible with drying oils. The differences in the technical coumarone resins depend on the variable proportions of a coumarone present. The following is a formula for a coumarone oil varnish: China wood containing 15 p.c. of linseed oil is mixed with the resin in the proportion of 5–40 per 100 lbs. resin. The driers used are or manganese linoleates, and the thinner heavy refined coal-tar naphtha, b.p. 160°C. Typical varnish mixtures for coumarone are described by King, Bayard, Rhodes, (J. Ind. Eng. Chem. 1923) and R. S. Morrell (Varnishes and Resins, 1923).

Cellulose Ester Varnishes.—Cellulose esters are of any importance.

industry, viz. the nitrate and the acetate, formed by combination of cellulose with nitric acid and acetic acid respectively. These substances are soluble in certain mixtures of organic liquids, which have a comparatively high rate of evaporation, and when the solutions are spread on solid surfaces they rapidly become dry, leaving the cellulose ester in the form of a continuous film. By making certain additions to the original solutions, the hardness and adhesiveness of the films may be modified. Owing to the rapidity with which the solutions dry, they may be applied at ordinary temperatures, although a warm room is advantageous. As a rule a coating is dry under an hour. All organic protective coatings consist of highly polymerised structures. The degree to which the original cellulose is depolymerised or degraded in structure before and during the manufacture of the ester determines to a considerable extent the properties of the resulting varnish.

Nitrocellulose Varnishes.—The cellulose ester varnishes may be either transparent or opaque. The transparent varnishes may be coloured in practically any tint so as to give a coloured transparent lacquer coating. The opaque varnishes containing pigments may also be obtained in any colour, and are usually termed enamels. It is customary to include all solutions of cellulose esters used for protective or decorative coatings under the general term of cellulose varnishes. They may be applied by brush, but better results are obtained by dipping or by use of an air spray. Under proper conditions the solutions dry with a high polish, and the films resist water, petrol, soap, turpentine, weak acids and weak alkalis.

Cellulose nitrate lacquers.—The common metal lacquer usually contains not more than 5 p.c. of cellulose nitrate, in a mixture of solvents, and serves to delay the tarnishing of metal, not acting as a finishing material. In order to increase the solid content it was necessary to produce cellulose nitrate, which, when dissolved in suitable solvents, gave a solution of low viscosity. The addition of natural resins was found to impart adhesion and rubbing properties in varying degrees according to the resin employed and the amount used. The constituents of finishing lacquers may be: cellulose nitrate of low viscosity, resins to make the film glossy and hard, solvents which control the rate of drying, degree of gloss and viscosity of the lacquer, and plasticides to remain in the film after the solvents have evaporated and so to give it elasticity. Scrap celluloid as a substitute for cellulose nitrate has many drawbacks, and its use is not to be recommended. The resins are either of the soft or medium hard varieties. Butyl alcohol, ethyl, butyl and amyl acetates, ethyl lactate and amyl formate may be used as solvents. D. B. Keyes classifies the solvents into three groups: (1) low boiling solvents, reducing the viscosity of the lacquers and possessing a high rate of evaporation; (2) medium boiling, giving the lacquers the property of flow; (3) high boiling, acting as a solvent, preventing the precipitation of nitrocellulose or the resin.

The lacquers are best applied by brush or spray. The finished surface may be brushed on.

The order of application of the cellulose coatings, careful consideration of their elasticity must be taken, so as to prevent subsequent cracking of the film. Pigmented lacquers and enamels have been used for many years as protective coatings for bathroom fittings, cycle and motor lamps and furniture. The following proportions of cellulose nitrate, resin and plasticide have been found satisfactory for interior lacquer enamels: cellulose nitrate 12 parts; resins 6 parts; plasticide 2 parts. This ratio will give a hard and elastic film provided too much pigment is not added. For further details reference may be made to F. Sproston, *Cellulose Ester Varnishes*, 1925.

Cellulose acetate varnishes.—Solutions of cellulose acetate in a mixture of high and low b.p. solvents are used for tautening and weather-proofing linen fabric composing the wing surfaces of aeroplanes. A typical three-coat formula would be cellulose acetate 8.5 parts, acetone 50, alcohol 24, benzene 24, benzyl alcohol 2 and triphenyl phosphate 1.5. For durability the dopes must be specially pigmented and generally require a protective coating of a seaplane oil varnish.

Natural varnishes or lacquers.—Japanese lacquer is the milky juice exuding from the trunk of *Rhus vernicifera* (Tsi-chou, varnish tree). The tapping of the tree resembles that of *pinus* for turpentine oleoresin. The raw varnish, which is frequently adulterated with tung and perilla oils, is known in Japan as Ki-urushi. The peculiarity of the varnish is that it hardens only in a moist atmosphere and remains in a tacky condition to sunlight and heat. It is the most durable varnish known and resists the action of air and water excellently. It is stated to be the best protective coating for aeroplane propellers. The application of the lacquer is said to be dangerous to western workers owing to the peculiar poisonous properties of the *urushiol* in the resin. The resin has been investigated by Japanese chemists, who have synthesised hydrourushiol, the reduction product of the active principle of Japan lac. A concise account of Chinese and Japanese manufacture will be found in the Bulletin of the Imperial Institute, 1910, 8, 32; and in Stewart Dick's *Arts and Crafts of Old Japan*, 1908.

R. S. M.

VARVIGITE. *Hydrated manganese ore*
 $\text{MnO}_2 \cdot \text{Mn}_2\text{O}_3 \cdot \text{H}_2\text{O}$ (Rammelsberg), or

(Phillips) (v. MANGANESE).

VASOTONIN. Trade name given to a combination of yohimbine and urethane which produces a fall of blood pressure, and appears to have considerable therapeutic value (China. Soc. Abstr. 1910, ii. 725).

VAT DYES. The term 'vat dye' is applied to those dyestuffs which, like indigo, are insoluble in water, dilute acids, and alkalis, but which, on being treated with suitable reducing agents, yield leuco compounds which are soluble in the hydroxides of the alkalis or of the alkaline earths, and in dyeing are taken up in such by textile fibres. By subsequent exposure to the air the leuco compound is oxidised to

and in the fibre, with the re-formation of the original colouring matter. The characteristic fastness of the colours thus produced is, in a large measure, due to the insolubility of the dyestuff.

Indigo (*q.v.*), which was formerly the only known vat dye, is by far the most important of this series of colouring matters, and has been used in dyeing from time immemorial. A blue, dyed with it on cotton, is still referred to as a 'vatted blue,' whilst in the woollen industry the term 'wooded blue' means a blue which is dyed either wholly or in part with indigo.

In preparing or 'setting' the indigo vat, various methods are employed in practice to bring about the reduction of the indigotin. This is effected either by purely chemical or by bacteriological means, but in either case the product of the reaction is the same, viz. indigo white, $C_{16}H_{11}N_2O_2$, or graphically,

which dissolves in caustic soda with the formation of either the mono- or di-sodium salt ($C_{16}H_{11}N_2O_2Na$ or $C_{16}H_{10}N_2O_2Na_2$), according to the amount of caustic soda present in the bath. It has been shown that indirubin and thioindigo red also require 2H for reduction, and by analogy it is presumed that the other indigoid dyestuffs behave similarly. In aqueous solution, the mono-sodium salt of indigo white has been shown to be an electrolyte, though it is not so strongly ionised as sodium chloride (Knecht and Batey, J. Soc. Dyers, 1910, 171).

The so-called chemical vats are distinguished, according to the reducing agent employed, as the copperas, the zinc, and the hydrosulphite vats. They are used in cotton dyeing, but the hydrosulphite vat also finds a limited application in wool dyeing. In the setting of any indigo vat, it is essential that the indigo should be in a finely divided state. The 20 p.c. artificial indigo paste contains the colouring matter in a sufficiently finely divided condition for the purpose, but the natural product must be ground, before use, to an impalpable powder.

The *copperas vat* depends upon the reducing action of ferrous hydroxide, and is made up of indigo, copperas and slaked lime. The lime reacting with the copperas forms ferrous hydroxide

which in turn reduces the indigotin to indigo white:

which then dissolves in the excess of lime present to form the soluble calcium salt. In the *copperas vat*, there is always a large amount of sediment, and to prevent this settling into con-

with the goods during dyeing, deeper vessels are required than with the other chemical vats. At the present time, the copperas vat is not largely used in this country, the main reasons being that its use involves a considerable loss in indigo, and the sediment in the vat is very bulky. On the other hand, the blues obtained in the copperas vat are faster than those obtained in the zinc or hydrosulphite vats.

In the *zinc vat*, zinc powder is the reducing agent. For satisfactory working, this should contain not less than 80 p.c. of metallic zinc. The vat is set with indigo, zinc powder and lime (or caustic soda). The reduction may be regarded as taking place as follows:

although, according to Binz (Chem. Ind. 11, 1902), it is probable that combination of the indigotin with the alkali takes place first, with the formation of a compound

which then reacts with the zinc, forming the same products as shown in the above equation.

This vat is the one which is most largely used in cotton dyeing.

The *hydrosulphite vat* depends upon the reduction of the indigotin by sodium hydrosulphite, which is usually prepared by stirring zinc dust into commercial sodium bisulphite, in the proportion of a pound of the former to a gallon of the solution; and after allowing to stand for some time, adding to the solution an excess of milk of lime. The so-called 'stock vat' or concentrated vat is made by dissolving the indigo in this muddy liquid. (A product of this kind, containing about 3 p.c. of indigotin, was formerly sold under the name of 'reduced indigo.') This stock vat serves either for making up or for replenishing the dye vat proper. The reduction by means of sodium hydrosulphite may be regarded as taking place according to the following equation:

By employing artificial indigo paste, caustic soda, and the solid commercial sodium hydrosulphite, which is now placed on the market in an almost pure condition and at a reasonable price, it is possible to obtain a vat practically free from sediment.

The dyeing of cotton in the indigo vat is in itself a comparatively simple operation, although the management of the vats requires careful supervision and considerable practical experience. In hank dyeing, the wetted-out hanks are immersed in the vat and turned by hand under the surface of the liquid until thoroughly impregnated with the vat liquor, after which they are withdrawn and wrung, the liquor being returned to the vat. The hanks are then exposed freely to the air, in order to allow of the oxidation of the indigo white to indigotin. By repeating this operation several times, the shade becomes successively darker, and its depth will

one and the same or in different vats. Although it is possible to obtain a dark shade by a single dip in a strong vat, this is not practised, because it would result in a large proportion of the indigo being loosely fixed and much of it would be lost in washing off; besides, the resulting blue would 'rub off' very badly. The oxidation of the indigo white taken up by the fibre from the vat is usually regarded as taking place in the following manner:—

though under chosen conditions it has been shown by Herzog and Manchot that auto-oxidation may take place, resulting in the formation of equal molecular proportions of indigotin and hydrogen peroxide (Annalen, 316, 318). This interesting observation may account, according to Crowther, for the presence of isatin in the hydrosulphite vat (J. Soc. Dyers and Col. 1911, 146). It is further evident that the dyed cotton material removes a considerable amount of alkali from the vat. Where lime is used in the vat in place of caustic soda, an accumulation of calcium carbonate on the fibre occurs through air exposure, and the goods therefore soured, after dyeing, in dilute sulphuric acid. In the dyeing of cotton warps and of piece goods, the material is guided through the vat by means of submerged rollers, so that it passes many times up and down between the time of entering and leaving; excess of liquor is expressed at the point of exit by means of a pair of squeezing rollers. In case it is desired to give the pieces two or more 'dips' in the same vat, they are stitched together, end to end, so as to form a continuous band, and, after leaving the vat, are passed up and down over a series of loosely running wooden rollers (which are usually placed immediately above the vat in order to economise space) for a sufficient length of time to allow of the oxidation of the indigo white before they re-enter the vat.

The reason why indigo white should be taken up from its aqueous solution by the cotton fibre is imperfectly understood. It has been suggested that it is a case of mutual precipitation between colloids, but as it has been definitely shown (see above) that indigo white lacks some of the most essential properties of a colloid, this theory cannot hold good. In any case, the affinity of indigo white for cotton is but slight, as, when once taken up, it can be completely removed by continued washing with cold, air-free water, whereas a boiling solution of dilute caustic soda removes it from the fibre almost instantaneously. The affinity of indigo white for cotton appears to be similar in character to that of tannic acid for this fibre (Knecht and Nair, *ibid.* 1912, 28).

If the cotton to be dyed in indigo or other vat dyes has been previously mercerised, darker shades are obtained than on untreated cotton. The same applies with regard to indigo and certain indigoid dyestuffs if the cotton has been previously dyed manganese bronze or has been steeped for some time in strong nitric acid (see *Mercerising*). In the latter case, the increase in depth is due in a greater measure to slight nitration of this fibre than to the mercerising effect of the acid.

Indigo dyed on cotton is sometimes associated with other colours. Thus, if a light shade of indigo is 'topped' or subsequently dyed chrome yellow, pleasing and very fast shades of green result. The old-fashioned 'fast black' was obtained by a combination of a heavy shade of indigo and catechu brown. The dyeing of a black of this description was practised by the Incas of Peru prior to the Spanish invasion.

Indigo dyed on cotton is usually regarded as fast to washing and to light. Strictly speaking, however, these qualities are only relative, for by repeated washing in soap or continued exposure to light, the colour (especially in light shades) gradually fades. But in fading it always retains the characteristic colour of indigo and does not change, as is the case with most other blues, to an unsightly grey or drab. It is noteworthy that the fastness of indigo to light may be considerably enhanced by treating the dyed fabric for a few minutes in a boiling dilute solution of copper sulphate.

In Egypt, Persia, India, China, Japan, and other Eastern countries, where dyeing is still almost entirely a household industry, fermentation vats are generally used for cotton dyeing. Such vats are occasionally used in this country for the dyeing of goods for certain markets. The fermentation vat imparts a certain peculiar smell to the goods dyed in it, and unless they possess this smell, the natives in some markets will not accept them as indigo-dyed. A product known as indigo essence, consisting of a mixture of the methyl ethers of α -naphthol and β -naphthol, is put on the market for the purpose of imitating this smell on material dyed blue with dyes other than indigo.

The dyeing of wool with indigo differs from the dyeing of cotton in that whereas cotton is invariably dyed cold, the temperature of the vat for wool dyeing must be maintained at from 50° to 55°. Another point of difference is that in the case of wool, the time of immersion in the vat has to be much longer than in the case of cotton.

For wool dyeing, especially where fermentation vats are used, natural indigo is generally preferred to the artificial product.

Only one of the vats generally used in cotton dyeing can be used with advantage in wool dyeing, viz. the hydrosulphite vat. This is set with indigo, sodium hydrosulphite and ammonia. Although the cost of working this vat is greater, as far as materials are concerned, than that of the fermentation vats, this is more than compensated by its greater output. It is, however, only suitable for light to medium shades of blue.

The fermentation vats, of which a considerable variety are in use in different countries and sometimes in one and the same country, might appear at first sight to depend for their action upon different principles. But it is probable that in all cases the action depends upon a bacterial decomposition (butyric acid fermentation) of the carbohydrates, in which hydrogen is generated. Various substances containing carbohydrates, such as bran, flour, sugar, meal or dates, are used along with lime, potash, or soda for the purpose. The setting and management of fermentation vats require considerable skill and experience, and in all large works these matters are under the sole

control of the 'blue dyer,' upon whose intelligence and efficiency the prosperity of the works depends.

The fermentation vat mostly used in this country is the so-called *woad vat*, which is set in a vessel having a capacity of from 1600 to 3000 gals. with indigo, woad, bran, madder and lime, the temperature being maintained at 60°. The fermentation will have set, as a rule, in from three to five days, and the vat will then be ready for use. Once set, a woad vat simply requires replenishing, from time to time, with the necessary additions of indigo, lime, and bran, and may remain in use continuously for many years. It should be explained that in this vat the woad, which in former times (before the introduction of indigo from India) was the only indigo-bearing dyestuff used in this country and on the Continent, now acts solely by virtue of the bacteria which it contains, for in commercial woad there is, at the present day, no indigotin, the whole of the colouring matter having been destroyed by bacterial action.

Dyed on wool, indigo resists the action of light better than when dyed on cotton.

The disulphonic acid of indigotin, which is obtained by heating the dyestuff to about 100° with excess of concentrated sulphuric acid, is known commercially as indigo extract or, in the form of its sodium salt, as indigo carmine. It dyes wool 'at the boil' from a bath containing sulphuric acid and Glauber salt a much brighter shade of blue than that obtained in the vat, but the colour is neither fast to light nor to soap, and goods so dyed cannot be classed as being dyed with indigo.

Silk is seldom dyed in the indigo vat, although fast and pleasing shades can be obtained in this way.

Indigo in printing.—In textile printing, notably in calico printing, indigo may be regarded as the most important individual dyestuff in use at the present time. This is partly due to the favour which it finds with the public as being pleasing to the eye and relatively fast, and partly to the variety of styles to which it lends itself in this branch of textile colouring. Effects are obtained with indigo in printing in three entirely different ways, viz. by direct printing, by the discharge process, and by the resist process.

In direct printing, the indigo is not printed on to the fabric in the reduced condition (a process which would obviously suggest itself at once to any one acquainted with its properties and its application in dyeing) owing to practical difficulties which this mode of application entails. The process in actual use is the so-called *glucose process*, in which glucose and caustic soda serve as the reducing agent. The pieces are first prepared by padding in a solution of glucose and are then dried. The finely ground indigo is made up with strong caustic soda thickened with maize starch and British gum. This is printed on to the prepared calico and the goods are run through a rapid ager containing air-free moist steam, the time required for this treatment being about half a minute. During the steaming, the indigo is reduced to indigo white which dissolves in the caustic soda and penetrates into the fibres. By subsequent exposure to air, the indigo white slowly oxidises

back to indigo blue. The operations of preparing in glucose and drying may be dispensed with by adding to the printing colour a suitable reducing agent such as the formaldehyde compound of sodium sulphoxylate (hydrosulphite NaF). This has no action on indigo in the cold, but reduces it on steaming for two to three minutes. The goods are then exposed to the air as in the glucose process.

Indigo may also be produced on the fibre in printing (or in dyeing) by means of *indigozol*, a product discovered by Messrs. Sunder and Bader, and recently introduced by Messrs. Durand and Huguenin. The new product is a comparatively stable compound of indigo white, soluble in water and in caustic soda. The printed or padded pieces are run through a weak bath of nitrite of soda and acid, when the indigo instantly develops on the fibre. The blues obtained in this way are faster to rubbing than those obtained in other ways.

In the discharge process, which lends itself to a greater variety of effects, the whole piece is first dyed to the required depth of blue in the vat and the colour is then removed locally either by destroying it by means of oxidising agents or by reducing it to the leuco compound and removing this by means of boiling dilute alkali. The former process, which is the one chiefly employed, consists in printing sodium chromate, suitably thickened, on to the blue fabric. After printing, the goods are run through a warm solution of sulphuric and oxalic acids, when in consequence of the liberation of chromic acid, the indigo is oxidised to isatin and this is removed in the subsequent washing, a white pattern on a blue ground resulting. For coloured discharges, the chromate is mixed with albumen and a suitable pigment, such as vermilion or chrome yellow, and the goods are run, after being printed, through the mixture of acids at a temperature high enough to coagulate the albumen. The fixation of the pigment and the destruction of the indigo thus take place simultaneously. The process is capable of many modifications. Thus, in order to obtain a bright scarlet on a blue ground, the indigo-dyed fabric is padded first with an alkaline solution of β -naphthol, dried and printed with a colour containing diazotised *p*-nitraniline and sodium dichromate. The *p*-nitraniline red thus formed resists the action of the chromic acid formed when the pieces are run through acid and a bright red on a blue ground results.

Indigo may also be discharged by printing on sodium nitrate and running the goods through warm sulphuric acid of 100°Tw. (Freiberger's process).

In the reduction discharge process, the pieces are printed with the formaldehyde compound of sodium sulphoxylate with or without the addition of a catalyst such as anthraquinone. They are then steamed in the rapid ager to reduce the indigo and immediately run through a boiling bath of caustic soda, soda ash, or sodium silicate. The indigo white is thus completely removed and there is no tendering of the discharged places, as is invariably the case when the chromate discharge is used.

In the resist process, the fabric is first printed with a mechanical or with a 'chemical resist,' and is then dyed in the vat. Wherever the resist

has been printed no colour is fixed, and a white pattern on a blue ground results. In the East, and also to some extent in European print works, wax is used as the resist. After dyeing it is removed by soap and alkali. When the goods are handled (as in dyeing) after the wax has been printed on, the latter cracks in places so that in the dyeing some of the reduced indigo liquor penetrates through the fissures, with the result that fine blue veins are afterwards seen in the pattern. This defect is characteristic of all true Battick work, which the modern printers are at pains to imitate.

The 'chemical resist' mostly used at the present time is a very thick colour containing copper sulphate, lead nitrate, and China clay, usually thickened with flour and British gum and with or without the addition of such mechanical resists as tallow or rosin. As with the wax resist, the dyeing is best conducted in the zinc vat. By increasing the amount of lead nitrate in this resist so as to exceed its equivalent in copper sulphate, and running the goods after dyeing through sodium dichromate, lead chromate is formed in the resisted parts and a yellow pattern on a blue ground results.

VAT DYES OTHER THAN INDIGO.

Although it has long been known that indirubin (an isomeride of indigotin which occurs in almost all natural indigos) can be dyed in the same manner as indigo, it has never found any technical application, partly on account of the shade it yields being undesirable and partly for other reasons. The tetrabromo (5:7:5':7') derivative, obtained by brominating the artificially prepared dyestuff in nitrobenzene solution is, however, a useful vat dye, and comes into the market under the designation *Ciba Heliotrope B*. *Indophenol*, which was discovered in 1882 by Koechlin and Witt, is also a vat dye, and although it was a commercial article in the '90's it was never much used, mainly because it produced loose colours, and it is now entirely obsolete.

The enormous development in the vat colour industry that has taken place during the last few years may be traced, on the one hand, to the discovery of indanthrene blue by Bohn in 1901, and on the other hand to the synthesis of thioindigo red by Friedländer in 1905. At the present time there are well over one hundred individual dyestuffs which may be strictly classed as vat dyes, without taking into account the large number of sulphide colours (*q.v.*) which, in a sense, might also be classed as vat dyes. It would obviously be out of place to embody the whole of our present knowledge of the vat dyes in this work, as that would require an amount of space which would not be commensurate with the general interest attaching to the subject. In the following, it will therefore be understood that the examples given are only typical of the various classes. For further information on the subject of vat dyes, see Engi, *Chem. Zeit.* 1908, 1178; Bohn, *Ber.* 1910, 987; Staebli, *Chem. Zeit.* 1910, 731 *et seq.*; Friedländer, *ibid.* 1911, 640; Masera, *Färber-Zeit.* 1911, 336; Grandmougin and Battagay, *Ela. Text. Bl.* 1910; Malloch, *J. Soc. Dyers*, 1910, 26; Ermen, *ibid.* 1910, 56 and 236; E. de Barry Barnett,

ibid. 1913, 185; L. E. Vlies, *ibid.* 1914, 22; Truttwin, *Enzyklopädie der Küpenfarbstoffe*, 1920; J. F. Thorpe and C. K. Ingold, *Vat Colours*, 1923; The 'Colour Index' of the Society of Dyers and Colourists, edited by F. M. Rowe, 1924; Knecht, Rawson and Loewenthal, *A Manual of Dyeing*; Knecht and Fothergill, *The Principles and Practice of Textile Printing*, 1924.

These vat dyes may be classed under two headings, viz. as (a) indigoid dyestuffs, and (b) anthraquinonoid dyestuffs. The former come into the market under various trade names such as indigos of various brands, the Durind colours (British Dyestuffs Corporation), anthrene colours (British Alizarine Co.), the Ciba colours (Soc. of Chem. Ind., Basel), while the latter are represented by the anthrene colours (British Dyestuffs Corporation), the Caledon colours (Solway Dyes Co.), and the Cibanon colours (Soc. of Chem. Ind., Basel). V. INDIGOID DYESTUFFS, Vol. III. p. 620.

The bromo derivatives of indigotin are brought into the market under different designations, such as indigo pure R.B.N., ciba blue, indigo K2B, and generally yield, in dyeing and in printing, either redder or greener shades of blue than indigo itself, according to the amount of bromine which they contain. Thus *indigo R* is 5 bromoindigo, *ciba blue 2B* is 5:7:5':7'-tetrabromoindigo, and *indigo KG* consists mainly of 4:5:7:4':5':7'-hexabromoindigo. There is no object to be gained in substituting more than five hydrogen atoms in the indigo molecule, as the leuco compounds of the more highly halogenated derivatives are so sparingly soluble as to preclude their practical application. The 6:6'-dibromoindigo synthesised by Friedländer, and shown by him to be identical with the *Tyrian purple* of the ancients, is not a commercial article. It is interesting to note that the 6:6'-dibromoindigo dyes an amethyst shade (Tyrian purple) whereas the isomeric 5:5'-dibromoindigo (*indigo RB*) dyes blue. The position occupied by the halogen atoms in the molecule is of importance in other instances. Thus the entrance of the halogen atoms in the para-position with reference to the nitrogen atoms causes but little alteration in the colour, although the shades are brighter than those from indigo itself. If the halogen atoms occupy the para-position to the CO groups, the dyes obtained are redder in shade than indigo.

Of homologues of indigo, the 7:7'-dimethylindigo (*methyl indigo B*), and the 5:5'-dimethylindigo (*methyl indigo R*) are the most important commercial representatives. The former dyes cotton a greener and the latter a redder shade of blue than indigo itself.

Thioindigo red B or thionaphthene indigo

was discovered in 1905 by Friedländer and is obtained by fusing *o*-carboxyphenylthioglycollic acid with caustic potash to form thioindoxyl, which is then oxidised to the dyestuff. This dye results from the action of dichloroethylene on thioacetylic acid, followed by treatment with sulphuric chlorhydric. The discovery of this product marked the beginning of

a new era in the history of organic colouring matters, for it opened up a new field and has resulted in the introduction of a large number of new and valuable vat dyes. Like artificial indigo and most other commercial vat dyes, thioindigo red B comes into the market in the form of a 20 p.c. paste. The pure colouring matter is readily obtained from the dried paste by crystallisation from benzene or toluene in well-defined dark red crystals. Its solution in benzene is red and shows a characteristic intense yellow fluorescence. In concentrated sulphuric acid it dissolves with a bluish-green colour; but on pouring the solution into water, the original dyestuff separates. By warming with fuming sulphuric acid, it is sulphonated and the soluble sulphonic acid thus obtained dyes wool from an acid bath a full bluish shade of red. Unlike indigo, thioindigo red is not affected by oxidising agents, remaining unaffected by chromic acid, alkaline ferrocyanide and bleaching powder; whilst, on the other hand, it is more readily reduced than indigo. It has been shown that the reduction of thioindigo red to its leuco compound is analogous to that of indigo, two atoms of hydrogen or their equivalent being required for one molecular weight of the dyestuff (Knecht, J. Soc. Dyers, 1906, 156). Like indigo white, the leuco compound dissolves readily in caustic alkalis, forming a yellow vat from which it is taken up by the cotton fibre, the red reappearing on exposure to the air.

Of derivatives of thioindigo red, the following may be mentioned:

Thioindigo red B.G (dichlorothionaphthene indigo) $C_6H_4Cl<\underset{S}{CO}>C=C<\underset{S}{CO}>C_6H_4Cl$; *thioindigo red 3B* (dichlorodimethylthionaphthene indigo)

thioindigo violet 2B (dichlorodimethyldimethoxythionaphthene indigo); *thioindigo orange R* (6:6'-diethoxythionaphthene indigo); and *thioindigo gray* (7:7'-diaminothioindigo). In general it may be said that the introduction of substituents such as OH, OCH₃, OC₂H₅, SCH₃, SC₂H₅, NH₂, &c., in the para- position to the sulphur atoms produces a deepening of the shade to blue-violet, greenish-black, &c. Substitution in the meta- position to the sulphur atoms produces yellower shades—orange, orange-brown and scarlet. Halogenation darkens the shade of thioindigo red.

Thioindigo scarlet R

obtained by the action of thioindoxyl on isatin contains the characteristic groupings of thioindigo red and of indirubin. When acted upon by bromine in sulphuric acid solution it yields a dibromo derivative which is placed on the market under the name of *thioindigo violet K*. The tribromo-amino derivative represents *thioindigo brown G*.

Ciba scarlet G (also known as *thioindigo scarlet 3G*) is a non-nitrogenous product, ob-

tained by the condensation of thioindoxyl with acenaphthene quinone and has the constitution

By the bromination of this dyestuff, *Ciba red R* results.

Of other indigoid dyestuffs, mention may be made of *Ciba yellow 3G*, which is obtained by boiling indigo with benzoyl chloride and copper powder in nitrobenzene, and to which the constitution

has been described. The complete change from blue to yellow is remarkable.

By the condensation of α -naphthol with α -isatinchloride, a compound is obtained with the following *orthoquinonoid* structure

and is, in a sense, also indigoid in character. The tribromo derivative is known as *Alizarin indigo 3R*. The corresponding compound from alpha anthrol and dibromoisatin is known as *Alizarin indigo G*.

The indigoid dyestuffs all behave very much like indigo towards reducing agents, i.e. they yield leuco compounds (corresponding to indigo white) which dissolve readily in caustic alkalis, and in this condition show affinity for the textile fibres. The affinity of the different dyestuffs for the cotton fibre varies, however, in each case, so that their successful application, especially in the production of mixed shades, requires a considerable amount of practical experience. The reducing agent employed for these colouring matters (in fact for all vat dyes other than indigo) is invariably sodium hydrosulphite, for although it is not the most economical, it is the most effective and convenient reagent for the purpose and yields vats which are free from sediment. In principle, the dyeing of cotton with these dyestuffs is the same as the dyeing of indigo in the hydrosulphite vat. The optimum temperatures vary, however, according to the individual dyestuff, from the ordinary temperature (as used for indigo) to temperatures as high as 70°. The range of shades obtainable contains almost every colour of the spectrum, and some of these vie in brilliancy with the basic colours. Most of the colours are characterised by great fastness, and are in this respect superior to indigo. Hitherto no indigoid black has been produced.

Although originally applied to dyeing and printing on cotton and other vegetable methods have been devised by which colouring matters can be successfully applied in wool dyeing, by substituting ammonium

the caustic soda in the vat or neutralising the effect on the fibre of the caustic soda by the addition of some soluble oil (see H. Kämmerer, J. Soc. Dyers, 1913, 68).

In calico printing, the indigoid dyestuffs can be applied by methods similar to those employed for indigo, with the exception of the chromic acid discharge, which cannot be used owing to these dyestuffs being either not affected at all by chromic acid, on the one hand, or yielding imperfect discharges on the other. They can, however, be discharged by means of the formaldehyde compound of sodium sulfoxylate. For further information on the use of these colours in calico printing, see N. Evans, J. Soc. Dyers, 1913, 144.

Anthraquinonoid dyes.—The first of these dyestuffs brought into the market was *indanthrene blue*, a product formed by the action of molten caustic potash on β -aminoanthraquinone, and possessing the constitution

It is a dark blue compound insoluble in water, dilute acids, alkalis and most ordinary organic solvents. It can be obtained in well-defined crystals from its solution in quinoline or by sublimation. Oxidising agents convert it into the yellow azine

(containing 2 atoms of hydrogen less), but this is readily reconverted into the dyestuff by the action of reducing agents. Acted upon by hydrosulphite in presence of an excess of caustic soda, indanthrene blue yields a blue vat from which cotton and other vegetable fibres can be dyed in exceedingly fast shades of blue. The composition of the leuco compound of indanthrene blue and other anthraquinonoid vat dyes is not known with certainty, but it is evident from the behaviour of anthraquinone, alizarin and the non-nitrogenous anthraquinonoid dyes that reduction takes place in the $-\text{CO}-$ group, resulting in the formation of compounds analogous to oxanthranol

or the isomeric anthrahydroquinone

where in either case 2H would be required for the reduction. The further reduction to anthranol

requires 4H or its equivalent. In this connection it may be mentioned that in the quantitative estimation of alizarin by titration with titanous chloride in presence of sodium tartrate (J. Soc. Dyers, 1915, 241) the analogous reduction to desoxyalizarin

takes place, 4H being required.

To what extent the four $-\text{CO}-$ groups of indanthrene blue suffer reduction in the formation of a 'vat' is not known at the present time, and this applies also to the other ant' quinonoid dyes.

Halogen derivatives (Cl and Br) of indanthrene blue are also commercial articles and yield in dyeing greener shades of blue which are fast to bleaching powder than ordinary indanthrene blue (v. INDANTHRENE), as the introduction of halogen atoms renders the oxidation to the azine less easy. *Indanthrene blue GCD* and *indanthrene blue GC* are the dichloro and dibromo derivatives respectively of indanthrene blue.

By the condensation of alizarin with 2:3-diaminoanthraquinone, a compound having the following constitution

is obtained, halogen derivatives of which come into the market under the names *algol blue* and *algol green*.

Flavanthrene or *indanthrene yellow* is formed as a by-product in the manufacture of indanthrene blue, but is obtained in much better yield, according to D. R. P. 138119, by the oxidation of β -aminoanthraquinone with antimony pentachloride in boiling nitrobenzene, or by the action of manganese peroxide in nitric acid solution (D. R. P. 141355). Flavanthrene has been shown to possess the constitution

and comes into the market in the form of a yellow paste. With caustic soda and hydrosulphite (or other reducing agents) it yields a deep cobalt-blue vat from which cotton takes up the leuco compound and is dyed, after exposure to the air, a fast yellow. The halogen derivatives of flavanthrene dye redder shades than flavanthrene itself.

That nitrogen and sulphur are not essential

constituents of vat dyes is shown by the fact that *pyranthrone* or *indanthrene golden orange G*

obtained by the condensation of two molecules of 2:2'-dimethyl-1:1'-dianthraquinonyl behaves in exactly the same manner towards reducing agents and in dyeing as the other vat dyes of this series. By the introduction of halogens into this dyestuff the shade is altered towards red. Thus, the brominated product represents *indanthrene scarlet G*.

By the alkaline condensation of two benzanthrone molecules, vat dyes are obtained, the simplest representative of which (*violanthrene BS*) is represented by the constitution

which, when nitrated, yields *indanthrene green*. This vat dye produces a green on cotton which is not very fast to light. *Indanthrene violet RT*, which dyes very fast shades, is a halogenated violanthrene. *Violanthrene R extra* is obtained by fusing halogen derivatives of benzanthrene with alcoholic potash. It is represented by the constitution

Indanthrene violet RR and *indanthrene violet B* are the dichloro and dibromo derivatives of this violanthrene.

Some of the dyestuffs of this series are derivatives of aminoanthraquinones and are represented by comparatively simple constitutional formulae. Thus, *algal yellow WG* is α -benzoylaminoanthraquinone

whilst *algal pink R* is the benzoyl derivative of a hydroxyaminoanthraquinone

A variety of shades are produced by the introduction of further groups such as OCH_3 , NH_2 , additional OH groups, &c., into the anthraquinone molecule, followed by benzoylation. Succinyl derivatives are also used. An example of these is the dyestuff known as *algal yellow 3G*, which is the succinyl compound of diaminoanthraquinone

It is noteworthy that the arylaminoanthraquinones do not act as vat dyes for cotton, although some of them are, in the form of the sulphonic acids, valuable wool dyes. In this connection it may be mentioned that whereas alizarin is quantitatively reduced by titanous chloride in presence of Rochelle salt to desoxyalizarin, alizarin orange cannot be reduced further than to β -aminoalizarin.

Another class of anthraquinonoid dyes, the anthraquinone acridones, are obtained by condensing 1:2 chloroanthraquinone carboxylic acids with aromatic amino compounds, followed by treatment with concentrated sulphuric acid. *Indanthrene violet 2B* is a member of this class. It is represented by the constitution

Some of the sulphide colours (*q.v.*) are also classed as vat dyes, though they do not appear to bear any relationship to the indigoid or anthraquinonoid dyestuffs as far as constitution is concerned. The points of similarity are the use of hydrosulphite to form a vat and the fastness of the resulting colours on cotton. Of these dyestuffs the best known is *hydron blue*, which is obtained by melting the indophenol of carbazol (from *p*-nitrosophenol and carbasol) with a sodium polysulphide rich in sulphur. The dyeing is done at an elevated temperature (50° - 70°), and shades are obtained which resemble indigo, though they are claimed to be faster. Some vat dyes obtained from anthracene or its derivatives, such as *algal brown B*, *indanthrene olive G*, and the *cibanon* colours are also sulphide dyes of unknown constitution.

The anthraquinonoid dyes are employed in cotton dyeing much in the same way as the indigoid dyes. Generally speaking, they require, however, a much larger amount of caustic soda in the vat and are not dyed cold, but at a

temperature of 50°-80°. In dyeing light shades, the dye-bath is generally exhausted under these conditions. After dyeing, the goods are soaped hot, a process which in most cases considerably enhances the brilliancy of the colour. With some of the colours, the fastness to bleaching powder is increased by steaming under pressure after dyeing. Although no black anthraquinonoid dyestuff is known, a black of extraordinary fastness can be obtained on cotton by dyeing it first indanthrene green and then subjecting the dyed material to the action of bleaching powder. The colours obtained with the dyes of the anthraquinonoid series are generally somewhat faster to light than those obtained with the indigo dyes. They are not applicable to wool dyeing owing to the necessity of keeping the vat strongly alkaline with caustic soda, with the inherent risk of damaging or destroying the fibre. It has been suggested that a preliminary treatment of the wool with formaldehyde would obviate this difficulty.

In calico printing, the anthraquinonoid dyes are largely used for some of the best classes of work. The usual method of using the indanthrene colours is to print a colour containing the vat dye, stannous chloride, ferrous sulphate and thickening, and after drying to pass rapidly through a hot strong solution of caustic soda. The fixation may also be effected in one operation by using a printing colour containing the vat dye, hydrosulphite-formaldehyde and soda ash, after which the goods are steamed for 5-7 mins. in air-free steam. The glucose process, as described for indigo, is also applicable to vat dyes in general.

In steaming or 'ageing' the vat dyes, it sometimes happens that the colours do not develop satisfactorily on subsequent exposure to the air, and faulty goods thus result. This is due to over-reduction of the vat dye to a stage at which neither air contact nor oxidising agents will develop the colour. See Reinking: Exothermic reactions in the rapid ager, *J. Soc. Dyers*, 1922, 306.

By the introduction of the vat dyes the public demand for fast colours, especially in dyes and printed cotton and linen fabrics, has been met, and it is now possible to obtain by means of them almost any shade fast to washing, light, perspiration, rubbing, and even bleaching powder. It should, however, not be taken for granted that a vat dye is of necessity a fast colour. Those on the market have, however, generally been carefully tested and selected by the makers and usually possess this attribute. Many of the vat dyes are so fast that they can be put through the full bleaching process for cotton pieces without suffering any material diminution of intensity and brilliancy, and advantage is taken of this in the production of white fabrics with coloured stripes or figures. Whereas it was formerly necessary, in order to obtain these effects, to bleach both warp and weft before weaving, the bleaching is now largely effected in the piece and considerable economy is realised. With the exception of indigo, the vat dyes are still too expensive to admit of their being employed for any but the best class of work. This is due in part to the high cost of manufacture, but more especially to the fact that most of them are tinctorially weak, as com-

pared with, for instance, the basic and direct cotton colours. Even indigo itself shows this drawback, but most of the other vat dyes show it to a greater extent.

For the identification of the vat dyes in dyed and printed fabrics, see A. G. Green and G. H. Frank (*J. Soc. Dyers*, 1910, 83), also G. E. Holden (*ibid.* 1909, 47), A. G. Green, W. Gardner, L. Lloyd, and G. H. Frank (*ibid.* 1913, 227), and J. I. M. Jones and W. Kilby (*ibid.* 1925, 127). Indigo can readily be distinguished from the other vat blues by dissolving the fabric in warm 80 p.c. sulphuric acid. The solution is poured into water and filtered through a small asbestos filter. After washing and drying, the residue on the filter is heated to about 100° with concentrated sulphuric acid and again poured into water and filtered. Under these conditions, the indigo is sulphonated and passes into the filtrate with a bright blue colour, whereas the other vat blues remain unaffected. E. K.

VAUQUELINITE. Native lead and copper chromate.

VAUXITE AND PARAVAUXITE. These occur on wavellite in brecciated tin-veins in rhyolite at Llallagua, Oruro. Vauxite occurs as radiating aggregates of sky-blue, triclinic crystals with $a:b:c=1.1510:1:1.2624$, $\alpha=99^\circ 32'$, $\beta=102^\circ 14'$, $\gamma=110^\circ 14'$; $d\ 2.375$, $H\ 3\frac{1}{2}$; refractive indices $\alpha\ 1.551$, $\beta\ 1.555$, $\gamma\ 1.562$, optically positive. Paravauxite forms colourless, triclinic crystals of prismatic habit with good $b\ (010)$ cleavage; $a:b:c=0.5058:1:0.6882$, $\alpha=97^\circ 42'$, $\beta=110^\circ 22'$, $\gamma=100^\circ 56'$; $d\ 2.291$, $H\ 3$; refractive indices $\alpha\ 1.554$, $\beta\ 1.558$, $\gamma\ 1.573$, optically positive. Analyses by J. E. Whitfield gave I for vauxite and II for paravauxite.

FeO	MnO	Al ₂ O ₃	P ₂ O ₅	H ₂ O at 104°	H ₂ O above 104°
I. 19.34	0.18	14.89	31.33	3.68	30.24
II. 15.47	—	17.89	29.80	16.40	20.34

The minerals are readily soluble in hydrochloric acid. The water content of the paravauxite varies considerably with the humidity of the atmosphere. Formulas:

Vauxite: $4\text{FeO}, 2\text{Al}_2\text{O}_3, 3\text{P}_2\text{O}_5, 24\text{H}_2\text{O} + 3\text{H}_2\text{O}$.

Paravauxite:

$5\text{FeO}, 4\text{Al}_2\text{O}_3, 5\text{P}_2\text{O}_5, 26\text{H}_2\text{O} + 21\text{H}_2\text{O}$.

(Samuel G. Gordon, *Proc. Acad. Nat. Sci. Philadelphia*, 1923, 75, 261-270; *Chem. Soc. Abstr.* 1923, 124, ii. 646).

VEGETABLE BUTTER v. **BASSIA OILS**; also **OILS, FIXED, AND FATS**.

VEGETABLE ETHIOPS. A form of charcoal obtained by the incineration of *Fuci*.

VEGETABLE FATS v. **OILS, FIXED, AND FATS**.

VEGETABLE IVORY. The fruit of *Phyt. elephas macrocarpa* (Ruiz. and Pav.) found in Colombia, South America.

VEGETABLE PARCHMENT v. *Parchment paper*, art. **CELLULOSE**.

VEGETABLE SPERMACEI. *Insect waxes*, v. **WAXES**.

VELOCITY OF REACTION v. **CHEMICAL AFFINITY**.

VELLOSINE v. **PERERO BARK**.

VENETIAN CHALK v. **STRAITTE**.

VENETIAN LAKE. *Crimson lake* v. **PIGMENTS**.

VENETIAN RED. *Ferric oxide*.

VENETIAN WHITE. A white lead pigment containing a large percentage of barium sulphate.

VENTILAGO MADRASPATANA (Gerten.) is a large climbing shrub belonging to the order *Rhamnaceae*, the root-bark of which furnishes a dyestuff much valued in Southern India. It is very common in the Western Peninsula from the Konkan southwards, as well as in Ceylon and Burma, and, according to Lostard, it is collected in Mysore at certain periods of the year and exported to other districts of India.

The following are a few of its vernacular names: pitti (*Hindi*); raktapita (*Bengali*); pappili-chakka, surralpattai (*Tamil*); poplichukai (*Kan*); lokandi, kanwai (*Bomb*).

The root-bark appears as dark purplish-brown scales, ribbons, or filaments, the dust from which, when it is ground to powder, irritates the throat in a marked manner. When treated with boiling water or alcohol it gives a red solution, which on addition of caustic alkali, changes to a deep crimson.

Perkin and Hummel (Chem. Soc. Trans. 1894, 65, 923), who examined this dyestuff, extracted the root-bark with carbon disulphide, and obtained in this manner a resinous colouring matter, *ventilagin*, together with the crystalline non-tinctorial substances described below.

Ventilagin $C_{11}H_{14}O_6$ consists of a reddish-brown brittle resin which, when distilled with zinc-dust, gives *a*-methyl-anthracene, and when treated with zinc-dust in alkaline solution behaves as a derivative of methyl-anthraquinone. Dilute alkalis dissolve it with a purple-violet coloration, and the corresponding salts are obtained as violet precipitates on adding sodium or potassium chlorides to these solutions. According to Perkin and Hummel, ventilagin is possibly allied to alkanin $C_{11}H_{14}O_4$, the colouring matter of alkanet, *Anchusa tinctoria* (Lam.), and may differ from this merely by the possession of two additional hydroxyl groups.

Emodin monomethyl ether $C_{15}H_{12}O_5$, m.p. 200°, consists of orange-red needles, and is identical with that subsequently isolated from the root of the *Polygonum cuspidatum* (Sieb. and Zucc.) (Perkin, Chem. Soc. Trans. 1895, 67, 1084). A similar, if not identical, substance was isolated by Schwabe (Arch. Pharm. 1888, 26, 569), and by Thorpe and Miller (Chem. Soc. Trans. 1892, 64, 6) from the bark of the *Rhamnus frangula* (Linn.), and it is also present in rhubarb and the *Rumex ecklonianus* (L.) and Goa powder.

Trihydroxy-a-methyl-anthranol monomethyl ether (A), $C_{15}H_{12}O_6$, colourless needles, decomposes about 260° before melting, and is soluble in alkaline solutions with a yellowish-brown coloration. On gentle oxidation with chromic acid it is converted into emodin methyl ether, m.p. 300° (Lc), and the same reaction takes place when its alkaline solution is oxidised with hydrogen peroxide. It closely resembles the dehydro-emodin-anthranol monomethyl ether, subsequently isolated from Goa powder by Tutin and Clewer (Chem. Soc. Trans. 1912, 101, 290).

Trihydroxy-a-methylanthranol monomethyl ether (B), $C_{15}H_{12}O_6$, pale yellow needles, m.p. 172°, when oxidised with chromic acid is also

converted into the emodin methyl ether, m.p. 300°. As two methyl anthranols are capable of existence, the isomerism of these compounds may possibly be thus explained:—

Substance $C_{15}H_{12}O_5$, orange-red crystalline powder, m.p. 275°–280°, is soluble in alkaline solutions with an orange-red coloration, and when heated with zinc-dust gives a hydrocarbon which resembles *a*-methyl-anthracene.

Substance $C_{11}H_{12}O_5$ is a chocolate, crystalline powder, soluble in dilute alkali with a yellow coloration, and this solution, on exposure to air, deposits a blue amorphous precipitate.

Dyeing Properties.—On striped printed calico the root-bark gives with alumina mordant a claret-red, not unlike that of alizarin bordeaux; with iron mordant a greyish-lilac, which in strong colours approaches a black; and with a mixture of the two a very purplish dark chocolate. The colours are moderately fast to soap, although considerably behind the alizarin colours in this respect. On oil-prepared calico ventilago gives with alumina mordant a rich claret-brown, with chromium mordant a very black-purple, and with iron mordant a good purplish-black shade. On wool chromium mordant gives a good purplish-brown, alumina a bordeaux red, tin a brighter red similar to an alizarin red, and iron mordant gives dark dull purple and black. On silk similar colours are produced. No difficulty is experienced in dyeing with ventilago, and no additions to the dye-bath are necessary, except in the case of wool, with which it is desirable to add calcium acetate in order to correct the strong acidity of the mordanted fibre. Owing to the slight solubility of the colouring matter in water, the dyeing does not commence until the temperature reaches 70°–80°. The root-bark appears to contain from 8–10 p.c. of ventilagin.

A. G. P.

VERATRALBINE, VERATRIDINE, VERATRINE v. CEVADINE.

VERATROLE (*o*-dimethoxybenzene)

is best obtained by dissolving catechol (100 grms.) in methyl alcohol (200 grms.) mixed with 75 grms. of methyl sulphate. The mixture is cooled to –5°, and 150 grms. of potash dissolved in 350 grms. of water are then added all at once. In 3 mins. the methylation is complete. The product is diluted with water, extracted with ether, and the extract is dried and distilled (Perkin and Weizmann, Chem. Soc. Trans. 1906, 1856). Veratrole is also formed by the distillation of guaiacol with lead oxide (Pechorr and Silberbach, Ber. 1904, 37, 2149). Veratrole forms a crystalline mass, m.p. 15°, b.p. 205°. It yields a number of halogen derivatives (Cousin, Compt. rend. 1898, 127, 759; 1902, 135, 967; Ann. Chim. 1898, [vi] 13, 483); also nitro derivatives (Cousin, Compt. rend. 1902, 134, 290; 135,

967; Salway, Chem. Soc. Trans. 1909, 1163),
a *phthalide*

(Perkin and Weizmann, *l.c.*) and other compounds (Kropp and Decker, Ber. 1909, 42, 1184).

Veratrole reacts with hippuryl chloride in presence of aluminium chloride, forming a crystalline product, m.p. 155°

from which valuable therapeutic products are said to be obtained (D. R. P. 185596; Frdl. 1905-1907, 1184).

For other literature, see Simonsen, Chem. Soc. Trans. 1917, 111, 69, 220; 1918, 22, 782; Jones and Robinson, *ibid.* 1917, 111, 903.

VERBENALIN. A crystalline glucoside found in *Verbena officinalis* (Linn.), m.p. 181.5°; $\alpha_D = -180.3^\circ$. Hydrolysed by emulsin, yielding dextrose (Bourdier, J. Pharm. Chim. 1908, 27, 49, 101).

VERDIGRIS, VERT-DE-GRIS, VERT DE MONTPELIER. Basic acetates of copper v. ACETIC ACID.

VERDITE. An ornamental stone of a rich green colour consisting mainly of hydrated magnesium silicate coloured by chromium. It represents a serpentine rock more or less completely altered to talc. The chromium is probably present as the chrome-mica fuchsite, which was no doubt derived from chromite. The rock shows mottlings of yellowish-green and bluish-green with splashes of brown and yellow, and it takes a high polish. Sp.gr. 2.8; H. 3½. It occurs in the Jamestown series (Swaziland system) of chloritic and talcose schists; and is obtained from small quarries at several places on the banks of the Kaap and North Kaap rivers near Barberton in the Transvaal, and more particularly at the Verdite mines at Jamestown near Barberton, which are worked for talc with gold as a by-product (A. L. Hall, The Geology of the Barberton Gold Mining District, Union of South Africa, Geol. Survey, 1918, Mem. No. 9). L. J. S.

VERDITER, GREEN AND BLUE, v. COPPER.

VERIDIAN. Guignet's green v. CHROMIUM.

VERJUICE. A kind of vinegar containing malic acid made from the juice of the crab-apple.

VERMILION v. MERCURY.

VERMILIONETTE. A red pigment made by adding eosin to white lead, barium sulphate or zinc white.

VERNINE $\text{C}_{16}\text{H}_{13}\text{O}_5\text{N}_3\cdot 2\text{H}_2\text{O}$ found by Schulze (Zeitsch. physiol. Chem. 1885, 9, 420) in seedlings of *Vicia sativa*, and later in a number of other plants. Is identical with *guanosine*, obtained by Levene and Jacobs (Ber. 1909, 42, 2469) by the hydrolysis with water of guanylic acid. M.p. 237°, $[\alpha]_D^{20} = -60.52^\circ$ in alkaline solution. It is hydrolysed by acids to guanine and a pentose, presumably *D*-ribose (Schulze and Trier, Zeitsch. physiol. Chem. 1910, 70, 143).

From the green leaves and berries of the coffee tree a pentoside has been isolated, containing guanine, which is probably identical with *guanosine* obtained by Schulze and Trier from other plants and from 'nucleic acid' by Levene and Jacobs. It is suggested that the

caffeine in the leaves and berries of the coffee tree is derived from *guanosine*, the latter being converted successively into *guanine*, *xanthine*, and *caffeine* by the action of enzymes (T. de A. Camargo, J. Biol. Chem. 1924, 58, 831; J. Soc. Chem. Ind. 1924, 43, B. 312), v. ERGOT.

G. B.

VERONAL. Trade name for diethylmalonylurea $(\text{C}_2\text{H}_5)_2\text{N}[\text{CO}\cdot\text{NH}]_2\text{CO}$, prepared by the condensation of urea and diethyl-malonyl chloride. A white crystalline powder of bitter taste, m.p. 191°. Soluble in water, ether, acetone, acetic ester. Used as a soporific (v. SYNTHETIC DRUGS and PYRIMIDINES). For the chemical detection of veronal poisoning, v. Macadie, Pharm. J. 1913, 90, 134; Richards, Analyst, 1919, 44, 192; van Itallie and van der Veen, Pharm. Weekblad, 1919, 56, 1112; J. Pharm. Chim. 1919, [vii.] 20, 337. Veronal and the malonylureas generally readily condense with xanthidrol to form crystalline dioxanthyl derivatives which may be used for the characterisation and identification of the malonylureas by observation of their melting-points (Fabre, J. Pharm. Chim. 1922, 26, 241). The veronal derivative melts at 245°-246°. Thus, if a solution of 1 grm. of veronal and 2 grms. of xanthidrol in acetic acid is boiled for a few seconds and cooled a crystalline precipitate of a dioxanthylated derivative is formed which can be purified by washing with boiling alcohol and its melting-point determined. In toxicological investigation the veronal has first to be isolated from the viscera. From 100 to 150 grms. of material are digested on a water-bath for 3 hours with a mixture of 95 p.c. alcohol and 5 grms. of tartaric acid, cooled, filtered and concentrated by distillation. The residue is dissolved in 50 c.c. of distilled water, and after being made slightly alkaline, the solution is shaken up several times with ether to eliminate fatty matter. After acidulation with dilute sulphuric acid the liquid is evaporated, and the residue taken up three times with ether which dissolves the veronal. The residue from the extract is purified by dissolving it in water, heating with animal charcoal, filtering and crystallising the filtrate. After several crystallisations the melting-point can be determined. The search for these hypnotic compounds may also be made in the urine, since 60 to 65 p.c. of the veronal absorbed can be found in the urine excreted during the four following days (Analyst, 1922, 47, 523).

VEROPYRIN. Trade name for a mixture of ethylmorphine hydrochloride, veronal-sodium and calcium acetylsalicylate.

VERT DE GUIGNET v. CHROMIUM.

VERVAIN. Cymylacetic aldehyde (1-iso-propyl-4-ethanalbenzene

possesses a strong odour resembling vervain, but not of such delicacy as that of the plant. As it may be easily and economically prepared, it is anticipated that it will be extensively used in synthetic perfumery. It is obtained by condensing magnesium cymyl chloride with ethyl orthoformate, hydrolysing the product with dilute sulphuric acid, and separating the aldehyde by means of its bisulphite compound. It is a pale yellow liquid, b.p. 243°C. (L. Bert,

Comptes rend. 1923, 177, 550-551; J. Soc. Chem. Ind. 1923, 42, 1099 A).

VESALVINE. Syn. for hexamethylenetetramine.

VESIPIRIN. Trade name for phenyl acetosalicylate, v. SALICYLIC ACID and SYNTHETIC DRUGS.

VESTORIEN v. EGYPTIAN BLUE; also ENAMELS.

VESUVIANITE or **IDOCRASE.** A mineral consisting of a complex silicate of calcium and aluminium, together with iron, magnesium, water, fluorine, boron, &c. F. W. Clarke's formula is $R'_4Al_2Ca_2Si_2O_{14}$, where $R'_4 = Ca_2, (AlOH)_2, H_4$, &c. Crystals are tetragonal and usually green or brown in colour; sp.gr. 3.35-3.45; H. 6½. The mineral is of common occurrence in contact-metamorphic rocks, particularly crystalline limestones. Lustrous, brown crystals are common at Monte Somma, Vesuvius (hence the name vesuvianite). Green crystals from Ala in Piedmont are cut as gems at Turin. A compact, massive variety has been found abundantly as blocks and boulders, measuring up to 6 by 3 ft., at several places in California (Siskiyou, Butte, Fresno, and Tulare counties). This has been called *californite* (G. F. Kunz, 1903), and is much used as a gemstone and for larger ornamental objects. It is somewhat translucent, takes a high polish, and ranges from bright green to yellowish-green and white in colour, thus closely resembling jade in appearance (D. B. Sterrett, Min. Res. U.S. Geol. Survey, annual reports for 1909 and 1910.)

L. J. S.

VICINE $C_{10}H_{14}O_2N_4.H_2O$ was discovered by Ritthausen (J. pr. Chem. 1870, [ii.] 1, 336; 1873, [ii.] 7, 374; 1881, [ii.] 24, 202) in the seeds of *Vicia* spp. According to Levene (J. Biol. Chem. 1914, 18, 305; Levene and Senior, *ibid.* 1916, 25, 607) it is a mononucleoside, or glucoside of 2:5-diaminotetrahydropyrimid-4:6-dione (2:5-diamino-uracil) of the following constitution:

It forms needles, m.p. 242°, $[\alpha]_D^{25} -11.7^\circ$. It is hydrolysed by 20 p.c. sulphuric acid at 100° to dextrose and *divicine* (of Ritthausen) = 2:5-diamino-uracil $C_4H_4O_2N_4$. Compare also Johnson, J. Amer. Chem. Soc. 1914, 36, 337; Johnson and Johns, *ibid.* 1914, 36, 545; Fischer, Ber. 1914, 47, 2611; Winterstein, Zeitsch. physiol. Chem. 1919, 105, 258.

Convicine $C_{16}H_{14}O_2N_8.H_2O(?)$ was also found by Ritthausen in vetch seeds and yields on hydrolysis alloxantin, ammonia and a hexose.

G. B.

VICIANIN v. GLUCOSIDES.

VIOLANOSE v. CARBOHYDRATES.

VICTORIA YELLOW. *Gold yellow, Aniline orange, Saffron surrogate.* This colouring matter, introduced by Mottenzwei, under the name of *Victoria yellow* or *aniline orange* (Wag. Jour. 1869, 593), consists of the potassium or ammonium salt of a dinitrocresol (Martius and Wichelhaus, Ber. 2, 206; v. Sommaruga, *ibid.* 2, 579). It is prepared by heating cresol, with three times its weight of sulphuric acid at 100°, until the product is soluble in water. After removing the excess of sulphuric acid by

means of barium carbonate, the cresol-sulphonic acid is converted into potassium salt, which in the dry state is nitrated by introducing it rapidly into about three times its weight of dilute nitric acid (sp.gr.=1.2), and is then poured into water, neutralised with potassium carbonate, and the resulting potassium dinitrocresol crystallised out. Obtained in this way, the colouring matter is a mixture of the potassium salts of dinitro-*o*- and dinitro-*p*-cresol, and varies in colour according to the proportions of these. Thus Victoria yellow is yellowish in colour, and consists chiefly of the potassium salt of dinitro-*o*-cresol (m.p.=86°), which crystallises in yellow needles (Wichelhaus, *ibid.* 7, 176; Piccard, *ibid.* 8, 685), whereas saffron surrogate is distinctly reddish in colour, and consists chiefly (80 p.c. according to Piccard) of the potassium salt of dinitro-*p*-cresol (m.p.=84°), which crystallises in red needles (Armstrong and Field, Chem. News, 27, 318; Hofmann and v. Miller, Ber. 14, 567; Staedel, *ibid.* 14, 900, 906; Nölting and Salis, *ibid.* 14, 986).

Victoria yellow is soluble in water and dyes wool and silk orange, but owing to the fugitive nature of the colour is no longer employed for this purpose. Saffron surrogate is still used to some extent as a colouring matter for butter, margarine, vermicelli, cheese, &c. (Piccard), but this is to be deprecated, since Weyl's experiments show that the compound is poisonous (Ber. 20, 2835; 21, 512). Cf. NITROPHENOLS AND THEIR HOMOLOGUES.

VIENNA BLUE. *Cobalt blue* v. PIGMENTS.

VIENNA GREEN. *Emerald green* v. PIGMENTS.

VIENNA PASTE. A mixture of lime and potash used as a caustic to extirpate malignant growths.

VIFERRAL. A polymerised chloral
($C_2HOC_2H_2$)_x

A white powder, m.p. 153°-155°, sol. in water. Used as a hypnotic.

VIMOPYRIN. Trade name for *p*-phenetidine tartrate.

VINASSE v. SUGAR.

VINE BLACK. *Blue black* v. PIGMENTS.

VINEGAR, AROMATIC. v. ACETIC ACID.

VINEGAR PLANT. v. ACETIC ACID; FERMENTATION.

VINOLINE. A mixture of coal-tar reds, mostly rosaniline salts, used for colouring wines.

VINOPYRIN v. SYNTHETIC DRUGS.

VIOFORM. Trade name for iodochlorohydroxyquinoline. A greyish-green powder used as a bactericide and antiseptic, and as a substitute for iodoform (v. SYNTHETIC DRUGS).

VIOLANE. A variety of the pyroxene (q.v.) group of minerals of a rich violet colour, and occasionally used as an ornamental stone. It is a silicate of calcium, magnesium, aluminium, sodium, iron, and manganese (about 2 p.c. MnO, to which the colour is due). It sometimes forms prismatic crystals of the monoclinic system, but more often compact masses with a lamellar or fibrous structure. It is found, together with other silicates coloured by manganese, in the manganese mines at San Marcel in the Aosta valley, Piedmont. L. J. S.

VIOLANIN v. ANTHOCYANINS.

VIOLANTHRENE v. INDANTHRENE.

VIOLET DE PARIS OR VIOLET DIRECT.

VIOLET DE PARIS or VIOLET DIRECT.
Methyl violet v. TRIPHENYLMETHANE COLOURING MATTERS.

VIOLET 5B, 6B, v. TRIPHENYLMETHANE COLOURING MATTERS.

VIOLET R and RR and 5R. *Hofmann's violet v. TRIPHENYLMETHANE COLOURING MATTERS.*

VIOLIN. An emetic substance contained in the common violet, supposed to be identical with emetine from ipecacuanha root.

VIOLINE or VIOLEIN. A synonym for mauve or aniline purple.

VIOLONES. Coloured anhydro-bases obtained by acting upon pyrylium salts with *p*-hydroxylated phenyl radicles by weak alkalis Dilthey and Burger, Ber. 1921, 54 [B], 825).

VIOLURIC ACID v. PYRIMIDINES.

VIRIDIAN. Hydrated chromium sesquioxide, v. CHROMIUM.

VIRIDINIC ACID v. TANNINS.

VIRIDITE v. THURINGITE.

VISCOSE v. SILK, ARTIFICIAL.

VITAMINS. To deal seriously from a standpoint strictly chemical with substances which have never been isolated in a pure condition is, of course, impossible. The constitution of the peculiar dietary constituents which have been called Accessory Food Factors (Hopkins), or Vitamines (Funk) is as yet entirely unknown. They are not, however, merely hypothetical substances. The evidence for their objective existence is ample enough, but as this evidence is in part, so to speak, of a negative kind, and in any case depends upon studies in which impure preparations have been perforce employed, it calls for critical consideration. The fundamental facts which make necessary a belief in the existence and physiological importance of nutrients differing in kind from those which until lately were alone recognised, can, however, be quite briefly enumerated.

Until fifteen years ago it was generally believed that the efficacy of a diet could be determined by three essential criteria. The first was the obvious one that it should provide enough potential energy for the current dynamic needs of the body. The second was that it should contain a certain minimum of protein, to exercise specific functions which the non-nitrogenous foodstuffs cannot subserve, and the third called for a balanced mineral supply. We now know that these criteria are insufficient. Although data from highly quantitative studies of human and animal nutrition have long existed in great numbers, these data were obtained during the administration of natural food materials. The fats, carbohydrates and proteins contained in these diets were accurately calculated and the effects of their variation evaluated; but that these constituents (with the necessary minerals) were alone responsible for the successful maintenance of the body was an unjustifiable assumption. Quantitatively they account for nearly the whole of the necessary supply, but hundreds of recent experiments and observations have shown that there are other substances in natural foods which, though present in only very small quantities, are yet absolutely essential for proper nutrition. These are the substances which,

pending a knowledge of their nature, it is agreed to call vitamins.

The assumption mentioned in the last paragraph was unjustified, because the food constituents which were thought to cover all needs were never administered in a pure form. It can be shown with the greatest ease that if an animal be supplied with purified protein and pure fats and carbohydrates, together with a salt mixture proved in other associations to be efficient, the food may be well eaten, well digested, and even fully metabolised, yet the animal's nutrition fails, and it finally dies. What, however, endows the phenomena we are considering with their fullest significance is the circumstance that the purified foodstuffs just mentioned become wholly efficient and fully maintain growth, health and activity when material is added to them in amounts so small compared with the whole quantity of food consumed that it would almost be negligible. This material must comprise at least three and probably more vitamins. The extraordinary importance of their nutritional effects and the remarkably small concentration in which these effects are produced are the characteristics which supply the only definition of vitamins at present available.

While, during the first decade of the present century, the facts just mentioned were being established by feeding experiments done mainly upon animals, evidence giving precisely similar indications arose from a new and enlightened study of certain human diseases. It was almost a pure coincidence that these two lines of evidence should have become available contemporaneously. Clear indications showing that the disease, Beri Beri, which mainly—though by no means exclusively—attacks rice-eating populations, is intimately related to diet, was indeed brought forward by Eijkman so far back as 1897. He showed that a condition very similar to the human malady could be induced in fowls by feeding them upon an exclusive diet of polished white rice, while a cure was at once established by adding rice polishings to the diet, or by replacing the polished grain by whole grain. The suggestion given by these experiments was followed up and observations made upon a great number of prisoners in the gaols of Java, and the fact established that Beri Beri is far more frequent among these eating rice deprived of the grain cortex than among those receiving the whole grain. This work was fully confirmed by that of W. Fletcher, published in 1907-8 (Lancet, 1907, 1776). The time was not even then ripe, however, for the simple interpretation of the facts. Only when later studies were published, and in particular those of Frazer and Stanton (Studies from the Inst. for Med. Research, Federated Malay States, No. 12, 1911) did the clear conception arise that the cortex of rice grain, unlike the endosperm, contains a specific substance of unknown nature, but certainly essential to life. It can be supplied in many other foodstuffs besides cereals, but the circumstance that it has a local distribution in grains, together with the one-sided character of Eastern dietaries, conspired to bring the facts to light. The disease scurvy yields even clearer evidence that healthy nutrition calls for a supply of a substance, or substances, not comprised in the ordinary categories of foodstuffs. Its

incidence and cure might, it would seem, have led long ago to a conception of what we should now call a vitamin. Preconceptions and prejudices led, however, to other explanations of the disease. Ultimately, however, though not until about 1912, the convergence of the pathological evidence and that obtained from feeding experiments led to a somewhat sudden emergence of the belief that nutrients must exist with the potent qualities now attributed to vitamins.

Though all attempts to isolate the substances with which we are concerned have so far failed, preparations have been made in a highly concentrated form, and work which, in a limited sense at least, is quantitative, has been done upon them. Certain of the properties of the vitamins are well characterised in a chemical sense, and there is every reason to believe that they will ultimately be isolated. It is as yet impossible, as already admitted, to define them except in terms of their physiological properties. They arise during the growth of the plant. For the animal they are essential, indispensable nutrients. There is clear evidence that at least three distinct members of the class exist and strong suggestions for the existence of a fourth. Each has its own peculiar influence in the body. While we are ignorant of their nature any scheme of nomenclature must be unsatisfactory. It is best to use names without special connotations, and to speak simply of the A-, B- and C-vitamins, respectively, is a justifiable custom.

The B-Vitamin.—Although this substance has received as a prefix the second letter of the alphabet, it will be convenient to deal with it first. It is the so-called 'water soluble vitamin,' or anti-neuritic factor. If it be absent from the diet, a young animal fails to grow, and soon, like the adult animal, develops symptoms which depend upon the occurrence of degenerative changes in the nervous system. In the human individual these symptoms in their more extreme form constitute the picture of Beri Beri. The substance, as its earliest name betokens, is freely soluble in water. It is also soluble in 80 p.c. alcohol, though much less so, if at all, in absolute alcohol. Acidified methyl alcohol extracts it from many tissues containing it. Insoluble in other ordinary organic solvents, it shows a rather remarkable solubility in oleic acid or olive oil (Myers and Voegtlin, *Proc. Nat. Acad. of Sc.* 1920, 6, 3). It is precipitated from aqueous solution by precipitants which throw down organic bases: phosphotungstic acid, for instance, or silver nitrate plus barium hydroxide. This behaviour, together with the fact that very active preparations obtained by the use of these precipitants contained nitrogen, led Funk to believe that the active substance was a base, and, in consequence, he suggested the name *vitamine*, which is now attached to all members of the class. Such precipitation may not be specific, however, but may be due to adsorption. The substance is freely adsorbed, for instance, by fuller's earth, and may be concentrated by its use. This property also allows of its separation from other vitamins (Harden). A silver compound has been prepared with high physiological potency (Seidell, *Pub. Health Reports, Washington*, 1921). The B-vitamin is a relatively stable substance, showing considerable

resistance to destruction by heat. It also resists the effects of acids, but is much more sensitive to alkalis (McCollum and Simmonds, *J. Biol. Chem.* 1918, 33, 55; Daniels and McClurg, *ibid.* 1919, 37, 201). Several attempts to isolate it have been described. Funk obtained, from extracts of rice polishings and yeast, crystalline products capable of curing birds suffering from polyneuritis due to feeding exclusively upon polished rice (*J. Phys. Chem.* 1913, 46, 173). Such results proved, indeed, the potency of almost infinitesimal quantities of the active substance, but unfortunately did not lead to its isolation. Funk believed at first that he had proved it to be a pyrimidine derivative, but when his crystalline preparations were fully purified they were found to be inactive and to consist largely of nicotinic acid, which itself is certainly without the characteristic activity. The purine base adenine has been stated to possess the properties of this vitamin, the remarkable statement being made that this base exists in two forms—one a physiologically active form, which by molecular rearrangement may pass over into a second and inactive form. Certain synthetic α -hydroxy-pyridines have been said to have similar properties (Williams, *J. Biol. Chem.* 1916, 25, 437; Williams and Seidell, *ibid.* 26, 431). These statements have been controverted, however (Harden and Zilva, *Bio-Chem. J.* 1917, 11, 172; Voegtlin and White, *J. of Pharm. and exp. Ther.* 1916, 9, 155). It must be admitted that all attempts to isolate the vitamin or to relate it to known substances have hitherto failed.

The B-vitamin is widely distributed in the tissues of plants, and is stored, though in low concentration, in many animal tissues. In the yeast cell it is especially abundant. As already pointed out, in the grains of cereals it has a local distribution, being present in the germ and pericarp, but not in the endosperm. The relative amounts present in various natural foods have been ascertained by determining on standard lines the minimum quantity of each food which is capable of preventing or curing polyneuritis in birds. The available data will be found in the Report upon Vitamins issued by the Medical Research Council. Such experiments consume much time. Endeavours to use its supposed effects upon the rate of growth of yeast as a measure of its amount have on the whole proved disappointing (*cf.* Funk and Dubin, *J. Biol. Chem.* 1920, 44, 487; McDonald and McCollum, *ibid.* 1921, 46, 525). No chemical means for its estimation are yet available.

Vitamin C.—This is the antiscorbutic substance which, while present in most uncooked foods, is found in exceptionally high concentration in certain fruits and in other vegetable tissues. The very fact that it is an unstable substance—easily destroyed by heat at temperatures not exceptionally high, prone to oxidation, and possibly destroyed under the influence of catalysts present in the tissues themselves—has been in itself the direct cause of much human suffering. Scurvy follows almost automatically when the substance is absent from the diet, and is often a devastating disease in communities cut off from a supply of fresh foods. The tentative efforts which have so far been made to

isolate the antiscorbutic agent, though without success, have served the useful purpose of making it clear that there is a definite substance to look for. We have not to deal with some vague 'property' of fresh foods, nor, as has been thought, with the influence of known constituents such as citrates, malates, or inorganic potassium salts. Because of its great importance to the body and the low concentration in which it is efficient the anti-scorbutic substance must certainly be recognised as a vitamin.

In the endeavour to study its distribution among foodstuffs, and the rate of its destruction by this or that agency, physiological methods have hitherto been perforce employed. For an account of methods whereby highly concentrated preparations of this vitamin are obtained and its main properties demonstrated the papers of Zilva should be consulted (*Bio-Chem. J. passim*). The discovery of even a purely empirical chemical method for estimating the vitamin would certainly be of the utmost practical importance. Determinations of its relative concentrations have been made by observing for each kind of material under study the minimal curative or preventative dose for scurvy in the guinea-pig. This animal reacts in a highly characteristic way when it is deprived of the factor in question, and also when after deprivation a supply is again provided (Axel Holst). Elaborate and careful experiments have been made on these lines (Chick and Hume, 1917, *et al.*). The vitamin is absent from dry cereal foods and from pulses, but appears suddenly in grains, beans, &c., during even the earlier stages of germination. It is present in all fresh vegetables though in varying concentrations. It is usually destroyed when these are dried, though it is stated that very rapid sun drying (an industry in Beluchistan) leaves it largely intact. Its concentration in fruits varies considerably. Those of the genus *Citrus* contain it in relatively large amount—as the long established empirical treatment of scurvy with lime juice would itself suggest. The fact that the concentration differs, however, in the juices of different varieties of citrus has affected the history of anti-scorbutic treatment. On several occasions in the past, and even during the war, 'lime juice' has appeared to fail and faith in its efficacy has consequently wavered. This occurred long ago when in the British Navy the juice of the West Indian lime was substituted for the lemon juice previously used. The explanation came when it was shown that the first-mentioned juice contained no more than one-fourth of the active substance present in the latter. Orange juice, on the other hand, contains about the same proportion as lemon juice (Chick, Hume and Skelton, *Biochem. J.* 12, 131; Davey, *ibid.* 1921, 15, 83). Orange juice retains its activity when wholly freed from its colloids and from citric acid and calcium (Harden and Zilva, *Bio-Chem. J.* 1918, 12, 259; McClendon, *J. Biol. Chem.* 1921, 46, ix.). Orange or lemon juice evaporated to a syrup under reduced pressure at 40°C. or concentrated by rapid methods at higher temperatures, retains its activity (Harden and Robison, *Bio-Chem. J.* 1920, 14, 171). The condition of the vitamin in the tomato is apparently such as to make it exceptionally stable. In all cases a slightly acid reaction in the material makes

for stability. Fresh tomato juice, for instance, boiled for one hour lost 50 p.c. of its activity; boiled for four hours it lost 70 p.c. When the juice was first made slightly alkaline, boiling destroyed it much faster (La Mer, Campbell and Sherman, *Proc. Soc. exp. Biol. and Med.* 1921, 18, 122). In the case of vegetables (cabbage) heating for twenty minutes at 100°C. may destroy 70 p.c. of the anti-scorbutic power (Delf, *Bio-Chem. J.* 1918, 12, 416). Oxidation plays a part in the destruction of this vitamin (Zilva, *Lancet*, 1921, i. 478; Anderson and others, *Science*, 1921, 53, 446). It would seem to be especially rapid in the case of some tissues. Fresh potato has marked anti-scorbutic power, but the juice, unless made acid, quickly loses it even at ordinary temperatures (Berzsonoff, *Compt. rend.* 1921, 173, 417). The anti-scorbutic value of milk, even when fresh, is relatively low, important as the function must be to the infant. The actual concentration of this vitamin (and, indeed, of the other vitamins in cows' milk) depends, however, upon the nature of the food supplied to the cow (Hess and others, *Proc. Soc. exp. Biol. and Med.* 1920, 18, 39; Drummond and others, *Bio-Chem. J.* 1921, 15, 540). The vitamin is largely destroyed by Pasteurisation, and it is becoming well recognised that infants receiving heated milk should be given a ration of fruit juice.

Vitamin A.—The 'Fat soluble' accessory factor. If animals be fed on a synthetic dietary such as that earlier described there may be complete failure of nutrition, even when Vitamins B and C are duly supplied, unless at the same time regard is paid to the nature of the fat comprised in the diet. Most vegetable fats, whether purified or not, prove unable to support nutrition in the circumstances mentioned, while most animal fats are found to be efficient, though in varying degrees. This is of course not due to any differences in the fats as fats. As a source of energy for the animal one type of fat differs but little from any other type. The difference, as abundant evidence proves, is due to the fact that associated with animal fats and not (at least as they appear on the market) with vegetable fats, is a specific substance, not itself a fat or other ester, which is essential to life. While actually made by the plant and present for instance in relative abundance in green leaves, it for some reason does not accompany vegetable oils when these are expressed from plant tissues. When, on the other hand, it is eaten by the animal in its food the substance tends to accumulate in its fatty tissues. It is stored in exceptionally large relative amounts in the livers of fish, but takes its origin from the marine vegetable organisms on which the fish feeds (Hjort, *Proc. Roy. Soc.* 1922, B). As in the case of other vitamins, its relative distribution has been in the main studied by means of standardised feeding experiments, but evidence is accumulating to show that its concentration in a fat is measured by the intensity of a colour reaction produced on the addition of arsenic chloride and certain other reagents (Rosenheim and Drummond, *Bio-Chem. J.* 1925, 19, 753). It is soluble in alcohol, ether, and benzene, and may be extracted, for example, from green leaves by these solvents. The vitamin is stable towards heat, and highly

resistant to the processes involved in saponification. It appears therefore greatly concentrated in the unsaponifiable residue from any fat which contains it. On the other hand, it is easily oxidised, and loses all activity when a fat or oil containing it is thoroughly aerated (Hopkins, *Bio-Chem. J.* 1920, 14, 725). Drummond and his co-workers have shown that when the unsaponifiable material from cod-liver oil is freed as far as possible from cholesterol and distilled in a high vacuum the active vitamin is found in fractions distilling at 184°-220° at pressures of 1 to 2 mm. (*Bio-Chem. J.* 1925, 19, 1047). An ethereal extract of green leaves has been prepared (Osborne and Mendel), of which a daily dose of 30 milligrammes contained enough of the vitamin (doubtless greatly diluted with other substances) to supply the needs of the rat, an animal highly sensitive to deprivation of the substance. Concentrations much greater than this have been obtained from the unsaponifiable residues of cod-liver oil prepared with avoidance of oxidation. Of one such preparation a daily dose of no more than 0.004 mgm. was sufficient to maintain a rat (Paulsen), and very small amounts of such concentrates will serve the purposes of the whole oil in therapeutic practice. The variation in animal fats is great. It has been estimated that cod-liver oil may be 250 times richer in the substance than butter (Zilva and Miura). For the influence of storage and emulsification on the vitamin A in cod-liver oil, see Drummond, Zilva and Coward (*J. Soc. Chem. Ind.* 1924, 43, 236 T).

The following figures have been obtained, representing the relative amount of the fat needed to supply a growing rat with its necessary supply of the vitamin. Crude cod-liver oil 2 mgms., haddock-liver oil 10 to 15 mgms., refined cod-liver oil on sale in this country 10 to 15 mgms., butter 500 mgms. (Zilva and Drummond, *Lancet*, 1921, ii, 753). The effects which follow upon an absence of this vitamin from the food, or a considerable deficiency in the supply, are failure of growth and maintenance, together with a specific form of degenerative changes in the eye, constituting what is known as xerophthalmia. It was for some time believed that the deposition of lime salts in growing cartilage on the lines necessary for the normal formation of bone called for a supply of vitamin A. The work of E. Mellanby has indeed shown clearly that something present in natural animal fats exerts an important influence on this process. When this substance is absent from its food a child becomes prone to develop rickets. It would seem, however, as McCollum and his co-workers were the first to suggest (*J. Biol. Chem.* 1922, 53, 293), that the dietary factor which prevents rickets, while usually associated with vitamin A, is not identical with it. It is a substance less readily oxidised. A fully aerated animal fat will fail to promote growth, but it may efficiently protect the young animal from rickets. It would seem that at least one other vitamin may therefore exist in addition to the three which have been discussed, and it is now usual to speak of this substance as Vitamin D. The remarkable relations between the activity of this food constituent and the effects of light

cannot be here discussed. It is probable that the list of existing vitamins is not exhausted by those discussed. Already there is evidence that a quite specific constituent in the diet is necessary for the maintenance of reproductive functions (Evans and Burr, *Proc. Nat. Acad. Sc.* 1925, 11, 334). F. G. H.

VITELLIN v. PROTEINS.

VITEXIN. The *Vitex littoralis* (A. Cunn.) or 'Puriri' is a large tree, 40-60 feet high, and 3-5 feet in diameter, which grows only in the northern portion of the North Island of New Zealand. The wood affords a very durable timber, and is chiefly used for house blocks, fencing posts, piles for bridges, railway sleepers, &c.

Vitexin, the main colouring matter, is present in the wood in the form of a glucoside which has not yet been isolated. It is prepared by digesting a purified extract of the dyestuff with boiling dilute hydrochloric acid, and by this means separates in the form of a yellow viscous mass. By extracting this crude product with boiling alcohol, a pale yellow crystalline powder remains undissolved, and this, owing to its sparing solubility, is most readily purified by acetylation, and the subsequent hydrolysis of the pure acetyl derivative (Perkin, *Chem. Soc. Trans.* 1898, 74, 1020).

Vitexin consists of minute canary-yellow prismatic or fine hair-like needles, soluble in alkaline solutions with a pale yellow coloration, and from these solutions when boiled it is deposited by acidification in a crystalline condition.

On fusion with alkali vitexin yields *phloroglucinol* and *p-hydroxybenzoic acid*, and when digested with boiling 50 p.c. potassium hydroxide solution *p-hydroxyacetophenone* is also produced. Boiling 15 p.c. nitric acid gives dinitro-*p*-hydroxybenzoic acid, together with a small quantity of *tetranitroapigenin*, m.p. 239°-241°. The formula first assigned to vitexin by Perkin was $C_{15}H_{14}O_7$, and the *acetyl derivative*, colourless prismatic needles, m.p. 251°-256°, was consequently represented as $C_{15}H_{12}O_7(C_2H_3O)_2$. In a later communication in view of its apparent relationship to apigenin, and the difficulty of accounting for the large number of hydroxyl groups which are present, it is suggested by this author (*Chem. Soc. Trans.* 1899, 77, 422) that vitexin is probably a very stable glucoside of apigenin represented by the formula $C_{21}H_{22}O_{10}$. Vitexin is a somewhat feeble colouring matter, and dyes shades similar to those given by apigenin; these, employing woollen cloth mordanted with chromium, aluminium, and tin, are respectively greenish-yellow, pale bright yellow, and pale brown.

In addition to vitexin the wood of the *Vitex littoralis* contains (as glucoside) a small quantity of a second colouring matter, *homovitexin*. It was obtained as a pale yellow powder, m.p. 245°-246°, and is distinguished from vitexin by its ready solubility in alcohol. Fused with alkali it gives phloroglucinol and *p*-hydroxybenzoic acid, and is possessed of feeble dyeing property. The analytical figures approximate to $C_{15}H_{14}O_7$ or $C_{15}H_{12}O_8$.

According to Barger (*Chem. Soc. Trans.* 1906, 89, 1120) the glucoside saponarin, which is present in *Sapindaria officinalis* (Linn.), yields on hydrolysis glucose, saponaretin and a small

VITEXIN.

quantity of vitexin. It is possible that saaponatin and homovitexin are identical. A. G. P.

VITRIFIABLE PIGMENTS v. POTTERY; also **PORCELAIN**

VITRIOL (*vitrum*, 'glass'). An old name for a sulphate, and still frequently applied to the sulphates of certain common metals on account of their vitreous lustre, e.g. white or zinc vitriol $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$; blue or copper vitriol $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$; green or iron vitriol $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$; red or cobalt vitriol $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$. Basic ferric or ferrous-cupric sulphates obtained in the extraction of copper sulphate from ferruginous minerals are known as Admont, Bayreuth, Salzburg vitriols, &c.

VITRIOL, OIL OF. *Vitriolic acid*. Sulphuric acid (*q.v.*).

VITRIOL STONE and COLCOTHAR. Vitriol is the material from which the so-called fuming or Bohemian sulphuric acid was formerly manufactured, and it is obtained from the rock known as vitriol slate ('Vitriolschiefer') in the following manner. Large masses of pyritous slate (which belongs to the Silurian formation, and consists of a quartzose matrix containing pyrites, carbon, and clay) are exposed to the weathering action of the atmosphere for three years. The products of oxidation so formed are ferrous sulphate and sulphuric acid, which latter acts upon the clay, yielding aluminium sulphate and other sulphates. The ferrous sulphate at first formed becomes by oxidation ferric sulphate, which, together with the aluminium sulphate, is the principal product of the weathering of the vitriol slate. Ferrous sulphate remains only in small quantities. The next operation is lixiviation of the mass with water, after which the liquor obtained is concentrated to a density of 40°B., and finally evaporated in pans until, on cooling, a crystalline cake of vitriol stone is obtained. The vitriol stone is now calcined, in order to remove the greater part of its water. The resulting product, when heated to a high temperature in clay retorts, yields sulphur trioxide; and a residue, termed *colcothar*, remains in the retorts. The composition of vitriol stone and colcothar may be seen from the following analyses:—

Vitriol stone.— Fe_2O_3 20.07, Al_2O_3 4.76, FeO 0.64, MnO traces, CaO 0.14, MgO 0.39, K_2O 0.07, Na_2O 0.05, CuO 0.10, SiO_2 0.10, P_2O_5 traces, SO_2 40.51, As traces, H_2O 32.58. Total 99.32; or combining acid oxides and bases: $\text{Fe}_2(\text{SO}_4)_3$ 50.17, $\text{Al}_2(\text{SO}_4)_3$ 11.94, FeSO_4 1.35, MgSO_4 1.17, CaSO_4 0.33, CuSO_4 0.20, K_2SO_4 0.13, Na_2SO_4 0.11, H_2SO_4 1.49, MnO , As , and P_2O_5 traces, SiO_2 0.10, H_2O 3.31—99.29.

Colcothar.— Fe_2O_3 7.62, Al_2O_3 12.53, MgO 3.23, CaO 0.82, SO_2 5.17, SiO_2 1.17, CuO 0.20, H_2O 1.30—99.04 (F. Stolba, B. Königl. Böhm. Gesells. 1885; J. Soc. Chem. Ind. 6, 30).

VIVIANITE. Hydrated ferrous phosphate $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, crystallised in the monoclinic system. The crystals have a perfect cleavage in one direction, parallel to the plane of symmetry; they are quite soft (H. 1½–2), sectile, and easily bent, being flexible but not elastic. Sp.gr. 2.58–2.68. Crystals from freshly opened rock

cavities are colourless, but on exposure to the air they very soon acquire a greenish-blue tinge, darkening to a characteristic deep indigo-blue. This change in colour is due to a partial oxidation of the iron, which in the black kertschenite $(\text{Fe}, \text{Mn}, \text{Mg})\text{Fe}^{III}(\text{PO}_4)_2 \cdot 7\text{H}_2\text{O}$, from the Kerch peninsula, Crimea, is almost complete. Vivianite is the commonest of the several iron phosphate minerals. The best crystals are found in metalliferous veins, e.g. at Wheal Jane, in Cornwall, with pyrrhotite, and at Leadville in Colorado. Crystals are also found in the interior of fossil shells, e.g. in the iron ores of the Kerch peninsula, Crimea; and also sometimes in bones and horns buried in peat deposits. More often the mineral has the form of a blue earthy powder ('blue iron-earth'), and it is in this form that phosphorus is present in bog iron-ore and other limonitic ores of iron. L. J. S.

VOLBORTHITE. Hydrated basic copper vanadate $(\text{CuOH})_2\text{VO}_4 \cdot 6\text{H}_2\text{O}$, with the copper in part replaced by calcium, barium, and magnesium. It forms olive-green or citron-yellow, pearly scales, which are often aggregated in globular forms. As a dissemination in sandstones of Permian age it occurs over a wide area in Govt. Perm in Russia.

Calciovolborthite is a mineral of very similar appearance and mode of occurrence. It contains, as a rule, rather more calcium and has no water of crystallisation; the composition approximates to the formula $\text{Cu}_2(\text{CuOH})_2(\text{VO}_4)_2$. This is found as golden-yellow or greenish-yellow pearly scales and rosettes on the surfaces of sandstone in Utah, Colorado, and Oregon, and also at Friedrichroda, near Gotha, in Thuringia. On the significance of these occurrences of vanadium and copper minerals in sandstones v. PSITTACINITE. L. J. S.

VOLCANIC GLASS v. OBSIDIAN.

VOLCANIC TUFF v. TUFF.

VOLEMITOL v. CARBOHYDRATES.

VOLUMENOMETER v. SPECIFIC GRAVITY.

VOROBYEVITE v. BERYL.

VRAIC. *Varech*. The French name for kelp, v. IODINE.

VRBAITE. Thallium sulph-arsenite and antimonite $\text{TlAs}_2\text{SbS}_8$ or $\text{Tl}_2\text{S} \cdot 2\text{As}_2\text{S}_3 \cdot \text{Sb}_2\text{S}_3$, containing Tl 32.15 p.c., crystallised in the orthorhombic system. It is greyish-black with metallic lustre, but in thin splinters dark red, and the powder is light red with a yellowish tinge. Sp.gr. 5.3. The small crystals are found embedded in realgar and orpiment, at Alchiar, in Macedonia. Another mineral containing thallium as an essential constituent yielded by this locality is lorandite (*q.v.*). L. J. S.

VULCANISED OILS v. OILS, FIXED, and FATS.

VULCANITE v. RUBBER. Also applied to a nitroglycerin explosive.

VULCAN POWDER v. EXPLOSIVES.

VULPIC or VULPULIC ACID v. LICHENS.

VULPINITE. A variety of anhydrite mixed with silica. That from Vulpino near Bergamo, known as the *Marmo Bardiglio di Bergamo*, takes a fine polish and is used for ornamental purposes.

W

WAD or **BOG-MANGANESE**. A black, earthy mineral consisting mainly of hydrated manganese dioxide, but of variable composition, barium and various other constituents being often present. Many varieties have consequently been distinguished by special names. *Asbolite* or 'earthy cobalt' is a cobaltiferous variety, and *lampadite* contains copper. The mineral may be regarded as an earthy form of psilomelane (*q.v.*); it is so soft and sooty that it soils the fingers, and is sometimes so porous that it floats on water. It has resulted from the weathering and decomposition of other manganese minerals, and is sometimes deposited from solution by springs and in swamps. It is of wide distribution and is mined at many places together with other oxides of manganese. Asbolite is of importance as an ore of cobalt (up to 35 p.c. CoO), as much as 5000 tons per annum having been exported from New Caledonia. L. J. S.

WALNUT HUSKS (*Brous des noix*. Fr.) are employed by the French dyers to give dun colours. The green shells contain *juglone* or *hydroxy-[α]-naphthaquinone*; *v.* NAPHTHALENE.

WALNUT OIL *v.* OILS, FIXED, AND FATS. Walnut oil is obtained from kernels of the walnut tree (*Juglans regia*), which contain from about 65 to 66 p.c. of oil. The best oil is separated by cold expression and from its pale colour is a favourite medium for white paints, and is commonly termed 'nut oil' by artists. It dries more slowly than linseed oil, but yields a more elastic film. In the bromination test it yields from 1.5 to 2 p.c. of an insoluble bromide, which appears to be that of a mixed glyceride.

An oil of similar character is obtained from the seed of the North American walnut, *Juglans niger*. This oil is termed *pecan oil*.

The fruit of *Juglans Siboldiana* gave 26.54 p.c. of kernel, which contained 4.99 p.c. of water, and gave 59.58 p.c. of oil by pressing. The oil has a light yellow colour and no odour, and has the following characters: sp.gr. 0.9332 at 15°; $N_{D^{20}} = 1.4800$; acid value 0.68; Hehner value 92.3; saponification value 191.1; Reichert-Meiss value 0.62; and iodine value (Hübl.) 150.8, and has the properties of a drying oil. C. A. M.

WALSRODE POWDER *v.* EXPLOSIVES.

WARAS, also called 'wars' and 'wurrus', consists of a purplish resinous powder which covers the seed pods of *Flemingia congesta* (Roxb.), an erect woody shrub growing in the thickets and forests of the warmer parts of India. According to Watt (*Dictionary of Economic Products in India*, iii. 482), it is collected also in Africa in the neighbourhood of Harrar, and is sent to Arabia, chiefly to Yemen and Haddramant, where it is used as a dye, as a cosmetic, and as a specific against colds. According to Wardle, waras is distinctly inferior as a dye to kamala, which it closely resembles, and contains only a small amount of colouring matter compared with the yellow vegetable dyes of commerce. It is suitable as a dye for silk rather than for wool, but is quite useless with cotton. It has been

introduced into England from Aden as an adulterant or substitute for kamala (Flückiger and Hanbury's *Pharmacographica*, 1879, 576). Under the microscope waras appears as orange-brown lumps, frequently circular and closely resembling kamala.

Flemingin $C_{12}H_{12}O_4$ (provisional) is a dull orange-red crystalline powder consisting of star-shaped groups of minute prismatic needles, which melt at 171°–172°, and closely resembles the rottlerin of kamala. Solutions of the alkali hydroxides dissolve it with an orange-brown tint, but these solutions when boiled do not deposit resinous matter, as is the case with rottlerin. On fusion with alkali *salicylic acid* and acetic acid are produced.

Silk suspended in a solution of *flemingin* in dilute sodium carbonate, and the whole gradually raised to the boiling temperature, is dyed golden yellow, slightly duller than the shade given by rottlerin; but, on the other hand, *flemingin* possesses much the stronger dyeing power of the two.

In addition to *flemingin* waras contains a trace of a yellow crystalline colouring matter, *homoflemingin*, m.p. 165°–166° ($C=69.97$; $H.=5.75$), together with some quantity of two resinous substances: (a) $C_{12}H_{12}O_3$ (?), m.p. 162°–167°, and (b) $C_{13}H_{14}O_3$ (?), melting below 100°. Fused with alkali these latter gave *salicylic* and *acetic acids*, and appear to be allied to *flemingin*.

Added to a boiling solution of its own weight of sodium carbonate, waras dyes silk golden yellow shades, which are brightened by rinsing in very dilute acetic acid. Contrary to the statement of Wardle, it is to be regarded as a decidedly superior dyestuff to kamala (Perkin, *Chem. Soc. Trans.* 1898, 73, 659). A. G. P.

WASH. The name given to the fermented wort of the distiller.

WATER.**ITS PHYSICAL AND CHEMICAL PROPERTIES.**

Purification.—Because of its solvent action on solids and gases, water is difficult to purify and still more difficult to keep in a pure state. It may be partially freed from dissolved salts by freezing, the ice separating from any unsaturated salt solution containing only the small quantity of the dissolved salt present in the mother liquor included in the ice crystals. The ice separating from, say, sea-water, is fairly free from saline matter. It is not known whether this method of purification eliminates, partially or completely, dissolved gaseous impurities. The method is relatively troublesome and costly, and has not been practically applied.

Water is commonly purified by distillation under atmospheric pressure. When adequate arrangements are made to prevent carrying over of entrained droplets of water formed upon the bursting of steam bubbles, the condensed steam contains only the solid and gaseous impurities it dissolves after condensation. Assuming dust to be excluded, the non-volatile impurities in the distillate will be confined to such traces of

lime, silica, alkalis, tin oxide, etc., as may be derived from condensers and containers, and the volatile impurities, which generally are much the more serious in amount and effect, will comprise volatile organic matter, ammonia, carbon dioxide, oxygen, nitrogen, and the like, originally contained in the raw water and carried over with the steam or dissolved from the atmosphere with which the condensate is in contact.

The proportion of non-volatile impurities may be reduced to insignificance by using suitable material for condensers and containers. Hot, newly condensed water has a much greater solvent action than when cold; therefore a material suitable to contain water for a given purpose may not serve for its condensation. Good resistance glass vessels, which have been freed from superficial soluble matter by blowing steam into them for some hours in such a way that the condensate drains away continuously, after long standing in cold water will yield little impurity to pure water during several weeks. Such glass, so treated, is suitable for the preservation for short periods of cold pure water for all but a few very special purposes. It is unsuitable for condensers, which are usually made of pure block tin or heavily tinned copper. The risk of introducing non-volatile impurity may be reduced by using pure fused silica, or, better, pure tin or silver as the material of condenser and receiver. Occasionally water has been condensed and kept in vessels of gold or platinum, but for all ordinary and most special purposes water condensed in pure tin and kept a short time in steamed resistance glass is quite satisfactory. Water kept in ordinary glass bottles for some weeks or months may dissolve sufficient silica, &c., from the glass to render it unsuitable for ordinary precise analytical work, especially that in which small amounts of silica must be determined.
